MEMOIRS OF THE QUEENSLAND MUSEUM, VOLUME 32

CONTENTS

PART 1 (Issued 29 June, 1992)

BRUCE, N.L.
Anopsilana barnardi, a new species of estuarine cirolanid crustacean isopod from tropical eastern Australia. 1
CHURCHILL, T.B. AND RAVEN, R.J.
Systematics of the intertidal trapdoor spider genus *Idioctis* (Mygalomorphae: Barychelidae) in the Western Pacific with a new genus from the Northeast 9
COLEMAN, R.A.
Shipwreck and historical survey: Chilcott Islet, Coral Sea 31
COUPER, P. J. AND INGRAM, G.J.
A new species of skink of *Lerista* from Queensland and a re-appraisal of *L. allanae* (Longman) 55
DAVID, B., CHANT, D. AND FLOOD, J.
Jalijbang 2 and the distribution of pecked faces in Australia 61
DAVIE, P.J.F
Revision of *Sarmatium* Dana (Crustacea: Brachyura: Sesarminae) with descriptions of three new species 79
HOOPER, J.N.A. AND BERGQUIST, P.R.
Cymbastela, a new genus of lamellate coral reef sponges 99
HUGHES, N.C. AND DROSER, M.L.
Trace fossils from the Phe Formation (Lower Cambrian), Zanskar Valley, northwestern India 139
JONES, D.S.
Scalpellid barnacles (Cirripedia: Thoracica) from the northeastern and central eastern Australian continental shelf and slope 145
KENNETT, R.M., GEORGES, A., THOMAS, K. AND GEORGES, T.C.
Distribution of the long-necked freshwater turtle *Chelodina novaeguineae* and new information on its ecology 179
LAMBKIN, K.J.
Re-examination of the venation of *Osmylopsychops spillerae* Tillyard from the Triassic of Queensland 183
LAMPRELL, K.
Notes on *Spondylus* Linnaeus with descriptions of two new species from Western Australia (Mollusca: Bivalvia: Spondylidae) 189
ROZEFELDS, A.C.
The subtribe Hicksbeachiinae (Proteaceae) in the Australian Tertiary 195
ROZEFELDS, A.C., CHRISTOPHEL, D.C. AND ALLEY, N.F.
Tertiary occurrence of the fern *Lygodium* (Schizaeaceae) in Australia and New Zealand. 203
RYLAND, J.S. AND HAYWARD, P.J.
Bryozoa from Heron Island, Great Barrier Reef 223
SHEA, G.M. AND HUTCHINSON, M.N.
A new species of lizard (*Tiliqua*) from the Miocene of Riversleigh, Queensland 303
WEBSTER, G.D. AND JELL, P.A.
Permian echinoderms from Western Australia 311

NOTES

COUPER, P.J.
Anomalopus pluto Ingram, a poorly known skink from Cape York Peninsula 54
COUPER, P.J., WHITTIER, J., MASON, R.T. AND INGRAM, G.J.
A nesting record for *Coeranoscincus reticulatus* (Günther). 60
DAVIE, P.J.F.
The rare shrimp, *Phyllognathia ceratophthalma* (Balss), discovered in Moreton Bay 98
RICHARDS, S.J.
The tadpole of the Australopapuan frog *Rana daemeli*. 138

ANOPSILANA BARNARDI, A NEW SPECIES OF ESTUARINE CIROLANID CRUSTACEAN ISOPOD FROM TROPICAL EASTERN AUSTRALIA

NIEL L. BRUCE

Bruce, N.L. 1992 06 29: *Anopsilana barnardi*, a new species of estuarine cirolanid crustacean isopod from tropical eastern Australia. *Memoirs of the Queensland Museum* 32(1): 1-8. Brisbane. ISSN 0079-8835.

Anopsilana barnardi sp.nov., the third species of *Anopsilana* recorded from Australia, is described from northeastern Queensland. A key to the Australian species is given and a list of all *Anopsilana* species is provided.□ *Isopoda, Cirolanidae, new species, northeastern Queensland, Southwest Pacific, taxonomy.*

Niel L. Bruce, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 10 January, 1992.

Anopsilana Paulian & Deboutteville, 1956, contains thirteen species. Its occurrence is restricted to the tropical regions of the world; about half the species are recorded from troglobitic habits (both freshwater and euryhaline), the others are all recorded from mangrove or estuarine habitats.

Anopsilana barnardi sp.nov. was taken from a mid-stream grab sample in the Murray River, and it is therefore not directly associated with mangroves as are the other Australian species of *Anopsilana.*

Anopsilana Paulian & Deboutteville

Anopsilana Paulian & Deboutteville, 1956: 87. Bruce, 1981: 955, fig. 5i-e; 1986: 196; Kensley & Schotte, 1989: 124; Brusca, Wetzer & France (in press).

Troglocirolana Rioja, 1956: 447 [Type species: *Cirolana cubensis* Hay, 1903, by monotypy].

Haitilana Notenboom, 1981: 314 [Type species: *Haitilana radicicola* Notenboom, 1981, original designation].

Type Species

Anopsilana poissoni Paulian & Deboutteville, 1956, original designation. The location of the types was not given in the original publication, but was cited as at the Institute Scientific de Madagascar, Tsimbazaza, Antananarivo, Madagascar by Brusca et al. (in press).

Diagnosis

Fronal lamina usually elongate (in two Pacific species as long as wide), anterior margin projecting or sessile; pentagonal or with anterior margin rounded or truncate. Antennule with peduncular articles 1 and 2 usually coalesced. Pereopods all ambulatory. Pleopod 2 of male with appendix masculina basally or sub-basally inserted, usually robust; endopods of pleopods 3-5 without plumose marginal setae, smaller than exopod; lamellar or thickened (*A. barndardi*, *A. oaxaca*). Mouthparts and other characters as for *Cirolana.*

Remarks

Anopsilana, with little question, constitutes a polyphyletic assemblage of species, differing from *Cirolana* primarily in the lack of marginal setae on the endopods of pleopods 3 and 4. These endopods are also reduced in size in comparison to those of *Cirolana* and in at least two species are thickened or fleshy. Other minor differences, none of which are shown by all of the species placed in the genus, are the fusion of peduncular articles 1 and 2 of the antennule; article 3 of the antennule peduncle being proportionally longer than in *Cirolana* and the appendix masculina varying from being relatively robust to slender and basally inserted.

Estuarine species tend to be well pigmented and have robust well-spined pereopods that are generally similar to those of the *Cirolana* '*parva* group' or 'tuberculate group' of species. Troglobitic species have relatively more slender pereopods with, by comparison, reduced spination. Additionally all the troglobitic species lack eyes.

The distribution of the genus is restricted to tropical localities. The cavernicolous species are from the peri-Caribbean region except for one species from Madagascar and one from Palau. The open-water species are all estuarine, tropical and all have been recorded from mangroves or in the vicinity of mangroves, with the exception of the poorly known *Anopsilana luciae*. *Anopsilana pustulosa* and *A. willeyi* have extensive Indo-Pacific distributions. Brusca et al. (in press) report that *A. browni* is widely distributed in the Caribb-

ean and also in the tropical East Pacific in suitable habitats.

KEY TO AUSTRALIAN SPECIES OF *ANOPSILANA*

1. Body with nodules on dorsal surfaces of pereon, pleon and pleotelson; pleotelson apex narrowly rounded; endopods of pleopods 3-5 lamellar.....2

   Body without dorsal ornamentation; pleotelson apex wide, subtruncate; endopods of pleopods 3-5 fleshy.....*A. barnardi* sp.nov.

2. Frontal lamina anterior margin rounded; pleotelson abruptly narrowed; uropod rami with dense mass of marginal setae.....*A. pustulosa*

   Frontal lamina pentagonal; lateral margins of pleotelson not abruptly narrowed; uropod rami with single rank of marginal setae.....*A. willeyi*

Anopsilana barnardi sp.nov.

MATERIAL EXAMINED

HOLOTYPE: ♂ (5.4mm), Murray R., north Queensland, 18°16'S, 146°01'E, 24 May 1978, salinity of 23-34‰, depth 1.5m, mid-estuary, mud bottom, coll. P. Davie (QM W17263).

PARATYPES: 13♂♂ (2.9-5.7mm, m = 3.9m, 5.7mm specimen dissected), 14♀♀ (3.0-5.9mm non-ovig, m=4.0mm; 6.4mm ovig), manca (2.7mm), same data as holotype (QM W17264).

DESCRIPTION

Male: Body about 2.8 times as long as greatest width; dorsal surfaces without nodules, unornamented. Cephalon with median rostral point visible in dorsal view; dorsal interocular furrow present; eyes together about 0.3 width of cephalon. Pereonite 1 about 1.6 times as long as pereonite 2; pereonite 2>3>4<5 = 6>7 in length; pereonite 7 shortest. Coxae of pereonites 2-7 each with distinct and entire oblique carina; coxae 4-7 with posteroventral angle becoming increasingly acute. Pleonite 1 concealed by pereonite 7; pleonite 3 with lateral margins posteriorly produced and overlapping lateral margins of pleonite 4 which are produced posteriorly beyond pleonite 5. Pleotelson 0.65 as long as anterior width; lateral margins convex, posterior margin subtruncate, provided with 8 (or 9, see Variation) spines, interspersed with 2 short setae between each spine pair.

Antennule peduncle articles 1 and 2 fused, article 3 about 1.2 times as long as fused articles 1 and 2; flagellum extending to middle of pereonite 1, with 8 articles, the distal 2 being minute, about 0.7 as long as peduncle. Antennal peduncle article 4 about 2.5 times as long as article 3; peduncular article 5 about 1.2 times as long as 4; flagellum extending to pereonite 4, composed of about 17 articles. Frontal lamina pentagonal, sessile; lateral margins diverging anteriorly. Mandible lacking lacinia mobilis; spine row with 9 spines; molar process very thin, with 13 or 14 teeth; palp article 2 with 12 serrate setae on distolateral margin, article 3 with 14 setae distal 3 of which are longer than remaining 11 and feebly serrate, others obviously serrate. Maxillule with 12 spines on gnathal surface of lateral lobe; medial lobe with 3 stout moderately plumose spines. Maxilla with 5 long setae on lateral lobe, 9 long setae on central lobe, medial lobe with 4 stout plumose setae proximally, distally 6 simple setae. Maxilliped with simple setae only; endite with 2 coupling hooks and 4 plumose setae.

Pereopod 1 basis with 1 long and 1 short seta at posterodistal angle; ischium with 2 setae at anterodistal angle, 2 small setae at posterodistal lateral margin and 1 spine at posterodistal medial margin; merus with 4 short stout tubercular spines on lateral posterior margin and 5th longer spine at posterodistal angle, posterior medial margin with 2 acute spines; carpus with single acute spine and 3 setae at posterodistal angle; propodus palm with 2 acute spines and third stout spine and 2 setae opposing dactylus. Pereopods 2 and 3 similar to 1 but less robust. Pereopod 2 ischium with 2 acute spines at anterodistal angle and 2 stout spines at posterodistal angle; merus with 2 large and 2 small spines at anterodistal angle, posterodistal margin with 6 blunt spines in 2 clusters; carpus with 3 spines at posterodistal angle; propodus with single spine on palm. Pereopods 4-7 essentially similar, becoming longer posteriorly. Pereopod 7 ischium with group of 5 spines at anterodistal angle, posterior margin with 3 groups of spines; merus with clusters of 6 and 4 spines at distal angles, 3 spines set posteromedially; carpus with abundant spines on distal margin (about 13), 1 and 2 spines set on posterior margin; propodus with 2 pairs of spines on posterior margin; some spines on anterior margins strongly pectinate; spines on posterior margin all simple. Penes small, inconspicuous (only easily visible on dissected male paratype) papillae, set submedially on posterior of sternite 7.

Pleopod 1 rami subequal length, endopod slight-

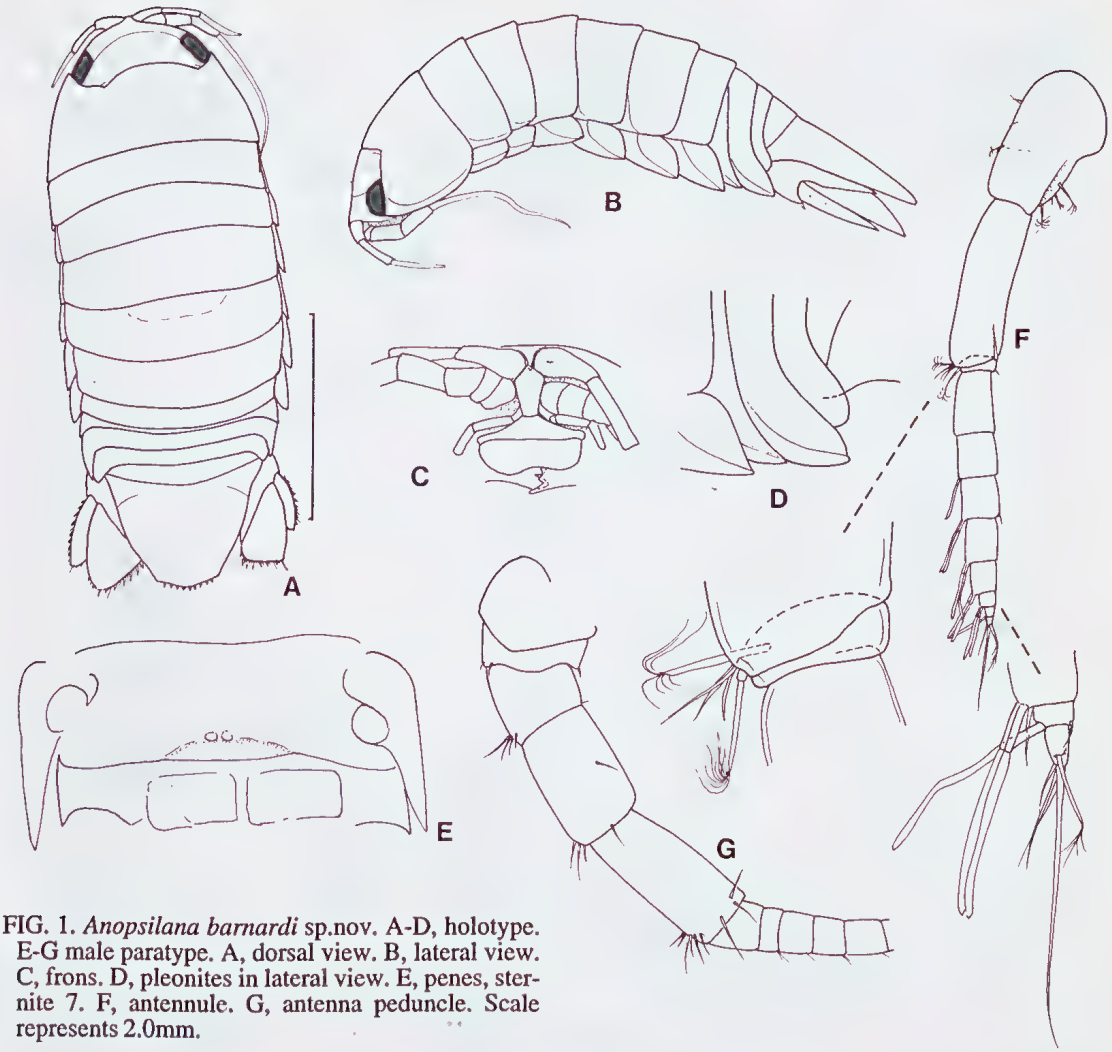

FIG. 1. *Anopsilana barnardi* sp.nov. A-D, holotype. E-G male paratype. A, dorsal view. B, lateral view. C, frons. D, pleonites in lateral view. E, penes, sternite 7. F, antennule. G, antenna peduncle. Scale represents 2.0mm.

ly less than half as wide (0.45) as exopod; peduncle about 1:8 as wide as long, medial margin with 4 coupling hooks. Pleopod 2 with rami subequal in length; appendix masculina broad, 0.3 as wide as endopod, arising basally and extending just beyond end of endopod. Pleopods 3-5 exopod with complete but faint suture; endopods fleshy and small, about 0.5 as wide and 0.7 as long as exopods. Uropod rami not extending beyond posterior of pleotelson, exopod 0.85 as long as endopod; exopod lateral margin with 9 spines, medial margin with 6; endopod lateral margin with 3 spines, medial with 7; peduncle with 2 spines at lateroventral angle; apices of both rami weakly bifid; both rami with plumose marginal setae among spines except for proximal three quarters of lateral margin of endopod.

Female: Slightly larger than male, differs in secondary sexual characters. Brood pouch made up of overlapping oostegites arising from sternites 1-5; embryos within dorsally oriented infolding of sternites.

Colour: Pale brown in alcohol, dorsal surfaces with brown chromatophores; eyes black.

Size: Males average at 3.9mm, non-ovigerous females at 4.0mm.

Variation: There is considerable variation in the number of spines present on the pleotelson and uropodal rami. The commonest spine counts are: pleotelson with 8 spines (47.6%) or 9 spines (33.3%), occasionally 7 or 10; exopod lateral margin with 7-10 spines, 9 spines (50.0%) or 8 spines (35.7%) commonest; exopod medial margin with 5 (71.4%) or 6 (19.0%) spines; endopod lateral

FIG. 2. *Anopsilana barnardi* sp.nov., male paratype. A, left mandible. B, right mandible, incisor. C, maxillule. D, maxilla. E, maxilliped. F, pereopod 1. G, pereopod 2.

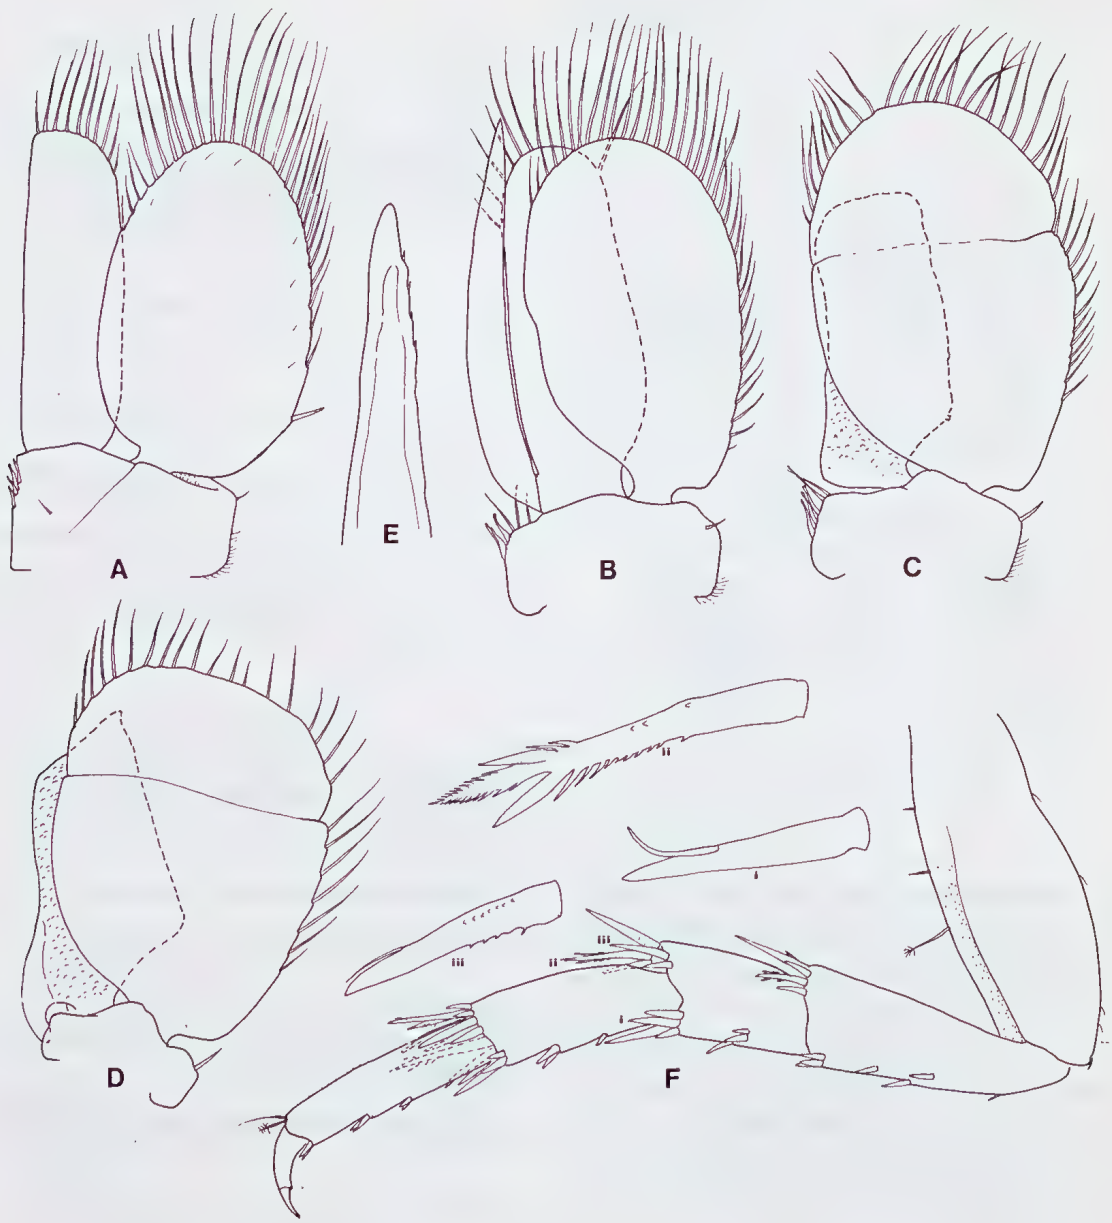

FIG. 3. *Anopsilana barnardi* sp.nov., male paratype. A-D, pleopods 1-3, 5 respectively. E, apendix masculina apex. F, pereopod 7.

margin with 3 (60%) or 4 (40%) spines, medial margin with 5 (15.0%), 6 (57.5%) or 7 (27.5%) spines (the holotype, 10 males and 10 females were examined for spine counts).

REMARKS

This species is easily separated from the two other Australian species by the lack of nodules or other cuticular ornamentation. The pleopods of *Anopsilana barnardi* have the endopod of pleopods 3-5 far smaller than those of *A. pustulosa* Hale (see Bruce 1981, fig. 5i-l) or *A. willeyi* Stebbing (see Bruce 1986, fig 138), and furthermore the endopod is thickened and semi-opaque,

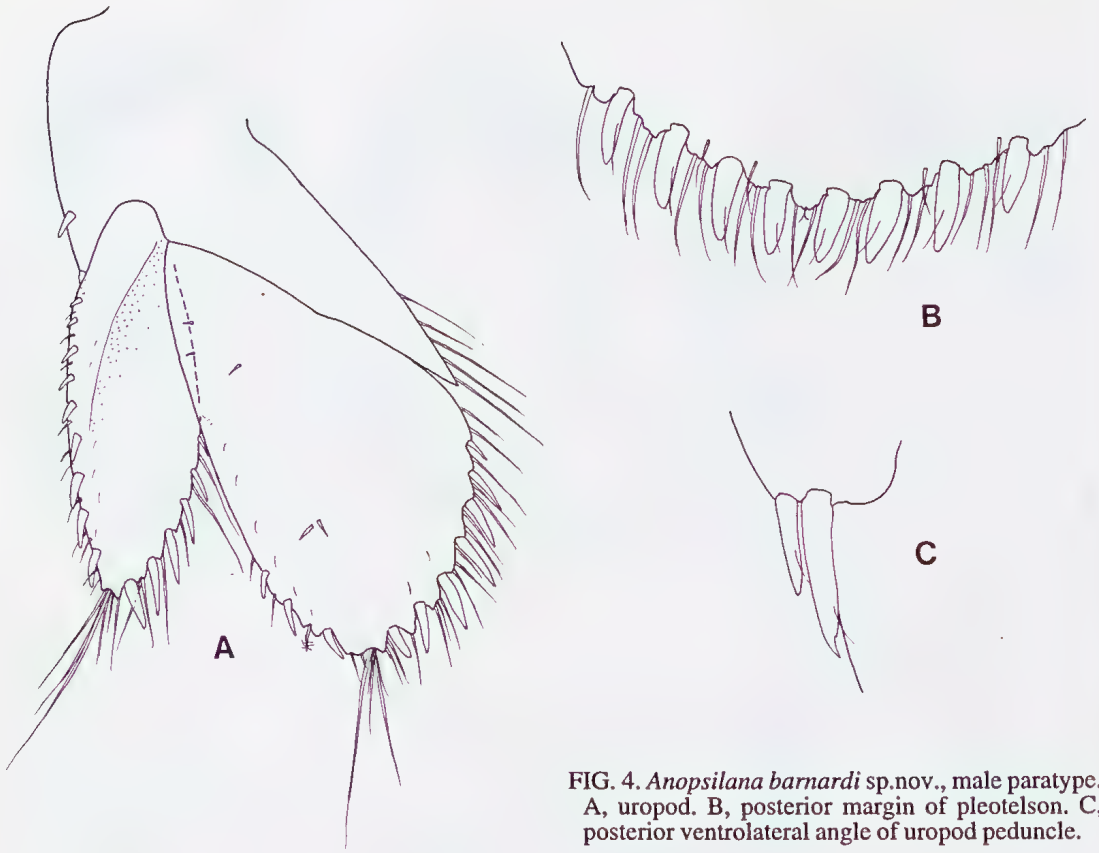

FIG. 4. *Anopsilana barnardi* sp.nov., male paratype. A, uropod. B, posterior margin of pleotelson. C, posterior ventrolateral angle of uropod peduncle.

not lamellar. There are only two other Indo-Pacific species of *Anopsilana*: *A. lingua* Bowman & Iliffe, 1987, which is a blind freshwater cave dwelling species from Palau, and *A. luciae* (Barnard, 1940) a poorly described estuarine species from South Africa. *Anopsilana luciae* differs by having a rounded projecting frontal lamina, a narrow pleotelson apex and two longitudinal submedian carinae on the pleotelson. It is possible that some estuarine species currently placed in *Cirolana* may prove to belong to *Anopsilana* when the pleopods have been examined.

ETYMOLOGY

The species is named to honour the late Dr J.L. Barnard who has made an immense contribution to the knowledge of Australian peracarid Crustacea.

SYNOPSIS OF *ANOPSILANA* SPECIES

Anopsilana acanthura (Notenboom, 1981)

DISTRIBUTION: Known only from a well in Haiti.

TYPES: Zoölogisch Museum, Amsterdam.

Anopsilana browni (Van Name, 1936)

DISTRIBUTION: Brackish and freshwater; Caribbean; Cuba and Belize; East Pacific: Costa Rica (Kensley & Schotte, 1989).

TYPES: American Museum of Natural History, New York.

Anopsilana crenata Bowman & Franz, 1982

DISTRIBUTION: Freshwater pool in a cave, Grand Cayman Island.

TYPES: Smithsonian Institution.

Anopsilana cubensis (Hay, 1903)

DISTRIBUTION: Caves in several localities in Cuba.

TYPES: Smithsonian Institution.

Anopsilana jonesi Kensley, 1987

DISTRIBUTION: Amongst mangroves, Belize.

TYPES: Smithsonian Institution.

Anopsilana lingua Bowman & Iliffe, 1987

DISTRIBUTION: Natural well on Peleliu Island, Palau.

TYPES: Smithsonian Institution.

Anopsilana luciae (Barnard, 1940)

DISTRIBUTION: Estuarine, South Africa.

TYPES: South African Museum, Cape Town.

Anopsilana oaxaca Carvacho & Haasmann, 1984

DISTRIBUTION: Mangroves roots, Pacific coast of Mexico; also Clipperton Island (Brusca et al. in press).

TYPES: Institute of Biology, National Autonomous University of Mexico.

Anopsilana poissoni Paulian & Deboutteville, 1956

DISTRIBUTION: Mitoho Cave, southern Madagascar.

TYPES: Not stated, but see type species entry after genus synonymy given here.

Anopsilana pustulosa (Hale, 1925)

DISTRIBUTION: Estuarine and mangrove habitats from East Africa to Australia; generally within the tropics (Bruce, 1986). Type locality: Cooktown, Queensland.

TYPES: Australian Museum, Sydney.

Anopsilana radicicola (Notenboom, 1981)

DISTRIBUTION: Natural spring, Haiti.

TYPES: Zoölogisch Museum, Amsterdam.

Anopsilana willeyi (Stebbing, 1904)

DISTRIBUTION: Estuarine and mangrove habitats from East Africa to Australia, within the tropics (Bruce, 1986). Type locality: Sri Lanka (Stebbing, 1904, as Ceylon).

TYPES: Not located.

SYSTEMATICS OF THE INTERTIDAL TRAPDOOR SPIDER GENUS *IDIOCTIS* (MYGALOMORPHAE: BARYCHELIDAE) IN THE WESTERN PACIFIC WITH A NEW GENUS FROM THE NORTHEAST

TRACEY B. CHURCHILL AND ROBERT J. RAVEN

Churchill, T. B. & Raven, R. J. 1992 06 29: Systematics of the intertidal trapdoor spider genus *Idioctis* (Mygalomorphae: Barychelidae) in the Western Pacific with a new genus from the Northeast. *Memoirs of the Queensland Museum* 32(1): 9-30. Brisbane. ISSN 0079-8835.

The circum-tropical trapdoor spider genus *Idioctis* included 6 species from Madagascar, east to Hawaii. A new genus, *Nihoa*, endemic to the Leeward Islands, north of Hawaii, is named and now includes *Idioctis hawaiiensis* Raven, 1988, endemic to Necker Island, and a further new species, *Nihoa mahina* sp.nov., endemic to Nihoa Island. Four new species of *Idioctis* from the Western Pacific are described: *I. yerlata* from north-eastern Australia; *I. ferrophila* from New Caledonia; *I. marovo* from the Solomon Islands; and *I. talofa* from Western Samoa, raising the number of species to nine. For the first time, the male of the type species *I. helva* Koch, 1874, from Fiji, is described. Variation in the shape of spermathecae in *Idioctis* is described. □*Chelicerata, Mygalomorphae, Barychelidae, systematics, phylogeny.*

Tracey B. Churchill and Robert J. Raven, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 3 February, 1992.

Spiders of a number of genera occur beside the sea. However, only few are intertidal in that their burrows are covered at high tide. Best known among araneomorphs are *Desis* and *Paratheuma* (Desidae), the latter having been revised recently (Beatty and Berry, 1988). In contrast, spiders of only one mygalomorph genus, *Idioctis* Koch, 1874, are known to live in the intertidal zone.

The genus *Idioctis* was first described by Koch (1874) including only *I. helva* from Fiji. No reference was made to the habitat. The first report of the intertidal habits of a barychelid was with the description of *Idioctis littoralis* Abraham, 1924, found in the intertidal mudflats of Singapore. Much later, *I. helva* was recorded from the littoral zone in Western Samoa (Marples, 1951, 1955). Soon after, another species, *Atrophonysia intertidalis* Benoit & Legendre, 1968, (transferred to *Idioctis* by Raven, 1985) was collected and described from the littoral zone of Madagascar and the Seychelles.

By 1988, six species of *Idioctis* had been described: the type species, *I. helva* from Fiji and Western Samoa (Marples, 1951, 1955); *I. littoralis* Abraham, 1924 from Singapore; *I. intertidalis* (Benoit & Legendre, 1968) from Madagascar and the Seychelles (Benoit, 1978); *I. xmas* Raven, 1988 from Christmas Island; *I. eniwetok* Raven, 1988 from the Caroline and Marshall Islands; and *I. hawaiiensis* Raven, 1988 from the Leeward Islands, near Hawaii.

After a revision of the genus (Raven, 1988), we discovered *Idioctis* in the intertidal or littoral zones in northern Australia, New Caledonia, and the Solomon Islands. Three new species are described here. Concurrently, the first male and more females of the type species, *I. helva*, were taken from the type-locality of Ovalau, a small island of Fiji. Females of *I. helva* were also collected from the coast of the large island of Vanua Levu, Fiji. With this new material we conclude that a new species occurs in Western Samoa. We also document variation in spermathecae for the first time in barychelids.

Raven (1988) noted that *Idioctis hawaiiensis* differed from all other congeners in the wider sternum, undivided spermathecae, and relatively shorter eye group. Since then, material from another island in the Leeward Islands has proved to be a new species for which a new genus is here created. This new genus recognizes the plesiomorphic nature of both *I. hawaiiensis* and its new sister species.

MATERIALS AND METHODS

All abbreviations are standard for the Araneae and explained in Raven (1984a). The width of the eye group or the median ocular quadrangle (abbreviated as MOQ) is the distance between the two most separated points in a line orthogonal to the long axis of the spider. All measurements except those for eyes are given in millimetres. Eye measurements are taken from camera lucida drawings made at × 50 magnification; any error was taken as 0.02 mm, or 1mm on the enlarged figure. Eye interspaces, which are measured along a line joining the centres of the respective eyes, are given as

diameters of an AME. Presence of leg spines are specified by the number recorded with their position (rare number occurring in parentheses) although ranges can include zero. Spine positions are as follows : dorsal, if on or close to the midline; pro- or retrolateral, if spine bases are visible pro- or retrolaterally when viewed dorsally; ventral, if bases are visible when viewed ventrally. Spines are considered weak, and probably the equivalent of attenuate macrosetae of Coyle (1971: 329), if only marginally thicker than other setae on that surface. Despite being weaker, they are treated as spines because their number and position suggest they are the weaker form of thick spines on other species. Descriptions of scopulae give the extent (measured from the distal end of the leg segment), the density of scopula hairs, and the number of rows of setae that part the scopula hairs.

Acronyms for museums are: AMNH, American Museum of Natural History, New York; BMNH, British Museum (Natural History), London; NHW, Naturhistorisches Museum, Vienna; QM, Queensland Museum, Brisbane. Other museums are given in full.

SYSTEMATICS

Idioctis Koch

Idioctis Koch, 1874: 484 (type species by monotypy *Idioctis helva* L. Koch). Simon, 1892: 125; 1903: 914. Rainbow, 1912: 115. Roewer, 1942: 214. Bonnet, 1957: 2286. Brignoli, 1983: 129. Main, 1985: 12. Raven, 1985: 113; 1988: 2. Platnick, 1989: 93.

Atrophonysia Benoit & Legendre, 1968: 330 (type species by original designation *Atrophonysia intertidalis* Benoit & Legendre). First synonymized by Raven, 1985: 113. Brignoli, 1983: 130. Raven, 1985: 113, 1988: 2; Platnick, 1989: 93

Diagnosis

Idioctis can be distinguished from *Idiophthalma* by the narrow sternum and narrow fovea and absence of a strong rastellum, and from other barychelid genera by the relatively short but strongly trapezoidal eye group and a narrow sternum. It is also readily distinguished from *Nihoa* gen. nov. and many other barychelids in the pallid pattern-free abdominal dorsum and the elongate sternum.

Description

Carapace hirsute, without pattern. Fovea very broad, procurved or straight. Abdomen pallid, without pattern. Rastellar spines few in line overhanging fang, not on raised mounds. Maxillae usually with c.18-20 cuspules on inner anterior corner; anterior lobe and posterior heel produced. Labium wide, without cuspules. Sternum long, narrow (about 1.5 times longer than wide, rarely wider), with small, marginal sigilla, if evident. Scopulae (♀ ♀) entire on metatarsi and tarsi I and II; for full length of prolateral face of metatarsi III and only rarely present elsewhere on segment; widely parted by setae on tarsi III; only narrow lateral bands of hair, if present, on tarsi IV; absent on metatarsi IV. Scopuliform brush present on the proventral face of tibiae I and II of ♀ ♀. Spines. Leg 1: fe d0-4; ti p0-1 v2-7; me r0-1. Leg 2: fe d0-4; ti p0-1 v0-4; me v1-2. Leg 3: fe p0-1, d0-5; pa p6-30; ti p(2), r(2), v0-7; me p0-3, r0-3, v0-13. Leg 4: fe d0-7; pa p3-16; ti r(2), v0-7; me p0-7, r0-4, v2-9. Paired claws of ♀ ♀ with teeth on lateral face (Fig. 3); claws of ♂ ♂ biserially dentate. Tarsi with clavate and filiform trichobothria. ♂ ♂: tibia I with prolateral spur and megaspine, more distal prolateral megaspine and associated cuticular 'thumb'; palpal bulb pyriform. Intertidal, rarely in forests.

Checklist of Species

Idioctis helva Koch, 1874, type species Fiji.
Idioctis eniwetok Raven, 1988 Caroline & Marshall Islands.
Idioctis ferrophila sp.nov. New Caledonia.
Atrophonysia intertidalis Benoit & Legendre, 1968 Madagascar, Seychelles.
Idioctis littoralis Abraham, 1924 Singapore.
Idioctis marovo sp.nov. Solomon Islands .
Idioctis talofa sp.nov. Western Samoa.
Idioctis xmas Raven, 1988 Christmas I., Australia.
Idioctis yerlata sp.nov. North-eastern Australia.

Distribution

Spiders of the genus *Idioctis* are now known near beaches and in littoral zones in Fiji, Singapore (Abraham, 1924), Western Samoa (Marples, 1951, 1955), Madagascar (Benoit & Legendre, 1968), Seychelle Islands (Benoit, 1978), Christmas Island (Indian Ocean, Raven, 1988), Marshall and Caroline Islands (Raven, 1988), north-eastern Australia, New Caledonia and the Solomon Islands. Habitats, life history observations and biogeography of the genus will be discussed elsewhere.

Remarks

This paper contains the first description of a ♂ of the type species. The diagnosis of *Idioctis* given by Raven (1988) is correct save for the removal of

characters present only in *I. hawaiiensis*, here transferred to *Nihoa*, gen. nov.

Idioctis helva Koch
(Figs 2-6, Table 1)

Idioctis helva L. Koch, 1874: 484, tab. 37, fig. 3 a,b. Hogg, 1901: 241-242, fig. 26a. Marples, 1955: 453-454; Raven, 1988: 4, figs 1-5.

Material Examined

Lectotype: ♀, (here designated), Ovalau I., 17°41'S, 178°50'E, Fiji, Mus. Godeffroy No. 8097, deposited in Zoologische Institut and Zoologisches Museum, Hamburg.

Paralectotypes: 1♀, 1 juvenile, same data, deposited in BMNH.

Other Material

Topotypes: 1♂, Naqeledamu, Ovalau I., 17°41'S, 178°50'E, Fiji, in mangrove root, 14.xi.1988, T.B. Churchill, QM S11229. 5♀♀, Naqeledamu, Ovalau I., Fiji, 14.xi.1988, T.B. Churchill, QM S12521-5; 6♀♀, Lotu I., Vanua Levu, 16°46'S, 179°20'E, Fiji, 20.x.1988, T. B. Churchill, QM S12526-30.

Diagnosis

Spermathecae two, each consisting of two short dissimilar lobes, ental lobe stout, ectal lobe slender. ♀♀ with c.18 thorns on patella III. 4-5 teeth on paired claws of ♀♀. Rastellum of ten thick (four as long as wide) coniform spines in short distal line. Preening combs absent. ♂♂. Tibia I with small distal spur and upcurved megaspine, prolateral face with distal triangular cuticular process and short lower angular downcurved spine. Bulb pyriform; embolus broad, not spiralled; cymbium with two divided lobes. Two rows of teeth on all paired claws.

TABLE 1. Leg measurements of *Idioctis helva*, ♂.

	I	II	III	IV	Palp
Femur	3.60	3.20	2.56	3.36	2.20
Patella	1.92	1.84	1.44	1.76	1.44
Tibia	3.04	2.64	2.16	3.52	1.52
Metatarsus	2.32	2.16	2.16	2.96

Total	12.24	11.12	9.52	12.80	6.00

Topotype Male

Carapace 4.36 long, 3.32 wide. Abdomen 4.16 long, 2.40 wide. Total length, 10.

Colour in alcohol. Carapace and legs yellow brown, chelicerae red brown; abdomen dorsally grey brown with dark 'V' dorsally showing location of heart; venter entirely yellow brown.

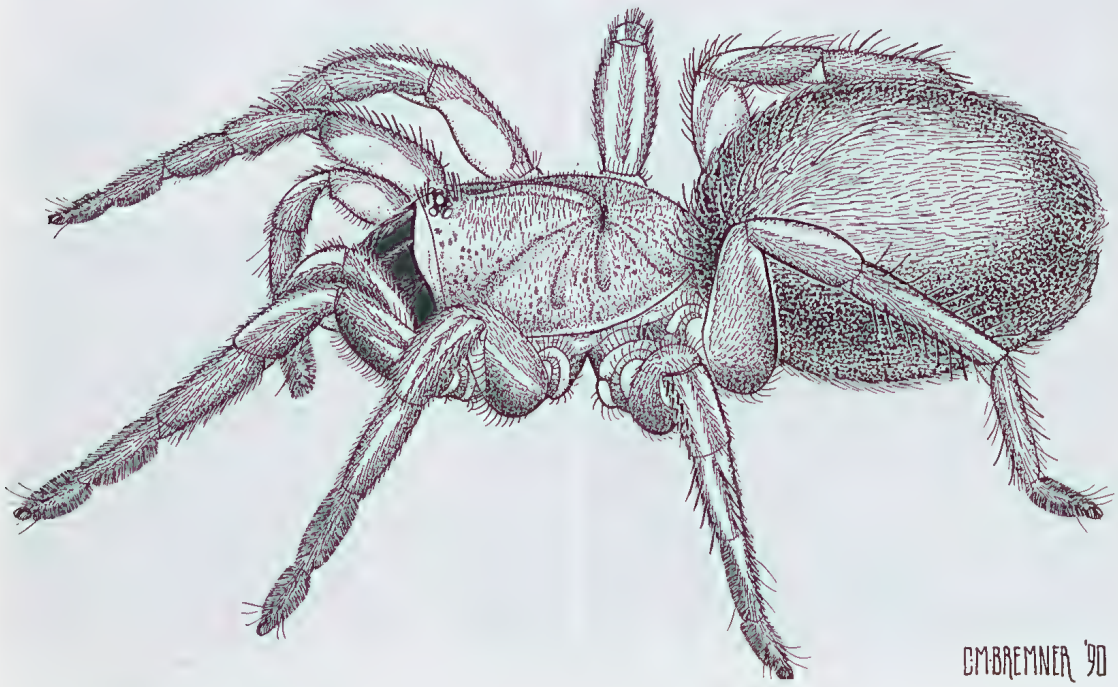

FIG. 1. *Idioctis yerlata* sp.nov., ♀.

FIG. 2. Distribution of *Idioctis* ★ and *Nihoa* ▲ in the Western Pacific and Indian Ocean.

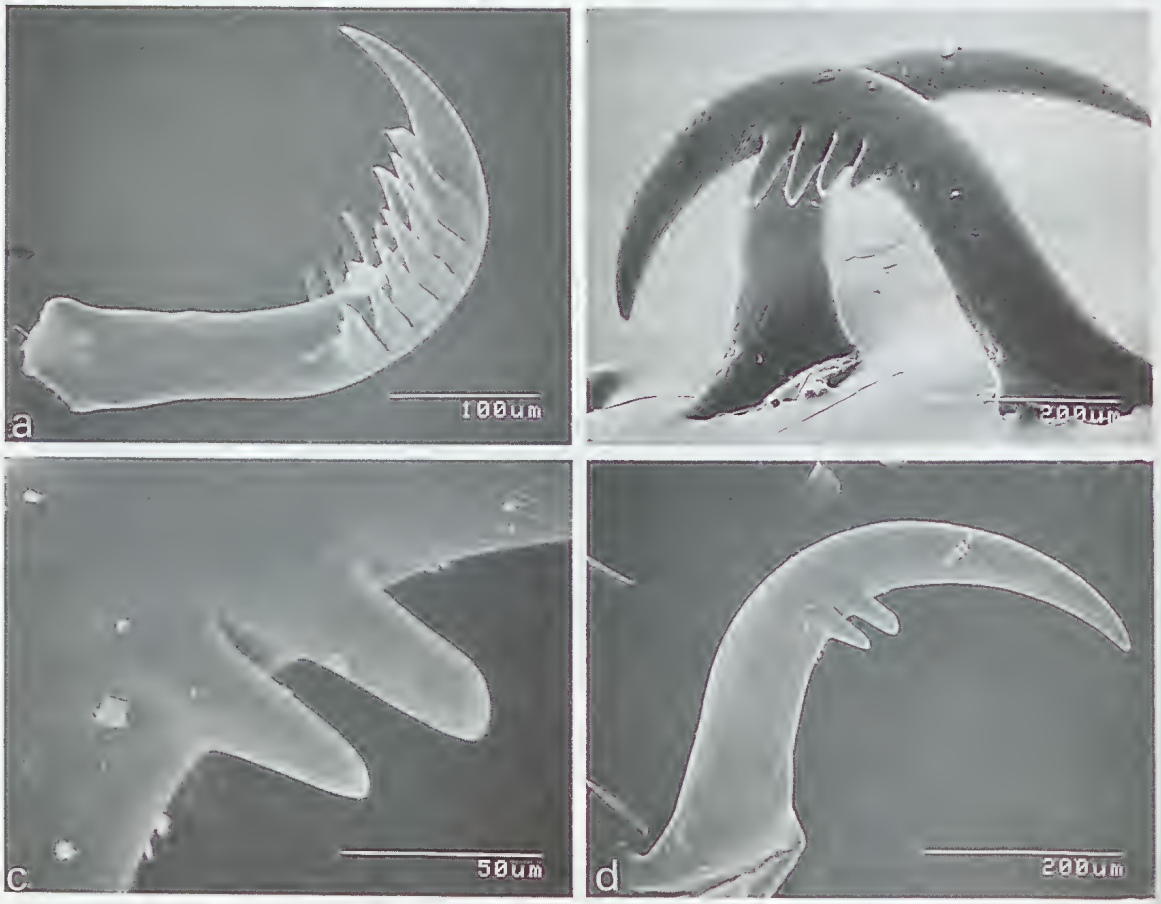

FIG. 3. *Idioctis helva*, scanning electron micrographs, paired claws, lateral view. a, b, leg I, ♂ (a), ♀ (b). c, d, leg IV, ♀.

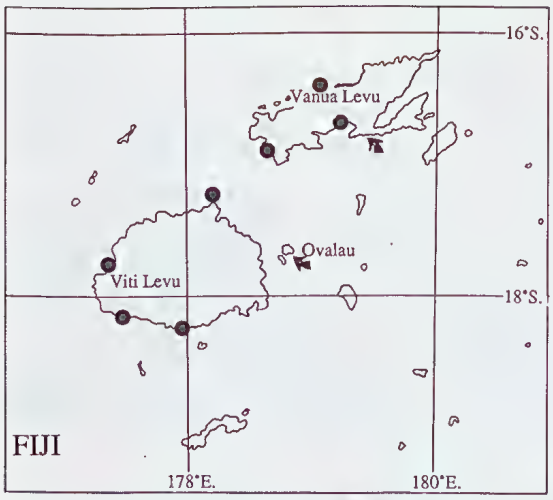

FIG. 4. Presence ➨ and absence ● of *Idioctis helva* at coastal localities sampled in Fiji.

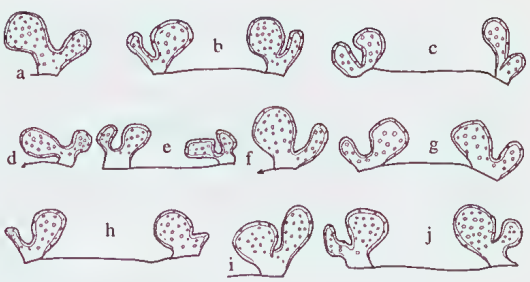

FIG. 5. *Idioctis helva*, dorsal view of spermathecae of ♀♀. a-d, g, Ovalau Island, Fiji. a, S12525. b, S12521. c, S12522. d, S12523. g, S12524. e, f, h-j, Lotu Island (Vanua Levu), Fiji. e, S12527. f, S12528. h, S12526. i, S12529. j, S12530. Scale line = 0.25mm.

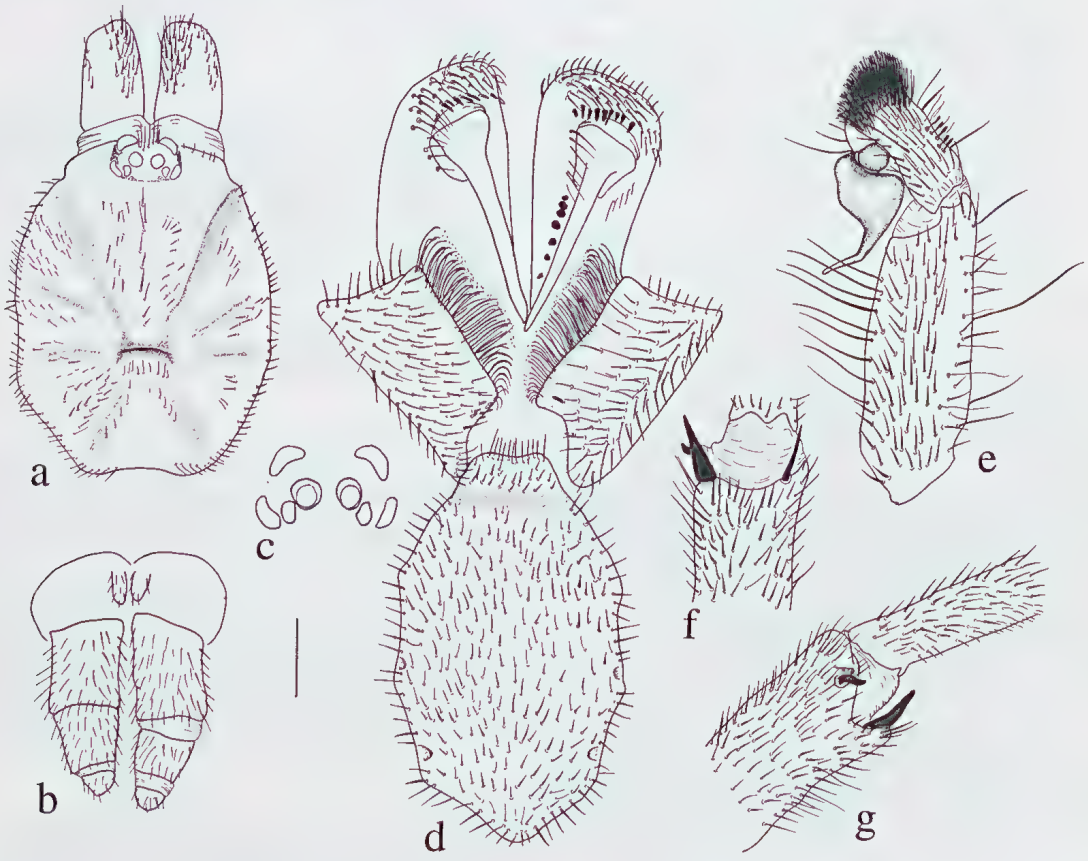

FIG. 6. *Idioctis helva*, topotype ♂. a, cephalothorax and chelicerae, dorsal view. b, spinnerets, ventral view. c, eyes, dorsal view. d, sternum, maxillae, labium and chelicerae, ventral view. e, palpal tibia, cymbium, and bulb, retroventral view. f, tibia I, ventral view, showing distal spur and megaspine. g, tibia I showing spur, prolateral view. Scale line = 1mm (a), 0.5mm (b-g).

Carapace. Uniform covering of short black bristles and fine grey hair, not obscuring cuticle; margins with longer setae and lower sclerotised shelf of hirsute chitin below main margin. An irregular row of 15-20 setae anteromedially; 2-3 pairs of fine setae; numerous thick setae between PME and ALE. Striae shallow, narrow, glabrous, recognised as areas intervening grey bush of hair. Fovea wide, recurved.

Eyes. Tubercle distinct. Group occupies 0.45 of head-width. Three rows; back row recurved. Front line of lenses of AME just behind line of back of ALE and 'iris' well back. Eye group front width, back width, length = 35:43:25. MOQ front width, back width, length = 21:29:14. AME:ALE:PME:PLE = 10:11:7:10. Eye interspaces:AME-AME, 0.5; AME-ALE, 0.5; ALE-ALE, 1.6; PME-PLE, 0.2; PME-PME, 1.8; ALE-PLE, 0.6.

Chelicerae. Wide band of brown setae and grey hair prodorsally, two narrower bands laterally. Promargin with 8 evenly spaced teeth, basomesally with 2 small teeth and 3 granules. Intercheliceral tumescence absent. Rastellum consists of 5 long thick pointed spines and c.5 thick setae.

Labium. 0.64 wide, 0.28 long. Cuspules absent. Labiosternal suture is two sigilla narrowed at their medial junction.

Maxillae. 1.04 long in front, 1.36 long behind, 0.64 wide; with c.5-8 pointed cuspules. Heel angular; anterior lobe distinct.

Sternum. 2.16 long, 1.48 wide. Only posterior sigilla evident as rounded glabrous marginal areas.

Legs. Formula 4123. All segments, especially femora, with mat of dark grey prostrate hairs; and erect black setae. All legs of similar diameter. Tibia I with small distal spur and upcurved megaspine, prolateral face with distal triangular cuticular process and short lower angular downcurved spine. Preening combs entirely absent.

Scopula. Never so thick as to obscure cuticle, individual hair bases distinct. Tarsi I-III ventrally pallid. Tarsi:I and II entirely ventral, thin, entire, full length; III, thin, divided by 8-10 setae; IV, with 10-15 scopula hairs in narrow triangle on proximal prolateral face. Claw tufts smaller than claws. Metatarsi: I, thin for full length, distally cuticle is pallid; II, similar but with single thick seta on ventrodistal edge; III, proventrally with light brush; IV, bare. Thorn spines: 10 on prolateral patella III.

Spines. Leg 1: fe d4, ti v3 +2 megaspines; me v1 weak, distal. Leg 2: fe d3, ti v4; me v1 weak, distal. Leg 3: fe d4, r1, pa p10 thorns, ti v5, me r1, v4. Leg 4: fe d6, r1w; ti r2, v7w; me v3 + 4 thick setae. Palp: fe d5w.

Claws. 2 full scooped rows of 8-10 teeth in each row on paired claws of leg I; claws of leg IV with 2 rows, 6 in each outer row and 2 in each inner row.

Trichobothria. In two rows, each of c.8 for 3/4 of tibiae; c.12 in proximally retrolateral row on metatarsi, distally row is irregular and trichae are longer; c.3 clavate and 15 filiform on tarsi in band.

Palp. Bulb pyriform; embolus broad, not spiralled; cymbium with two divided lobes.

Spinnerets. PMS 0.20 long, 0.08 wide, 0.08 apart, c.0.18 of basal PLS in diameter. PLS basal, middle, apical, and total article lengths = 0.64, 0.26, 0.14, 1.04, respectively.

Distribution and Habitat

I. helva is known from mangrove roots and trunks on Ovalau Island, east of Viti Levu, Fiji, and from coral rock on Lotu Island, south of Vanua Levu, Fiji.

Remarks

Females of *I. helva* differ from those of other species by the wider configuration of the eyes and the smaller PMS. Spermathecae consist of two short almost amorphous lobes joined basally to form a common aperture. Males differ from those of *I. eniwetok* Raven by the absence of preening combs.

Idioctis yerlata sp.nov.
(Figs 1, 2, 7-9, Table 2)

Material Examined

Holotype: ♀, Cape Tribulation, 16°05'S, 145°26'E, in mangroves, North Queensland, Australia, 28-29.viii.1988, R.J. Raven, T.B. Churchill, J.A. Gallon, QM S7213.

Paratypes: 7♀♀, Cape Tribulation, 16°05'S, 145°26'E, in mangroves, North Queensland, 28-29.viii.1988, R.J. Raven, T.B. Churchill, J.A. Gallon, QM S7204-9, S7212, S11181. 1♀, Noah Head, S. of Cape Tribulation, 16°08'S, 145°28'E, 30.viii.1988, R.J. Raven, T.B. Churchill, J.A. Gallon, QM S7206.

Diagnosis

Spermathecae with one large medial lobe and variable basal lobe ectally; basal lobe small with common atrium with lateral lobe or separate lobe arising above base of medial lobe (Fig. 9). Three closely spaced teeth on cheliceral promargin near fang base. Numerous (28-30) thorn spines on prolateral patellae III. 5-7 teeth on paired claws of

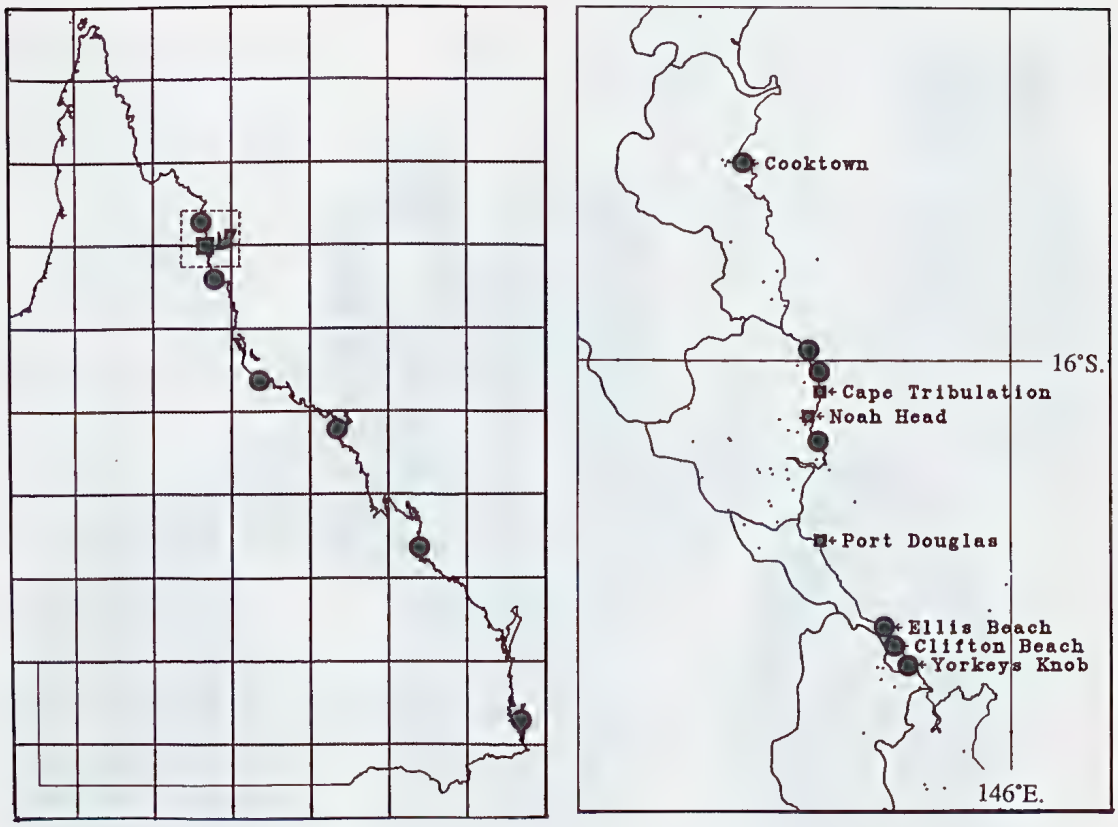

FIG. 7. Presence of *Idioctis yerlata* sp.nov. at coastal localities sampled in Queensland, Australia; inset enlarged at right, presence ■ and absence ●.

leg I. Preening combs absent. Rastellum is 12-14 long curved spines.

HOLOTYPE FEMALE

Carapace 5.36 long, 4.40 wide. Abdomen 8.80 long, 5.28 wide. Total length, 16.

Colour in alcohol and life. Carapace and legs yellow brown, chelicerae red brown, abdomen uniform yellow brown.

Carapace. Uniform cover of fine prostrate wavy grey hairs; 10-15 long erect setae on medial caput lateral of centre line; c.4 pairs of fine foveal bristles; 27 long erect black setae anteromedially; 7 long black anteriorly directed bristles and numerous fine black setae between PME; 2 long recurved and 10-15 shorter black bristles between ALE; caput raised; striae distinct. Fovea broad, straight with recurved ends.

TABLE 2. Leg measurements of *Idioctis yerlata*, holotype ♀

	I	II	III	IV	Palp
Femur	3.28	2.88	2.24	3.44	2.64
Patella	2.48	2.32	1.84	2.64	1.84
Tibia	2.48	2.24	1.84	3.44	1.64
Metatarsus	1.84	1.76	1.12	2.80	
Tarsus	1.36	1.20	0.88	1.20	1.52
Total	11.44	10.40	7.92	13.52	7.64

Eyes. Tubercle low. Group occupies 0.33 of head width. Three rows; back row more or less straight. Eye group front width, back width, length = 44:58:34. MOQ front width, back width, length = 23:42:17. AME:ALE:PME:PLE = 7:13:7:15. Eye interspaces: AME-AME, 1.3; ALE-ALE, 3.4; AME-ALE, 1.6; PME-PLE, 0.1; PME-PME, 4.0; ALE-PLE, 1.6.

Chelicerae. With moderately dense bush of black hairs dorsally and in lateral band; rastellum consists of 12-14 long strong spines; promargin of furrow with two very large and five smaller teeth, and six small teeth basally.

Labium. 0.92 wide, 0.48 long, without cuspules, separated from sternum by narrow groove.

Maxillae. 1.60 long in front, 2.04 long behind, 0.96 wide; with 6-9 spindle-shaped cuspules in

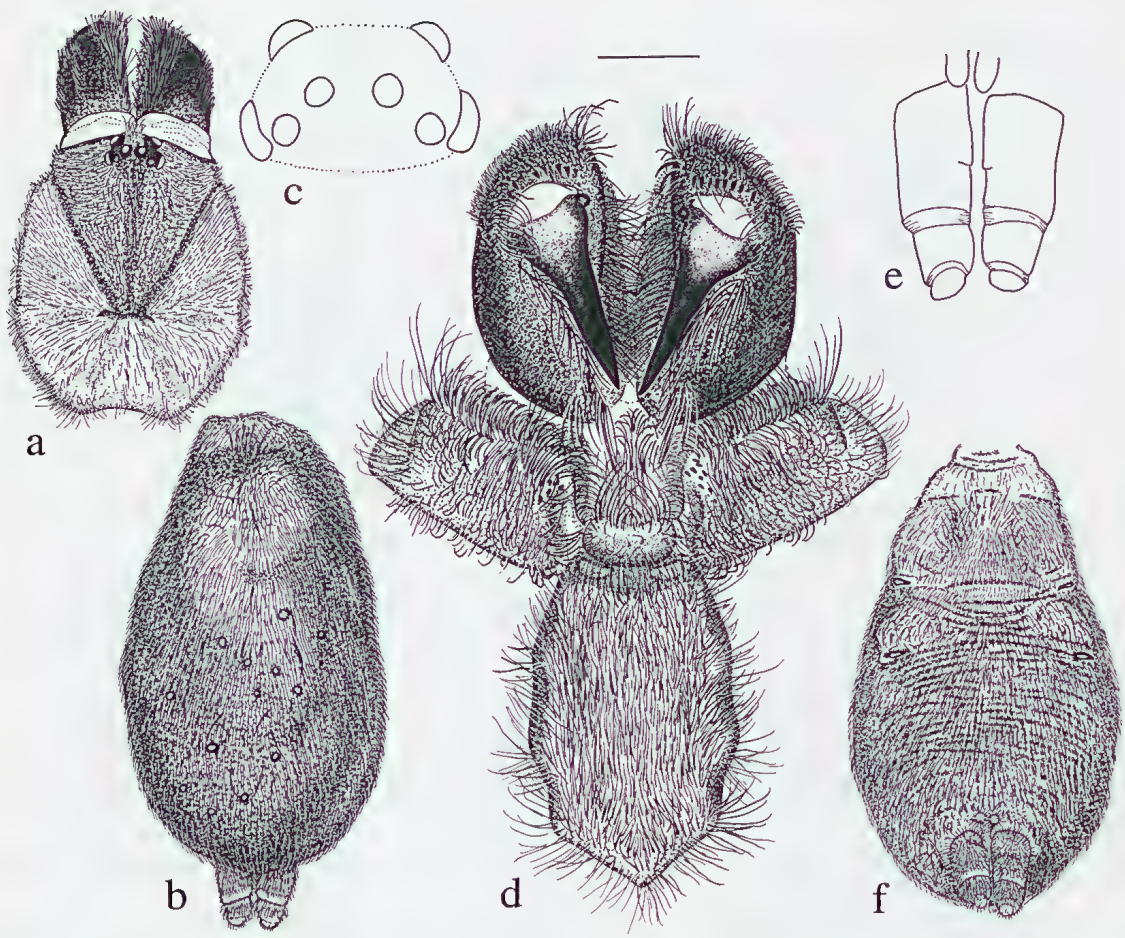

FIG. 8. *Idioctis yerlata* sp.nov. holotype ♀. a, cephalothorax and chelicerae, dorsal view. b, abdomen, dorsal view. c, eyes, dorsal view. d, sternum, maxillae, labium and chelicerae, ventral view. e, spinnerets, ventral view. f, abdomen, ventral view. Scale line = 2 mm (a, b), 1mm (d), 0.5mm (c, e).

close group on inner angle; anterior lobe indistinct, posterior 'heel' produced.

Sternum. 3.12 long, 2.00 wide; sigilla evident as shallow depressions in margin.

Legs. Formula 4123. Legs I and II much thicker than III and IV; tarsi as fat as distal metatarsi. Dorsal tarsi and metatarsi with pile of short straight grey hair. Tibia through tarsus IV asetose, almost glabrous. With numerous short coniform spines on prolateral patellae III, IV. Preening combs consist of group of 8 spines on metatarsi III, outer pair and middle pair long and slender, others short, thick; eight also on metatarsi IV, two long slender setae separated by shorter spines on ventral edge of metatarsi IV.

Scopula. Full and entire on metatarsi and tarsi I, II; divided by setae on metatarsi and tarsi III; one narrow prolateral band on tarsi IV; elsewhere absent. Palpal tarsal scopulae entire.

Spines. No spines on tarsi. Leg 1: fe 0, (d11 thick setae); ti p1 weak, v7 weak; me v1 distally with thick bristle. Leg 2: me v2 distally 1v with thick bristle. Leg 3: pa p28-30; tibia v1 + 6w, me distoventral 2 long medial with 4 on each side and one between 2 long. Leg 4: fe 0, pa p11-16, ti v5, me 0. Palp, ti v1 or v0.

Claws. Paired claws with 5-7 teeth on ectally displaced keel on leg I; 3 teeth on leg III; 2 on leg IV; palpal claw without teeth. All paired claws extending beyond tufts, except on palp.

Trichobothria. c.8 for 3/4 of tibiae; c.12 on metatarsi; 5 clavate and 12 filiform on tarsi.

Spermathecae. Two, each with one large medial and one ectal lobe.

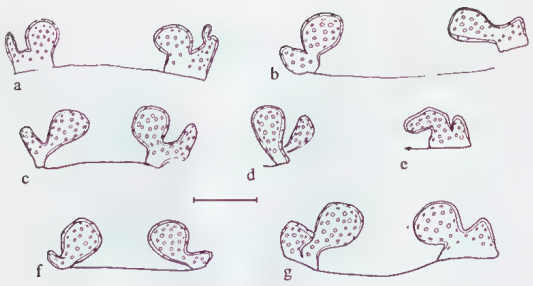

FIG. 9. *Idioctis yerlata* sp.nov., dorsal view of spermathecae of ♀♀. a, S7204. b, S7207. c, S7212. d, S7213. e, S11181. f, S7206. g, S7208. Scale line = 0.25mm.

Spinnerets. PMS 0.48 long, 0.22 wide, bases 0.10 apart, c.0.24 of basal PLS in diameter. PLS basal, median, and apical total article lengths = 1.14, 0.60, 0.20, 1.94, respectively.

DISTRIBUTION AND HABITAT

Known only from mangroves and loose coral rubble in the intertidal zone near Cape Tribulation, north Queensland, Australia. A trapdoor burrow like that of *Idioctis* was noted in the intertidal zone on a mangrove tree just south of Port Douglas, about 30km north of Cairns, north Queensland.

ETYMOLOGY

The specific epithet is an aboriginal work meaning oyster, which is often the impression conveyed by the door of *I. yerlata* burrows.

REMARKS

Females differ from all species of *Idioctis* in the larger relative size (3.4 times an AME diameter) of the ALE-ALE interspace.

Idioctis ferrophila sp.nov.
(Figs 2, 10-12, Table 3)

MATERIAL EXAMINED

HOLOTYPE: ♀, Port Boisé, 22°20'S, 166°59'E, New Caledonia, ironstone boulder in water on beach, 25.x.1988, R.J. Raven, T.B. Churchill, QM S13537.

PARATYPES: 7♀♀, Port Boisé, 22°20'S, 166°59'E, New Caledonia, ironstone boulder in water on beach, 25.x.1988, R.J. Raven, T.B. Churchill, QM S12511-3, S12515-7, S13538; 3♀♀, same data, 6.ix.1990, P. Goloboff, N. Platnick, R.J. Raven, AMNH.

DIAGNOSIS

Spermathecae with large medial lobe and short basal lobe with axes perpendicular. Thorn spines: c.30 on prolateral patellae III, c.11 small on proximal prodorsal patella IV. 3-5 teeth on paired claws of ♀♀. Rastellum a line of 10 short conical spines, not on mound, on edge above fang. ♂♂ unknown.

HOLOTYPE FEMALE

Carapace 5.28 long, 4.12 wide. Abdomen 8.48 long, 4.88 wide. Total length, 17.

Colour in alcohol and life. Carapace yellow brown with light brown mottling, chelicerae dark reddish brown-burgundy; legs, sternum, maxillae, and labium yellow brown; abdomen light yellow brown with slightly darker medial band over heart.

Carapace. With fine gray hairs forming uniform covering; hairs become larger and paler on margins and darker and thicker near anteromedial line. Striae glabrous, narrow, barely distinct. Narrow sclerotised and hirsute ledge below edge of carapace. Fovea very slightly procurved. About 10 thick and several finer anteromedial setae; two long setae between PME; 5-8 long recurved and several shorter setae and fine hairs between ALE. Clypeus absent.

Eyes. Tubercle low. Group occupies 0.32 of head-width. Three rows; back row procurved. Eye group front width, back width, length = 44:55:32. MOQ front width, back width, length = 25:33:19. AME:ALE:PME:PLE = 10:14:8:14. AME-AME, 0.4, AME-ALE, 0.8, ALE-ALE, 1.7, PME-PLE, 0.3, PME-PME, 2.2, ALE-PLE 1.0.

Chelicerae. Porrect with prodorsal and lateral bands of long fine hairs. Slight ridge parallels upper cheliceral face. Rastellum a line of 10 short conical spines, not on mound, on edge above fang.

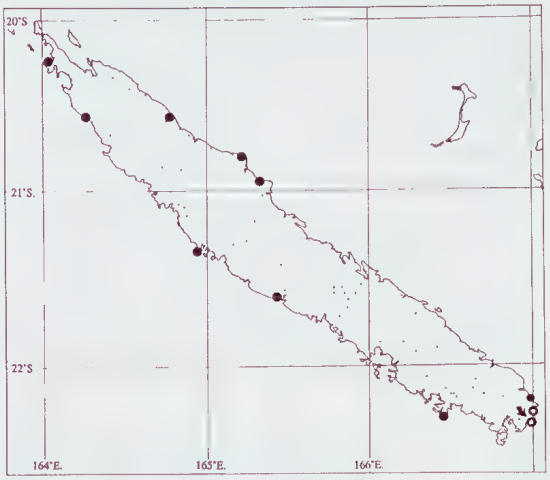

FIG. 10. Presence ● and absence ○ of *Idioctis ferrophila* sp.nov. at coastal localities sampled in New Caledonia.

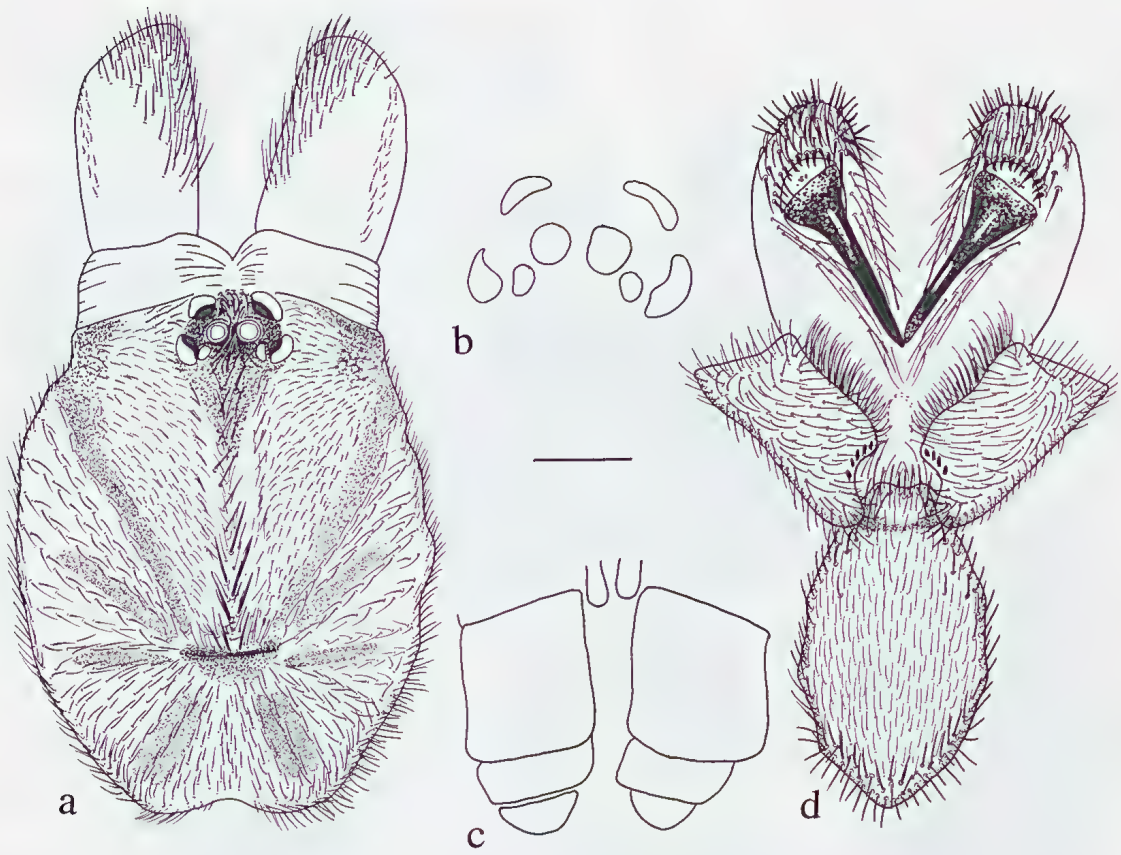

FIG. 11. *Idioctis ferrophila* sp.nov., holotype ♀. a, cephalothorax and chelicerae, dorsal view. b, eyes, dorsal view. c, spinnerets, ventral view. d, sternum, maxillae, and labium, ventral view. Scale line = 1mm (a, d), 0.5mm (b, c).

Furrow promargin with 7 thick teeth, basomesally with 1 minute and three small teeth.

Labium. 0.88 wide, 0.44 long. Labiosternal suture a narrow groove.

Maxillae. 1.52 long in front, 2.16 long behind, 1.04 wide; with c.4-6 cuspules on inner edge. Heel distinct; anterior lobe, indistinct.

Sternum. 2.80 long, 1.88 wide. With slightly darker and thicker hairs on margin; otherwise fine grey hairs medially. Sigilla shallow, indistinct.

Legs. Formula 4123. I, II thicker than III, IV.

TABLE 3. Leg measurements of *Idioctis ferrophila*, holotype ♀

	I	II	III	IV	Palp
Femur	2.88	2.68	2.08	3.08	2.24
Patella	2.40	2.16	1.52	2.24	1.68
Tibia	2.08	2.04	1.36	3.28	1.36
Metatarsus	1.60	1.52	1.36	2.44	
Tarsus	1.12	1.12	0.80	0.88	1.44
Total	10.08	9.52	7.12	11.92	6.72

Covered with fine grey hairs mixed with black setae; fine 'furry' grey hairs form narrow band near trichobothria on tibiae and metatarsi. Metatarsi I, II with distinct darker pair of setae distoventrally. Thorn spines: c.30 on prolateral patellae III, c.11 small on proximal prodorsal patella IV.

Scopula. Metatarsi and tarsi I, II, full, entire but not obscuring cuticle and separate hairs distinct. Metatarsi: III, one wide band prolaterally, ventrally and retrolaterally with setae and spines; IV, absent. Tarsi: III, full, parted by band 6-8 setal rows wide; IV, only small cluster in proximal proventral corner.

Spines. True spines only ventrally on palpal tibiae and distal metatarsi III, IV; 6-8 thicker setae on dorsal femora. Leg 1, 2: none except tibia v2 (w) and v4, respectively. Leg 3: thorn spines plus, ti v6 (w), me v8 on distal edge plus 1 thick and 4 thinner medially. Leg 4: thorn spines plus, tibia v7

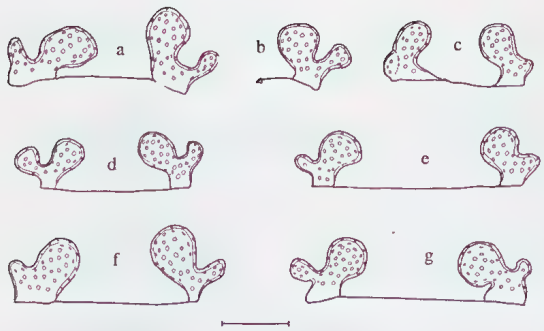

FIG. 12. *Idioctis ferrophila* sp.nov., dorsal view of spermathecae of ♀♀. a, S7211. b, S12513. c, S12517. d, S12511. e, S12512. f, S13538. g, S13537. Scale line = 0.25mm.

(w); me, v8 distal (4 close enough to be almost a comb) and 3 thinner proximad. Palp, ti v5.

Claws. 5 short (leg I) to 3 (leg IV) teeth on paired claws, palpal claw bare. Tufts dense, not enclosing claws, divided.

Trichobothria. In 2 rows, each of c.6 for 3/4 of length of tibiae; c.6-7 in short diagonal row on metatarsi; 5 clavate and c.14 filiform on tarsi in two triangular bands. Trichobothria associated with fine grey hairs.

Spermathecae. Two, each with two lobes, medial lobe broad, lateral lobe small digitiform.

Spinnerets. PMS 0.22 long, 0.08 wide, 0.08 apart, c.0.12 of basal PLS in diameter. PLS length of basal, middle, apical, and total articles = 0.76, 0.22, 0.18, 1.92, respectively.

Distribution and Habitat

Idioctis ferrophila is known from ironstone boulders on the beach at Port Boisé at the south eastern corner of New Caledonia. A trapdoor burrow with a spider like that of *Idioctis* was noted in intertidal rocks just south of Goro, 5-7 km east of Port Boisé. The specimen was not collected. At both locations, the boulders and rocks had water around their bases at low tide.

Etymology

The specific epithet is latin derived for iron (*ferros*) and greek love (*philos*) and relates to the original collection of this species from only ironstone boulders in southern New Caledonia.

Idioctis talofa sp.nov.
(Figs 2, 13-15, Table 4)

Material Examined

Holotype: ♀, Upolu, 13°55'S, 172°45'W, close to high tide mark, Western Samoa, B. J. Marples, BMNH 1974.129.1.

Paratypes: 2♀♀, Upolu, 13°55'S, 172°45'W, close to high tide mark, Western Samoa, B. J. Marples, BMNH 1974.129.2. 14♀♀ and eggs from Nu'ulopa Islet, Western Samoa, B. J. Marples, BMNH 1974.135. 1♀, 'Samoa', 19.ii.1882, Kauf, Godeffroy collection in NHW.

Diagnosis

Spermathecae two, each consisting of two similarly sized lobes, one lobe pointed. 18-20 thorn spines on prolateral proximal corner of patella III; c.9 on patella IV; prolateral distal corner of femur IV with 2-3 short spines. 4 teeth on all paired claws. Preening combs absent. Rastellum is 11 thick curved spines in single line with bases touching.

Holotype Female

Carapace 5.00 long, 4.08 wide. Abdomen 7.17 long, 4.00 wide. Total length, 15.

Colour in alcohol. Carapace orange brown, darker on caput, legs orange brown. Abdomen dorsally pallid with purplish tinge and ventrally pallid.

Carapace. With light uniform covering of silvery brown hairs, none in striae, light bush on margins, numerous brown bristles beside 10 thick and several smaller anteromedial bristles, 6-8 thick bristles between PME, c.10 between AME. Fovea distinctly procurved; clypeus absent.

Eyes. Tubercle low, distinct. AME pigmented. Group occupies 0.35 of head-width. Three rows; front row widely separated from middle row, back row slightly procurved. Eye group front width, back width, length = 40:52:33. MOQ front width, back width, length = 24:35:19. AME:ALE:PME:

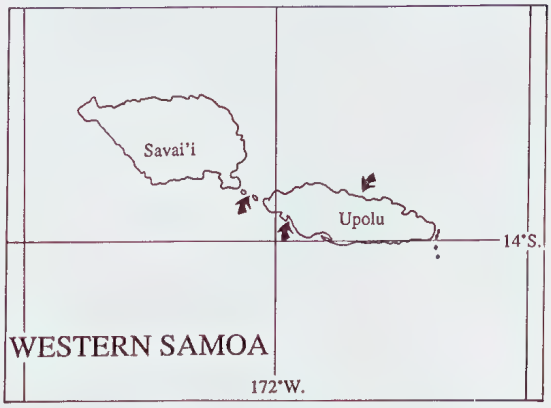

FIG. 13. Localities of *Idioctis talofa* sp.nov. in Western Samoa ➨.

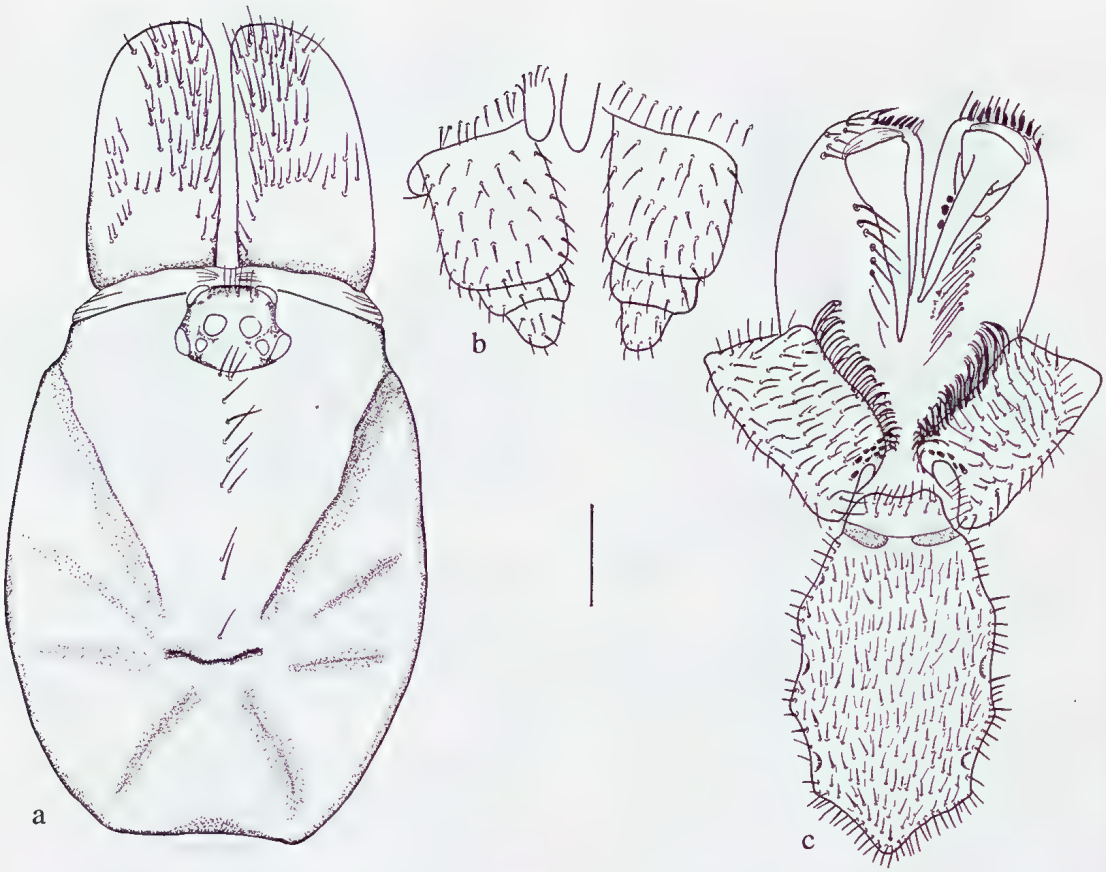

FIG. 14. *Idioctis talofa* sp.nov., holotype ♀. a, cephalothorax and chelicerae, dorsal view. b, spinnerets, ventral view. c, sternum, maxillae, labium and chelicerae, ventral view. Scale line = 1mm (a, c), 0.5mm (b).

PLE = 10:12:8:14. Interspaces: AME-AME, 0.5, AME-ALE, 1.0, ALE-ALE, 1.9, PME-PLE, 0.2, PME-PME, 2.4, ALE-PLE, 1.3.

Chelicerae. Band of moderately long brown bristles prodorsally and narrower band laterally. Rastellum is c.11 thick curved spines in single line hanging over long cheliceral edge, with bases touching. Furrow promargin with 8 teeth, all bases separate but most anterior teeth bases very close, basomesally with 6 small teeth.

Labium. 0.92 wide, 0.84 long. Separated from sternum by narrow groove.

Maxillae. 1.44 long in front, 1.96 long behind, 1.20 wide; with 5-8 pointed cuspules on inner angle. Heel rounded; anterior lobe just distinct.

Sternum. 3.24 long, 1.96 wide. Widest between coxae I. Sigilla small, marginal, indistinct.

Legs. With uniform covering of moderately long brown hairs. Scopula. Metatarsi and tarsi I, II entire, full; metatarsi III, only on proventral face; metatarsi IV absent; tarsi II with narrow band of 4-6 rows parting scopula; tarsi IV thin, short hairs, only on proventral face. Thorn spines: 18-20 on prolateral proximal corner of patella III; c.9 on patella IV; prolateral distal corner of femur IV with 2-3 short spines. Preening combs absent.

Claws. All paired claws with 4 distinct teeth; palpal claw bare. Claw tufts not enclosing claws.

Spines. No true spines dorsally or laterally except for femora and patellae III, IV. Spines on ventral legs generally weak, strong only on distal metatarsi III and IV but no so close as to form comb. Leg 1: ti p3, me 0. Leg 2: ti v3, me v1. Leg 3: pa p18, ti v6w, me v9. Leg 4, fe p3, pa p6, ti v8w, me v5 short plus 4-6 thinner. Palp: ti p1, v4.

Trichobothria. In two rows, each of c.11 for 3/4 of tibiae; c.9 in curving row on metatarsi; 3 clavate and c.15 filiform on tarsi.

Spermathecae. Two, each consisting of two similarly sized lobes, one lobe pointed.

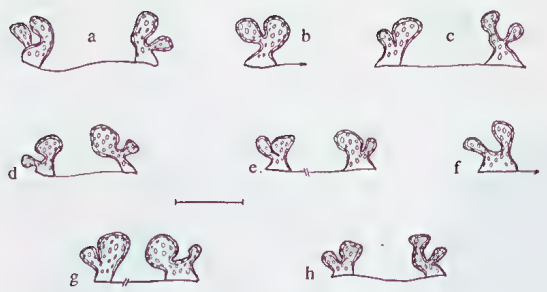

FIG. 15. *Idioctis talofa* sp.nov., dorsal view of spermathecae of ♀♀, a-h. Scale line = 0.25mm.

Spinnerets. PMS 0.36 long, 0.12 wide, bases 0.06 apart, c.0.19 of basal PLS in diameter. PLS basal, middle, apical, and total article lengths = 0.74, 0.26, 0.18, 1.18, respectively.

DISTRIBUTION AND HABITAT

Known from laval rock on beaches on the island of Upolu, and the islet of Nu'ulopa, Western Samoa (Marples, 1955).

ETYMOLOGY

The specific epithet is a Samoan word meaning 'welcome', in appreciation of the warm reception given to TBC.

REMARKS

Differs from *I. helva* in the spermathecal lobes being equal in size, anterior most teeth in cheliceral margin not fused basally, and has 1-2 thorns on prolateral distal femur IV. Of the 17 adults examined, one from 'Upolu' has only 4-6 spines on prolateral patella III of both legs. In all others, the number varies from 10-20 on a single specimen.

Idioctis marovo sp.nov.
(Figs 2, 16-18, Table 5)

MATERIAL EXAMINED

HOLOTYPE: ♀, Uepi Island, Marovo Lagoon, Western Province, Solomon Islands, Western Pacific, 8°27'S, 157°56'E, intertidal limestone beach rock, 7.vii.1990, T.B. Churchill, QM S17121.

PARATYPE: 5♀♀, same data as holotype, 7.vii.1990, T.B. Churchill, QM S17118-20, QM S17122, QM S17123.

DIAGNOSIS

Spermathecae two, each consisting of large terminally enlarged lobe with smaller one attached to the outer base of the former. Thorn spines: 25 on prolateral proximal corner of patella III; 10-16 on patella IV; prolateral distal corner of femur IV with 5 short spines. 2-4 teeth on paired claws. Rastellum of 10 strong spines in single line with bases touching. Preening combs a whorl of spines on metatarsi III, IV. ♂♂ unknown.

lum of 10 strong spines in single line with bases touching overhang cheliceral edge. Furrow promargin with 7 teeth, all bases separate but most anterior teeth bases very close, basomesally with 4 small teeth.

Labium. 0.64 wide, 0.28 long. Separated from sternum by distinct narrow groove.

Maxillae. 1.00 long in front, 1.44 long behind, 0.76 wide; with 5 pointed cuspules on inner angle. Heel rounded; anterior lobe just distinct.

Sternum. 2.24 long, 1.52 wide. Sigilla small, oval, and marginal, increasing in size posteriorly.

Legs. With uniform covering of moderately long brown hairs. Scopula: metatarsi and tarsi I, II, entire, full; metatarsi III, only on proventral face; tarsi III, with band of 4-6 rows of setae parting scopula; metatarsi and tarsi IV absent. Thorn spines: 25 on prolateral proximal corner of patella III; 10-16 on patella IV; prolateral distal corner of femur IV with 5 short spines. Preening combs a whorl of spines on metatarsi III, IV.

Spines. No true spines dorsally or laterally but 3-5 long fine black setae on femora I. Spines on ventral legs generally weak, strong only on distal metatarsi III and IV but no so close as to form comb. Leg 1: fe 0, pa 0, ti v2w, me 0. Leg 2: fe 0, pa 0, ti v2, me v1w. Leg 3: fe 0, pa p24 thorn spines, ti v2w, me v10. Leg 4: fe p5 thorn spines, pa p10-16, ti 0, me v7 in distal whorl. Palp, ti r1, v4 + 3w.

Claws. Paired claws with 2-4 distinct teeth; palpal claw bare. Claw tufts just enclosing claws.

Trichobothria. In two rows, each of c.11 for 3/4 of tibiae; c.15 in curving row that splits into two rows for the distal half on metatarsi; 6 clavate and c.16 filiform that split into two rows each two wide, two centrally and distally, on tarsi.

Spermathecae. Two, each consisting of large terminally enlarged lobe with smaller one attached to the outer base of the former.

Spinnerets. PMS 0.26 long, 0.14 wide, bases 0.06 apart, c.0.30 of basal PLS in diameter. Basal, middle, apical, and total article lengths of PLS = 0.74, 0.12, 0.14, 1.00, respectively.

Total	16.32	14.88	12.80	20.16	10.56

Distribution and Habitat

Known from limestone beach rock and the root bases of coconut trees in the littoral zone on the island of Uepi, in the Marovo Lagoon, Western Province, Solomon Islands.

Etymology

The specific epithet is taken from Marovo Lagoon, Solomon Islands (where the spiders were collected), which has been nominated for World Heritage listing. In the face of increasing pressure from mining and logging activities, its pristine state is a credit to the wisdom of the local people.

Remarks

Females of *I. marovo* differ from those of all other species except *I. eniwetok* in that patella III is clearly shorter than tibia III, and from *I. eniwetok* in the presence of numerous thorn spines on patella IV.

Nihoa gen.nov. Raven & Churchill

Diagnosis

Nihoa can be distinguished from *Idioctis* by the wider sternum, the medially located teeth on the paired claws of ♀♀ and the absence of a second row of teeth on the claws of ♂♂. The two genera are readily distinguished by the presence of distinct pattern dorsally on the abdomen of *Nihoa*. *Nihoa* also differs from both *Idioctis* and *Idiophthalma* in the absence of a rastellum and from *Rhianodes* Raven in the absence of a groove on the anterior face of the maxillae.

Description

Carapace hirsute, without pattern. Fovea very

broad, straight to slightly procurved. Abdomen with distinct pattern or mottling. Rastellum absent. Maxillae usually with c.10-20 cuspules on inner anterior corner; anterior lobe indistinct, posterior heel produced. Labium wide, without cuspules. Sternum long, narrow (about 1.4 times longer than wide, rarely narrower), with small, marginal sigilla, if evident. Scopulae (♀ ♀) entire on metatarsi and tarsi I-III, in distal half mixed with setae on metatarsi III, and one small triangle proventrally on metatarsi IV, if present; dense and divided by narrow band of setae.

Spines (rare value in parentheses). Leg 1: femur, p0 d0-4 r0, patella, 0, tibia, p0-1 v2-7, me p0 r0-1. Leg 2: femur, p0 d0-4 r0, patella p0, tibia p0-1 v0-4, metatarsus 0 v1-2. Leg 3: femur p0-1 d0-5 r0, patella p6-30, tibia p0(2) r0(2) v0-7, metatarsus p0-3 r0-3 v0-13. Leg 4: femur p0 d0-7 r0, patella p3-16, tibia p0 d0 r0(2) v0-7, metatarsus p0-7 r0-4 v2-9.

Paired claws of ♀ ♀ with teeth on medial keel; claws of ♂ ♂ with or without one row of teeth. Tarsi with clavate and filiform trichobothria. ♂ ♂: tibia I with prolateral spur and megaspine, more distal prolateral megaspine and associated cuticular 'thumb'; palpal bulb pyriform; embolic tip flanged.

Type Species

Nihoa mahina sp.nov.

Remarks

Raven's (1988) inclusion of *Idioctis hawaiiensis* in *Idioctis* was presumably based upon the notion that it was the only genus that could be on such remote islands. He did identify that the species was the sister group of all other *Idioctis* species but lacked data on the ♂ of the type species to confirm the generic diagnosis.

Distribution and Habitat

Known from Nihoa Island in the northern group of the Leeward Islands from terrestrial habitats.

Included Species

Nihoa mahina sp.nov.Nihoa I., Leeward Islands, NW Pacific

Idioctis hawaiiensis (Raven, 1988)Necker I., Leeward Islands, NW Pacific

Nihoa mahina sp.nov. Churchill & Raven (Figs 19-22, Table 6)

Material Examined

Holotype: ♂, Nihoa I., 22°10'N, 163°10'W, Leeward Islands, northwest Pacific Ocean, 40ft.[12.2m] above sea-level, on rocks near camp in moonlight, 15.ii.1981, S. Conant, Bernice P. Bishop Museum.

Paratypes: ♀ (allotype), Nihoa I., 22°10'N, 163°10'W, Leeward Islands, Hawaii, in sleeping bag, vi.1981, S. Conant; ♀, Nihoa I., 2.ii.1981, drowned in seep pool, S. Conant; ♀, Miller Valley, Nihoa I., vi.1982; all in Bernice P. Bishop Museum.

Diagnosis

Paired claws of ♂ ♂ with teeth. Upper cuticular process on tibia I of ♂ ♂ at base of spur. Spermathecae two coniform mounds.

Holotype Male

Carapace 10.00 long, 9.67 wide. Abdomen 10.00 long, 6.83 wide. Total length, 24.

Colour in alcohol. Carapace, legs and chelicerae red brown. Abdomen dorsally yellow brown with medial longitudinal discontinuous band of brown flanked laterally by somewhat paired, brown spots anteriorly and recurved brown bands posteriorly. Abdomen ventrally yellow brown with four small brown marks almost equidistant, centrally. Sternum, maxillae, and labium red brown. Spinnerets yellow brown.

Carapace. Fine silvery hairs form uniform covering intermixed with numerous setae; line of 6 thick and several finer anteromedial bristles, and several thick bristles between ALE; striae glabrous. Fovea slightly procurved.

Eyes. Tubercle low. Group occupies 0.24 of head width. Eyes in three rows. Eye group: front width, back width, length = 71:82:60. MOQ front width, back width, length = 44:60:31. AME:ALE:PME:PLE = 16:22:16:24. Eye interspaces: AME-AME, 1.1, AME-ALE, 1.0, ALE-

ALE, 2.3, PME-PLE, 0.1, PME-PME, 2.4, ALE-PLE, 1.1.

Chelicerae. With prodorsal and lateral bands of setae and fine silver hairs. Rastellum only a line of 20-25 long pointed bristles on distal edge. Furrow promargin with 8 thick teeth and 3 smaller teeth; 12 small teeth basomesally. Intercheliceral tumescence absent.

Labium. 1.76 wide, 0.72 long. Labiosternal suture a distinct groove.

Maxillae. 2.96 long in front, 3.60 long behind, 1.60 wide; with c.12 cuspules on inner edge. Heel distinct; anterior lobe indistinct.

Sternum. 5.60 long, 4.08 wide. Sigilla marginal, round, and posterior pair largest.

Legs. Formula 4123. Tibia I with distal, prolateral spur and short megaspine; base of spur with broad cuticular process below which is one (rarely two) spine. Scopulate surface of tarsi pallid.

Scopula. Leg I, full, thick, entire and undivided on metatarsi and tarsi I, II. Leg II scopula extends

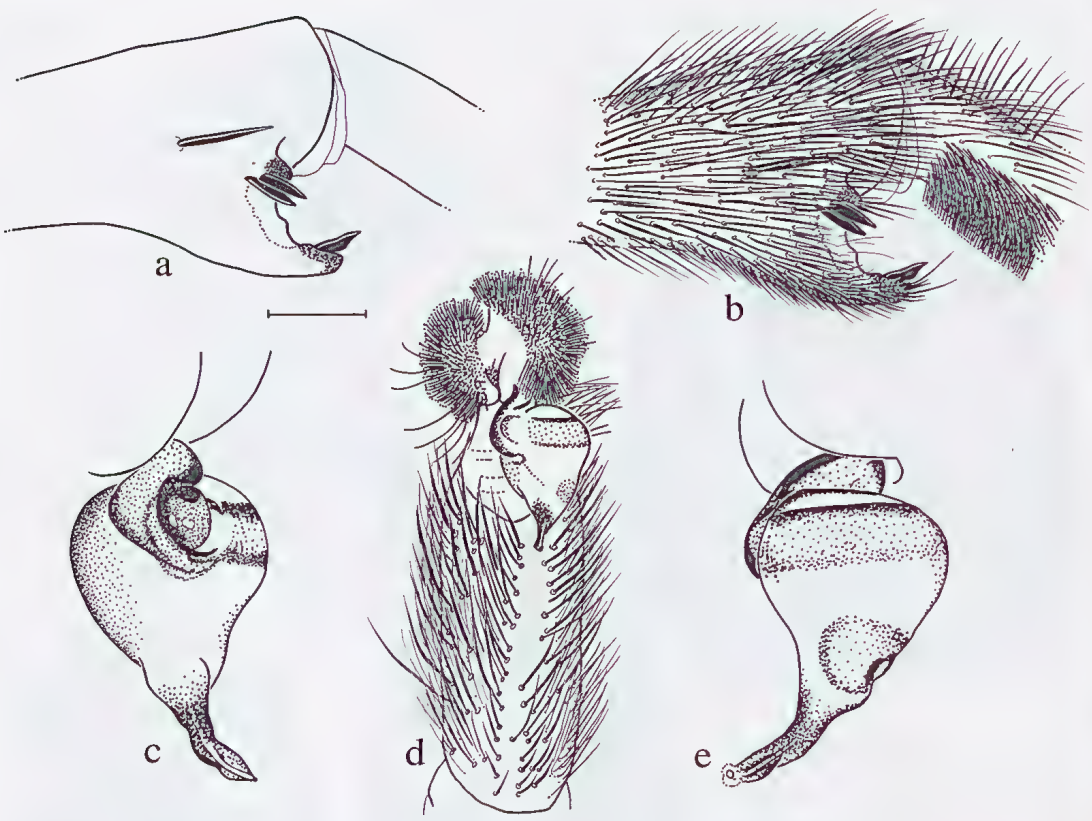

FIG. 21. *Nihoa mahina* sp.nov. holotype ♂. a, tibia I, prolateral view showing distal spur and megaspine, hair and scopula omitted. b, tibia I showing distribution of hair and scopula. c, palpal bulb. d, palpal tibia, cymbium and bulb, ventral view. e, palpal bulb. Scale line = 1mm (a, b, d), 0.5mm (c, e).

to retrolateral side; metatarsi III, thin on distal half extending to prolateral side with setae intermixed; tarsi III, entire, thick with setae intermixed; metatarsi IV, with distal prolateral 1/4 with thin scopulae; tarsus IV with setal band 2-4 rows across intermixed with thin scopulae.

Spines. Leg 1: fe p2, pa 0, ti p2+2, v3+2, me 0. Leg 2: fe p2, pa 0, ti p1, v2, me 0. Leg 3: fe p2, r3, pa 0, p2+1w, ti p2, r2, v5, me p4, r5, v10. Leg 4: fe p2, d2, r2, pa 0, ti r5, v10, me p6, r5, v17. Palp: pa 0, ti v1.

Palp. Bulb with distally flanged embolus. Cymbium with two deeply divided lobes, retrolateral face slightly convcave.

Claws. 2-4 (leg I) to 0 (leg IV) teeth in medial keel on paired claws. Tufts dense, enclosing claws.

Trichobothria. c.8 for half length of tibia, c.12 on metatarsi in single curving row; two bands each of c.4 small clavate and c.10 filiform on tarsi.

Spinnerets. PMS 0.84 long, 0.36 wide, bases 0.32 apart, c.0.33 of basal PLS in diameter. PLS basal, middle, apical, and total article lengths = 1.12, 0.64, 0.52, 2.28, respectively.

ALLOTYPE FEMALE

Carapace 10.00 long, 8.33 wide. Abdomen 10.33 long, 7.33 wide. Total length, 25.

Colour in alcohol. Carapace and legs orange brown, chelicerae red brown. Abdomen dorsally yellow brown with medial longitudinal discontinuous band of brown, flanked laterally by somewhat paired, brown spots anteriorly and recurved brown bands posteriorly. Abdomen ventrally yellow brown with four small brown marks almost equidistant, centrally. Sternum, maxillae, and labium orange brown. Spinnerets yellow brown.

Carapace. Fine silvery hairs form uniform covering intermixed with numerous setae well developed between head region and fovea; striae glabrous; fovea straight; c.30 setae between AME, c.14 between PME, c.40 long setae along medial

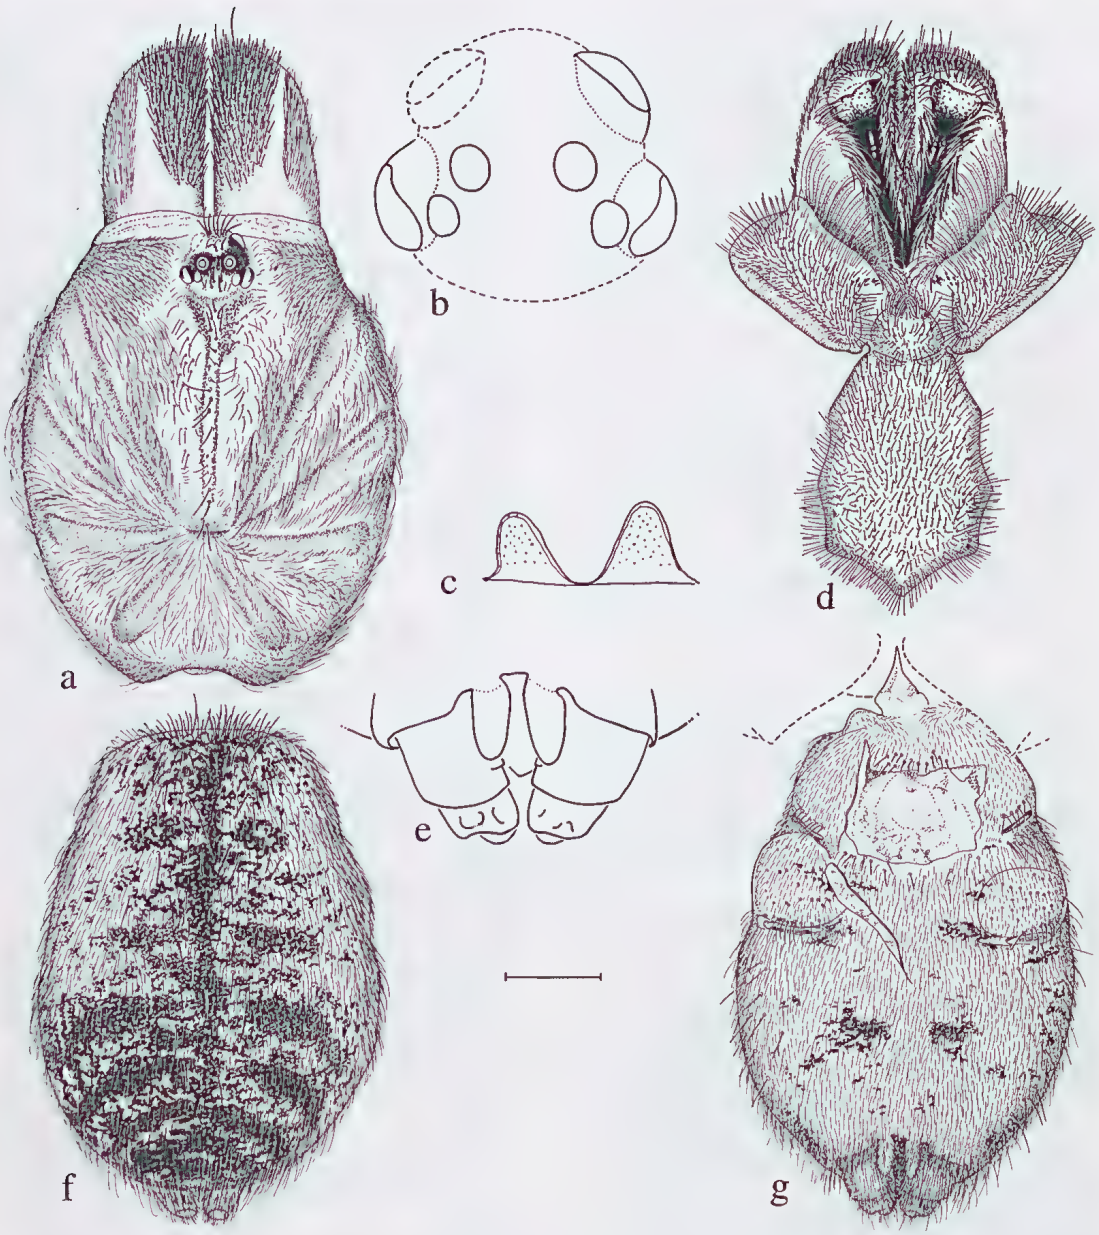

FIG. 22. *Nihoa mahina* sp.nov. paratype ♀. a, cephalothorax and chelicerae, dorsal view. b, eyes, dorsal view. c, spermathecae. d, sternum, maxillae, labium and chelicerae, ventral view. e, spinnerets, ventral view. f, abdomen, dorsal view. g, abdomen, ventral view. Tarsus	3.50	3.83	2.83	3.16	2.50
Total	29.16	27.81	24.12	32.32	14.49

promargin with 8 thick teeth and 3 smaller teeth; 6 basomesal granules.

Labium. 1.76 wide, 1.12 long. Labiosternal suture broad.

Maxillae. 2.72 long in front, 3.68 long behind, 1.60 wide; with c.10-12 cuspules on inner edge. Heel angular; anterior lobe, indistinct.

Sternum. 5.44 long, 3.76 wide. Sigilla: anterior and medial pair not evident; posterior pair small, round, marginal.

Legs. Thorn setae and preening combs absent. Tarsi broad, tarsi I c.60% of length wide; tarsi IV distally incrassate, distal width c.1.4 times basal width.

Scopula. Very dense on legs I, II: metatarsi and tarsi I, II, full, thick, entire, undivided; metatarsi III, thin on distal half with thick setae intermixed; tarsi III, entire, thick with 3-5 setae intermixed; metatarsi IV, thin in distal prolateral 1/4, divided; tarsi IV, thick, full, divided by narrow setal band 2-4 rows across and few setae intermixed, setal brush dense distally.

Spines. Leg 1, 0. Leg 2: 0, save ti p1. Leg 3: fe p2w, r2w, pa p2 thorns, ti p2, r1, v3, me p3, r3, v7. Leg 4: fe 0, pa 0, ti r1, v4, me p2, r1, v9. Palp, fe p1w, pa 0, ti p3w, v6w.

Claws. 4 (leg I) to 0 (leg IV) teeth on paired claws on medial keel. Tufts dense, just enclosing claws. Palpal claw very small, curved, bare.

Trichobothria. In two rows each of c.8 for half length of tibia; c.11 on metatarsi in single curving row; c.3-5 clavate and 12-14 filiform in each of two bands on tarsi.

Spermathecae. Two coniform mounds.

Spinnerets. PMS 0.96 long, 0.44 wide, bases 0.16 apart, c.0.53 of basal PLS in diameter. PLS basal, middle, apical, and total article lengths = 1.12, 0.44, 0.48, 2.04, respectively.

Distribution and Habitat

Known only from the island of Nihoa in the Leeward Islands, northwest of Hawaii.

Etymology

The generic name refers to the type locality. The species name is a Hawaiian word for moon, given that the type specimen was collected in the moonlight.

TABLE 7. Leg measurements of *Nihoa mahina*, allotype ♀

	I	II	III	IV	Palp
Femur	6.66	6.50	5.66	7.33	5.00
Patella	4.66	4.16	3.50	4.66	3.50
Tibia	3.83	4.00	3.33	5.50	2.66
Metatarsus	3.50	3.16	3.50	5.33	
Tarsus	2.00	2.33	1.83	2.66	3.16
Total	20.65	20.15	17.82	25.48	14.32

Remarks

Males of *N. mahina* differ from those of *N. hawaiiensis* in the presence of teeth on the claws of leg I and in the basal position of the cuticlar process on tibia I. Females differ in the coniform spermathecae, in having 4, rather than 2, teeth on the claws of leg I, and in the darker abdomen dorsally.

Nihoa hawaiiensis (Raven), new comb.
(Fig. 19)

Idioctis hawaiiensis Raven, 1988:6; Platnick, 1989:93.

Material Examined

Holotype: ♂, Necker I., Leeward Islands, north-west Pacific, 23°35'N, 164°42'W, E. H. Bryan Jr, 29.vi.1923, AMNH.

Paratype: ♀, same data as holotype, AMNH.

Other Material

The types and also from Necker I., Leeward Islands: ♂ 23.vi.1982, S. Conant; 4♀♀, Annex Hill, alt. 82m. 24.vi.1984, S. Conant; all in Bernice P. Bishop Museum, Hawaii.

Diagnosis

Paired claws of ♂♂ without teeth. Upper cuticular process on tibia I of ♂♂ prolateral, well above spur. Spermathecae two long domed mounds.

Distribution, Burrow and Habitat

The spiders were found under rocks in burrows on very sparsely vegetated hillsides on Necker Island, one of the Leeward Islands, northwest of Hawaii.

SPERMATHECAL VARIATION IN *IDIOCTIS*

This paper includes the first documentation of spermathecal variation in a genus of the family Barychelidae. Shape of spermathecae has been

used widely in mygalomorphs to distinguish between species (e.g., Schiapelli & Gerschman de Pikelin, 1962; Forster & Wilton, 1968; Raven, 1984a). As such, spermathecal shape has been considered a relatively stable and useful diagnostic character. Rarely are exceptions well supported. In his excellent and detailed revision of *Euagrus*, Coyle (1988) showed extensive variation in the shapes of spermathecae of one species, *E. mexicanus*. On the other hand, Raven (1984b, 1990) found in the *Aname maculata* group (Nemesiidae) and *Trittame* (Barychelidae), respectively, that spermathecae are almost constant within a species group. Moreover, Raven & Churchill (1991) noted that one shape is widespread in barychelid genera and may be the family synapomorphy.

Among mygalomorphs, barychelids have received little attention from taxonomists or ecologists, presumably because they build cryptic burrows. They are also under-represented in museum collections. Hence, from the limited material available variation in shape of spermathecae has been unclear but assumed to be minimal. In *Idioctis*, we find that this variation is usually too great to be useful as a specific character on its own, even though it was stable in species of *Encyocrypta* .

Recognition of a number of species in which the shape of the spermathecae cannot be diagnostic may seem unwarranted. In a major revision of Pacific barychelids (Raven & Churchill, in prep.), a plesiomorphic spermathecal shape has been identified and found to be widespread. However, as with *Idioctis*, barychelid males do show mutually exclusive differences where none were evident among their (unequivocally) conspecific females. Hence, interspecific differences can be sufficiently clarified with non-sexual somatic characters.

ACKNOWLEDGEMENTS

We sincerely dedicate this paper to Ms Julie Gallon, who assisted with the collection of *Idioctis yerlata*. Julie has been missing since 2 August, 1990, and we will continue to miss her dearly. This research, visits to European museums, and collections made in New Caledonia, Fiji, the Solomon Islands, and Singapore were funded by an Australian Research Council grant to RJR. The authors are indebted to the generous hospitality of Dr Jean Chazeau of O.R.S.T.O.M., Nouméa, New Caledonia. Ms Clare Bremner and Mrs Bronwyn Mitchell made the excellent figures 1, 8, 11, 14, 17, 20-22; RJR did the rest. We kindly thank Mr Joseph Koh, and Associate Professor Dennis Murphy of the University of Singapore, for their hospitality and assistance to RJR in acquiring comparative material of *I. littoralis*. Mr John Ravenscroft kindly assisted in the search for *Idioctis helva*, in Fiji. We are grateful to Dr G. Rack, Zoologisches Institut and Zoologisches Museum, Hamburg, for the loan of types of *Idioctis helva*, to Dr J. Gruber, Naturhistorisches Museum, Vienna, and Mr P.D. Hillyard, British Museum (Natural History), London for the loan of *Idioctis*, material from Samoa, and to Ms Sabina Swift, Bernice P. Bishop Museum, Honolulu, for sending the new material of *Nihoa*. The invitation of Dr Harry Parnaby to TBC to accompany the Australian Museum expedition to the Solomon Islands is gratefully appreciated. TBC warmly thanks the local people of the Marovo Lagoon area for their co-operation and hospitality. We are grateful to Dr S. Conant for data on habitats of *Nihoa mahina* and *Nihoa hawaiiensis* in Hawaii.

SHIPWRECK AND HISTORICAL SURVEY: CHILCOTT ISLET, CORAL SEA

R.A. COLEMAN

Coleman, R.A. 1992 06 29: Shipwreck and historical survey: Chilcott Islet, Coral Sea. *Memoirs of the Queensland Museum* 32(1): 31-53. Brisbane. ISSN 0079-8835.

Many Coral Sea reefs appearing on modern charts were first discovered by unsuspecting sailing ships that struck the reefs and were wrecked in the 18th and 19th centuries. In 1845 the teak, India-built barque, *Coringa Packet*, was totally wrecked on a reef surrounding a small sand islet subsequently named Chilcott Islet after the ship's Captain.
In the late 1870's, Chilcott Islet was briefly mined for guano (phosphate) by F.E. Beaver & Co. of Melbourne. During 11-12 December, 1991, the author located wreckage believed to be the remains of *Coringa Packet* and conducted a brief preliminary survey. The wreck is considered to be archaeologically significant because of its potential to illustrate technical detail of a poorly-documented vessel type ('Country vessel'/Opium Clipper) and of Indian shipbuilding practice during the first half of the 19th century. □ *shipwreck, Indian shipbuilding, guano mining, archaeology, history, Coral Sea.*

R.A. Coleman, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; *14 January, 1992.*

The Coringa Islets, comprised of Chilcott Islet and South West Islet, lie respectively in 16°57'S by 150°00'E and 16°59'S by 149°53'E in the Coral Sea.

The group is named after the sailing barque *Coringa Packet*, which was wrecked there in 1845. Chilcott Islet, where the wreck actually occurred, is named after the ship's Captain, F. Biggar Chilcott.

The Coringa Islets are within the Coringa-Herald National Nature Reserve which was proclaimed under the *National Parks and Wildlife Conservation Act 1975* on 16 August, 1982. The Reserve is managed by the Australian National Parks and Wildlife Service (ANPWS).

The Queensland Museum administers the Commonwealth *Historic Shipwrecks Act 1976* in the Commonwealth Coral Sea Territory on behalf of the Department of Arts, Sport, Environment, and Territories (DASET). An essential administrative duty of the Museum, under the Act, is to locate, identify and assess the Australian maritime heritage resource and make recommendations to the Minister for its better appreciation, protection and preservation.

On the basis of archival research, it was determined that the *Coringa Packet* wreck had the potential to meet criteria for additional protective measures and warranted preliminary field investigation.

An opportunity was presented for the author and a volunteer assistant to join a multidisciplinary scientific charter organised by Dr James Charley of the Botany Department, University of New England, Armidale. Dr Charley obtained the necessary permit to conduct scientific research within the Reserve. The charter vessel, TSMV *Kanimbla* was to visit a number of reef and islet systems in the area including Lihou, Tregrosse, Diamond, Magdelaine, Coringa and Herald for a total voyage time of fourteen days.

Although it was intended to locate and examine two nineteenth century wrecksites at the eastern end of Lihou Reef, whilst there bad weather caused the abandonment of that part of the program. However, the position of a recent, unidentified wreck was noted but persistent rain squalls prohibited our approaching the site with safety. Only its two masts and central stack are visible above water and it appears to be a cargo vessel or bulk carrier of approximately 120-150m in length. The condition of the mast tops suggest that the wreck occurred within the past 10-20 years.

Whilst ashore at Turtle Islet, Lihou Reef, material was discovered on the beach near the waterline at the northern end, which may warrant an investigation of the surrounding reef when the opportunity presents itself. The material consisted of a stone (suggestive of ship's ballast), a lip fragment of a nineteenth century bottle, an unidentified small circular copper attachment plate and several small pieces of iron (which were suggestive of hoop iron from wooden casks).

Our main objective was to locate and examine the wreck of the *Coringa Packet* at Chilcott Islet. Due to the constraints of a very tight schedule, only one and one half days could be spent there, one third of which time was only partially produc-

tive due to hazardous sea conditions on the reef flat.

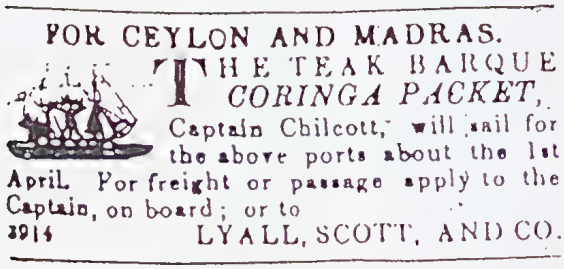
HISTORY OF *CORINGA PACKET*

Today, little is known of the early history of the *Coringa Packet*. However, shortly after the British Expeditionary Force was sent to resolve the opium issue in China in 1840 (an action now generally referred to as the 'Opium Wars'), she was for a period engaged in the Opium Trade. At that time she was described as being rigged as a brig.[1]

The vessel, under the command of F. Biggar Chilcott, arrived in Sydney on 11 March, 1845 and anchored off Campbell's Wharf having departed Calcutta the 11th December, Madras the 5th January, Trincomalee the 14th January, and Hobart Town the 2nd March. She carried twelve passengers and a general cargo.[2]

Advertisements in the *Sydney Morning Herald* during March, 1845 announcing her availability for cargo for Ceylon and Madras described the vessel as 'Teak Built'.

These items of information suggest that she was built and registered in India, probably Calcutta, as



FOR CEYLON AND MADRAS.
THE TEAK BARQUE
CORINGA PACKET,
Captain Chilcott, will sail for the above ports about the 1st April. For freight or passage apply to the Captain, on board; or to

a 'Country Vessel' (India based, under European, American, or Parsee ownership: a concession begrudgingly given by the East India Company, which had earlier held the monopoly on East Indian trade.). Correspondence subsequent to her wreck, and the quantity of return cargo belonging to Chilcott, suggests that she was owned by Chilcott and possibly under charter to the Honourable East India Company as an 'Extra Ship'. This would explain why she was not listed in *Lloyd's Register*. The H.E.I. Co. maintained its own insurance. Phipps [3] lists most ships built in, and operating from, India up to 1839. He makes no mention of *Coringa Packet*, which may have been built in 1840-1.

For reasons explained later in this report, it is important to discover where the ship was built and archival research will need to continue into the problem.

When *Coringa Packet* departed Sydney bound for Ceylon and Madras with a mixed cargo and a consignment of mail on 26 April, 1845, she was listed as a 230 ton barque. Four passengers were officially recorded as being on board: Lieutenant Blackhall, Ensign Bloomfield, Mr E. Lord, and Mr Henry Van Deerlin. A large part of the crew were Indian seamen or 'Lascars' making a total complement of forty. Lyall, Scott, and Company acted as her agents in Sydney.

Chilcott, upon his arrival in Sydney, had been the bearer of correspondence addressed to the prominent pastoralists and horse breeders James and William Macarthur of Camden from their agent in Calcutta, G.A. Plaistowe and the auction house, Cockerell and Company. The Macarthurs had found a ready market for good horses among the officers of the Bengal Army and other affluent Europeans in India and had recently sent a shipment to Calcutta on the East Indiaman *Blundell*. Plaistowe reported, '...there appears a great demand for these horses, and they have been expected and talked of, three months before our arrival, and I hope they may go off well. Auction sales appear the best and most fair way of each horse attaining its value, and it is arranged that the 16th and 21st December, be the days of sale - half each day. I could sell several privately, well, but I find that would prejudice the remaining ones at auction, wherein purchasers would say the best had been taken, and the culls, only, sold publicly. I am advised, also, from Cockerell's House, to such a course.'

'Good horses will sell well here, but it is great folly in shippers sending unbroken horses. The first question I am asked here, speaking of horses - What kind of cattle? Are they broken to saddle, side-saddle, harness, double or single? I have horses that are not broken upon the Catalogue; then, they say, What a pity - you should always bring horses here, thoroughly broken, and they will meet ready sale and realise good prices.'[4]

Chilcott was not slow to realise the potential for profit and when *Coringa Packet* finally cleared Sydney Heads there were three horses on board as part of the cargo consigned under the Captain's name. His speculation may have been influenced by one of his passengers, Lieutenant Blackhall, who had been sent to Australia to investigate the potential supply of horses and other livestock to the British military in India.

What then took place is best described by Chilcott himself:

'On the 5th May, passed Wreck Reef; the wind hanging far to the eastward prevented us from weathering Alert Reef and shoals in the vicinity; bore away to the westward to clear these dangers.'

'May 7. Passed through the group of islands known by the name of Tregoss's Islands [Diamond Islets in the Tregrosse reef system]; shaped a course N.W. by W. with the intention of sighting Lizard Island, and at 9:45 P.M. while sailing at the rate of eight knots an hour, the ship struck with a tremendous crash, on a reef, and slewed broadside on; sounded the well, found seven feet water - cut away the mast and let go the anchor, for fear the ship might beat out into deep water and sink, as we could not make out anything about us but a foaming sea: the vessel continued striking violently, and the sea making a complete breach over all, and, as you may suppose, daylight was most anxiously looked for; and to our great joy, a small island or sand bank was observed to the S.W., distance about half-a-mile; (fortunately the mast had gone over the side without injury to the boats). We then rigged a pair of shears, and with great difficulty got the long boat out; all hands next employed in procuring water and provisions, and landing it on the island.'

'At night, all hands left the wreck, and slept on shore; at daylight, went again to the wreck, which we found had suffered much during the night, and got the water and provisions out; remained on the island until the 21st of May, when we then decided to man the three boats and proceed for Torres Straits, in the hope of falling in with Her Majesty's ship *Fly*, or seeking some means for the rescue of the remainder of the crew left on the island, composed of twenty-four souls. We left on the island 800 gallons of water, and provisions sufficient for four months; and I trust, ere that time expires, some measures will be taken to remove them.'

'...We had a boisterous passage in the boats, from the wreck to the Barrier Reef, and I am sorry to say, we lost the gig, which upset on the night of the 23rd, and Mr. E. Lord, passenger, was drowned; the remainder of the crew were picked up by myself and the cutter, under the charge of the chief officer.'[5]

Chilcott and his group of fourteen sailed the remaining two boats through the Barrier Reef to Booby Island, on the western side of the Torres Strait, arriving on the 31st. There, they not only found sustenance in the cave later known as the 'Post Office cave', but another group of shipwrecked people. These were the survivors of the *Hydrabad* which had been wrecked a few days earlier near Murray Island and who had arrived at Booby the day before.[6]

It was immediately obvious to Chilcott and Captain Robertson of *Hydrabad* that although a ship might be expected to call into the island at any time, the huge number of people who must survive on the limited supplies in the cave could not remain there for long. Also, Chilcott knew that to notify the authorities of his remaining crew on the islet, he must quickly convey the news to a port from which ships sailed to Sydney. Chilcott and his group were exhausted after eleven days in the boats. With a volunteer crew and several of his passengers, Captain Robertson immediately set out for Port Essington in their long boat.

In the meantime, the twenty-four Lascars left on Chilcott Islet had reached a decision. The construction of a raft from materials salvaged from the wreck had begun before Chilcott and the others had departed in the boats. Having little faith in the boats' chances of success, twenty-one of them decided to attempt to reach the mainland. They set out two days behind Chilcott, on the 23rd of May, leaving three less venturous men on the Islet.

Two days after Robertson's long boat left Booby Island, on 2nd June, the schooner *Shamrock*, Captain G. Browning, called in and took on board Chilcott and the fifty remaining survivors of the two wrecks. Their first port of call was Port Essington where, on the 7th June, they found Robertson had safely arrived. Chilcott had left letters at Booby Island for Captain Blackwood of HMS *Fly* advising of the wrecks, the survivors' progress to Port Essington, and of the situation of the Lascars left at Chilcott Islet.

The *Fly* with her small tenders *Prince George* and *Midge* had been conducting surveys off the south coast of New Guinea and had become separated from the *Midge* and the ship's second gig. Captain Blackwood dispatched the *Prince George* to Booby Island for intelligence, as that was their emergency rendezvous, and on 2 June the *Fly* weighed anchor and followed.

J. Beete Jukes, Naturalist on *Fly* recorded, 'On nearing Booby Island [on the 8th of June], we saw the appointed signal for good news flying, and found that our boats, having missed us on the coast of New Guinea, after a vain attempt to reach Caedha, or Bramble Key, had run for this little islet. We had left provisions here in the early part of the year for any ship-wrecked people that might come in their boats [the N.S.W. Government maintained supplies in the "Post Office cave"]. Availing themselves of these, and procuring a

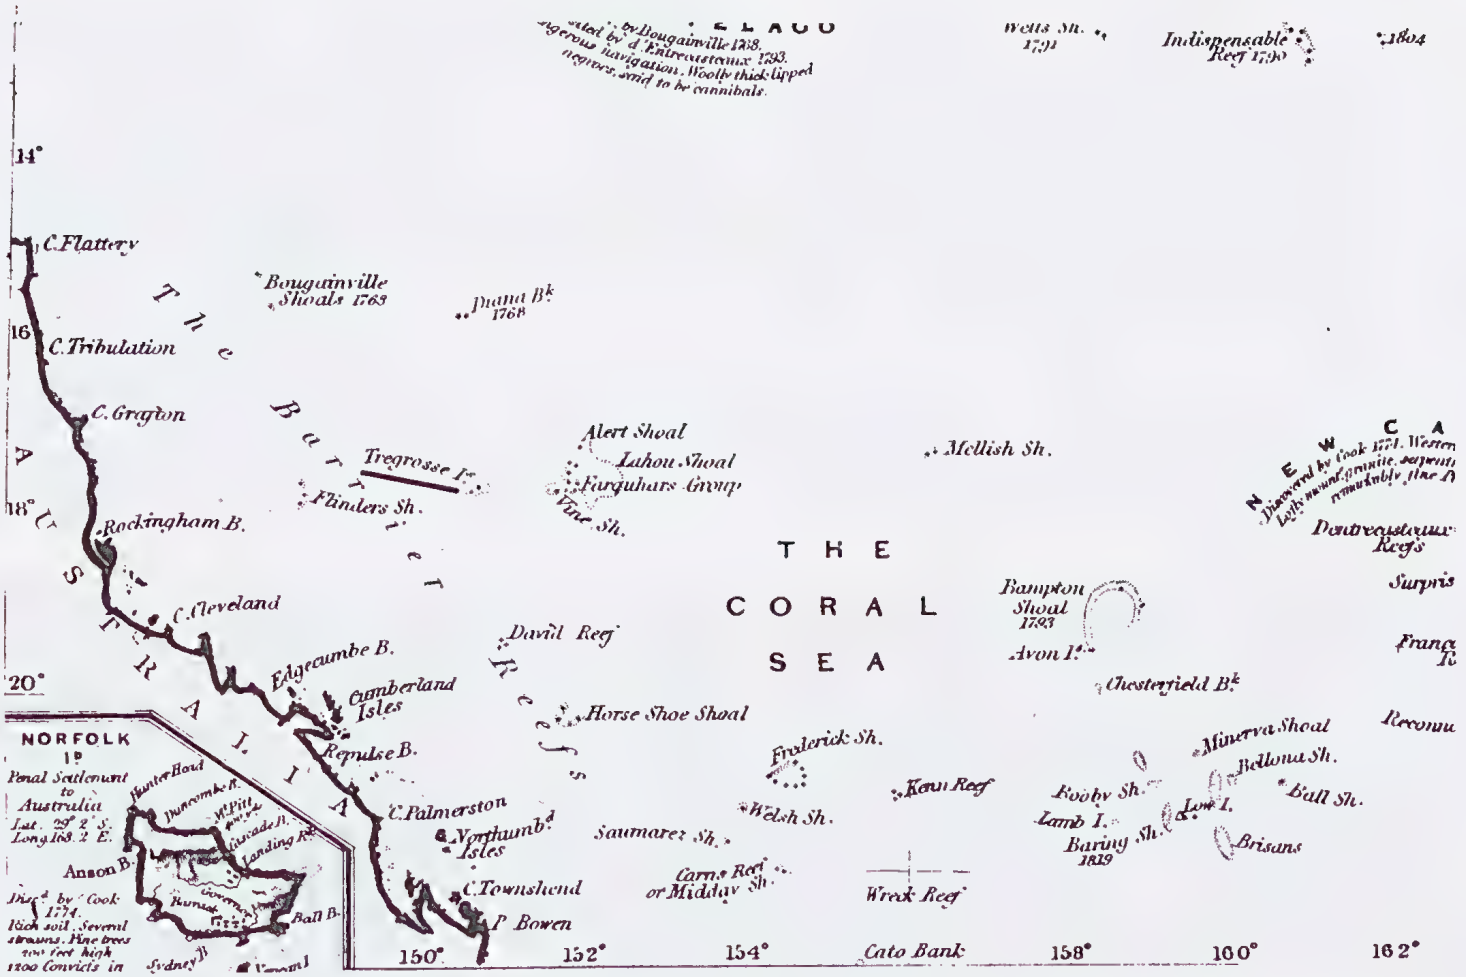

FIG. 4. Portion of a chart c.1840 published by Edward Stanford, London, and probably similar to that used by Captain Chilcott. The area immediately north and northwest of the Tregrosse Islets (underlined) would appear clear of dangers.

fresh supply of water near Port Lihou, in Endeavour Strait, [a bay on the south side of Prince of Wales Island, twelve miles to the east. The *Coringa Packet* and *Hydrabad* survivors had evidently used all the cask water in the cave. The only other water on the island is in a small rock catchment which is difficult to locate and few knew about its existence at that time], our people had left the second gig on Booby Island, and gone on in the *Midge* to Port Essington. We also found intelligence that two large vessels had been wrecked - one the *Hyderabad*, in the Cumberland Passage, near Murray Island, another the *Coringa Packet*.'

'The crews and passengers of these, consisting altogether of seventy or eighty people, had also visited Booby Island, and gone on to Port Essington, partly in their boats and partly in a small schooner [*Shamrock*] that happened to pass by. Among the passengers by the *Hyderabad* were some ladies from Van Diemen's Land, on their way to India, whose acquaintance we had had the pleasure of making when in Hobarton.'[7]

The *Fly* immediately sailed to Port Essington arriving on the 12th of June. They found that *Shamrock* had already sailed on the 10th for Ceylon with Chilcott, his mates, and two or three hands. The remaining shipwreck survivors, '...amounting to nearly 70 persons were now residing [there], and as it was impossible for the garrison to support this number much longer, and there was no probability of any other vessel touching for some months, the "*Fly*" was under the necessity of taking them to Sincapore....'[8]

Port Essington was out of the way and of no commercial interest to merchantmen coming through Torres Strait. Most sailed directly northwest from Booby Island for Coupang in Timor or through one of the Indonesian straits to Singapore.

'On the 11th of June', Captain J.B. Pain of the brig *Spy* reports, '...I took eleven of her crew [all that remained of *Coringa Packet's* Lascars who had sailed on the raft] off the nethermost [northernmost] of Sir Everard Home's Islands [at the tip of Cape Grenville], where they had been for fifteen days, subsisting on shell-fish and what little water they could find in the cavities of the rocks; three died the morning I fell in with them, and the others were in a dreadful state of exhaustion. These are the only survivors of twenty-one men who left the wreck on a raft on the 23rd of May.'[9] It would appear that a mistake in dates was made here and that the Lascars had arrived at the Home Islands on the 30th of May. According to Captain John Hews of the *Maid of Athens*, Pain picked up the surviving Lascars on the 15th of June. And Pain varies his figures in subsequent reports to say that he rescued ten, not eleven men, that eleven, not ten had died, and that they had been in the Home islands sixteen, not fifteen days.[10]

Captain Pain had been busy. On the 31st of May, he had picked up the survivors of the *Maid of Athens*, which had been wrecked, just after midnight on the 30th, southeast of Sir Charles Hardy Islands, which are a couple of miles east of Home's Islands.[11] His delay of several days in picking up the Lascars a few miles away must have been occasioned by his standing by the wreck of *Maid of Athens* to salvage what he could.

Arriving at Booby Island on the 17th of June, Pain found that Chilcott's group and the *Hydrabad* survivors had already departed for Port Essington and that *Fly* had proceeded after them. Pain left a letter at the Booby Island 'Post Office' advising of his rescue of eleven of the Lascars and the wreck of *Maid of Athens*. A copy of his letter was entrusted to the Captain of the brig *Joseph Wheeler*, then anchored at Booby enroute to Manila. *Spy* then proceeded with her passengers directly to Coupang arriving there on the 4th of July.[12] As a consequence, those at Port Essington were unaware that only three men remained at the *Coringa Packet* wreck.

Prince George, with some of the survivors on board, parted company with *Fly* at Port Essington on the 18th of June and proceeded to Sydney by the western route. The cutter arrived at Sydney on the 13th of August bringing news of the shipwrecks and the mistaken advice that twenty-four *Coringa Packet* Lascars were awaiting rescue.[13]

Governor Gipps immediately called for tenders for a vessel to proceed to the reef, '...and a schooner called the "*Frolic*" was chartered for the purpose. The Government however required that she should be commanded by a competent navigator and Mr. Yule [Commander of the survey vessel HMS *Bramble* which was at Sydney undergoing a refit] was requested to examine the candidates: the former master of her, [William Pilfold], broke down at once, and out of 6 or 7 others examined only one understood how to work out a common set of sights for time!: the owners were also very anxious for the master of the "*Frolic*" who had been a long time in their employ to continue in her, but this Mr. Yule would not consent to unless a competent "navigator" went with him, and the only one who had passed a satisfactory examination objected to go in a subordinate capacity: all this occasioned considerable

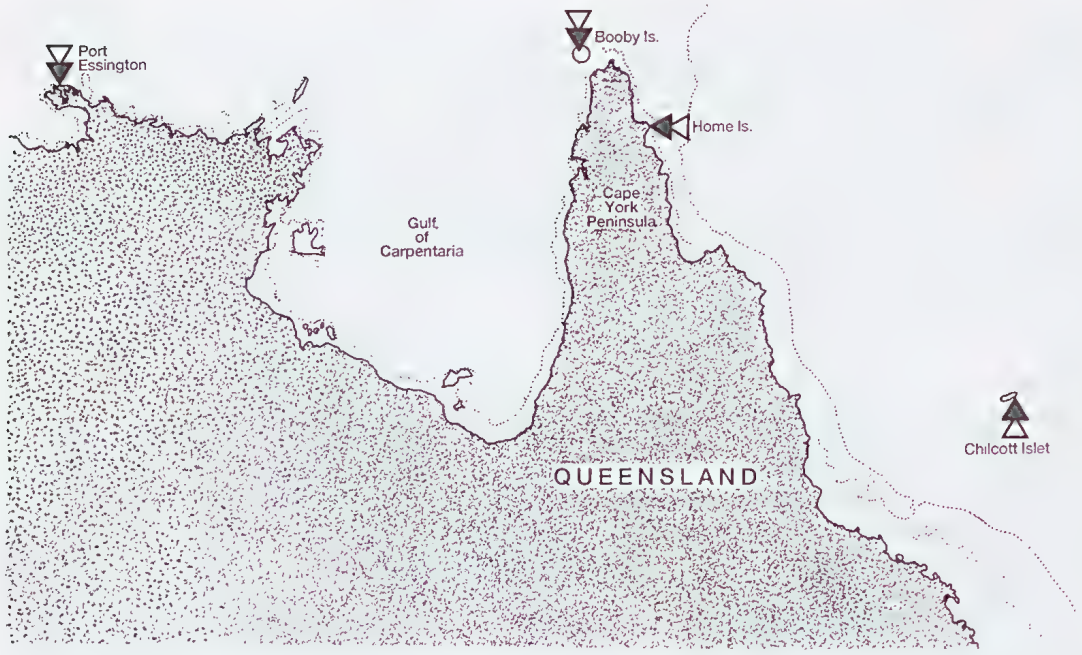

FIG. 5. Chart showing relative positions of Chilcott Islet, Home Islands, Booby Island, and Port Essington.

delay but at length a person [Mr G. Levian] was found who proved fit & willing to go as "mate & navigator" with the former Skipper and on the 19th of August the "*Frolic*" sailed.'[14]

'In the mean time however the "*Heroine*" ... whose master, McKenzie [Martin MacKenzie], a very clever enterprising little fellow had also applied, tho' in vain, for the contract, sailed for Java and in her passage touched at Chilcott's Bank [Islet] a fortnight before the "*Frolic*"....'[15] MacKenzie took the three remaining Lascars on board, dug up a chest of silver plate and other valuables which Chilcott had buried, recovered the mails, and, as was his habit, planted several coconuts so that in future, unsuspecting mariners could see the low-lying islet, before sailing on to Port Essington where (it is presumed) he lodged a claim for salvage.[16] In fact, MacKenzie was an excellent navigator and must have derived a great deal of satisfaction from having shown the bumbling bureaucrats in Sydney, and particularly Lieutenant Yule, who had insulted his sensitivities, a thing or two. He now had a double-axe to grind. Enroute to Port Essington with the men and goods he had rescued, *Heroine* struck a rock in the middle of Endeavour Strait where Yule had surveyed previously and declared free of dangers. Now who was the incompetent navigator?

Of course, the *Frolic* found no one or thing to rescue when they finally arrived at Chilcott Islet. Captain Pilfold's log book explains what took place:

'Saturday, 6th September, 1845. - At 9:30 A.M., sighted the wreck of the *Coringa Packet*, on Chilcott Island, a sand key, bearing S.W., distant three leagues. At 10:15 landed on the island (north end), and saw the place where a tent had been erected, but no trace of the shipwrecked crew. I then searched for the mails and property said to have been buried about ten paces from the tent (no parts of which were left), but I found a large hole, about that distance, in which I supposed them to have been buried; in this hole many pieces of tarpauline were strewed about, which bore the appearance of having been lately dug up, as did the hole itself. I, Mr. G. Levien [the mate], and three of my crew, then searched the island throughout, to see if we could find any letter, mark, or notice, by or through what means these men left the island; and after a fruitless search of near three hours, gave up all hope of gaining any clue of their destination, and returned on board. The *Coringa Packet* is now lying with her head to the eastward, and by all the appearances, in which I am borne out by the opinion of my crew, the copper has been stripped off on the starboard side, and the whole of the rigging, masts, and everything moveable, have been taken or carried away. There is a derrick

rigged out of the main hatchway, and the hatches all off. On the island everything valuable has been taken away; no part of the raft, spars, or casks, of any description are remaining - saving a piece of one of the lower masts [probably the one which was cut away shortly after the wreck] and an old scuttle butt, a few rags of canvas, and clothing of the crew.'[17]

Checking at the Raine Island beacon for the missing survivors, Pilfold found a letter which had been left by MacKenzie with the confusing news that *Heroine* had rescued the mails and goods but only three Lascars. *Frolic* then proceeded to Booby Island where he found Captain Pain's account of the rescue of all that remained of the twenty-one on the raft and letters explaining the others' departure for Port Essington. He then sailed on to Port Essington where he found two Lascars (one had joined the crew of *Heroine*), Chilcott's valuables, and the mail which he subsequently took on to Singapore in accordance with his charter with the New South Wales Government.[18]

Governor Gipps advised the Secretary of State, W.E. Gladstone, in a dispatch dated June 16, 1846, that he chartered the *Frolic* for £294/19/11. He had every reason to believe, he wrote, that the East India Company directors would gratefully take the charge upon themselves, and he sent Gladstone the charter documents and the details of the *Frolic*'s services; a letter from the Resident Councillor at Singapore reporting the *Frolic*'s arrival; a certificate that the men and the *Frolic*'s owners had done their work satisfactorily; and a declaration by the treasurer and auditor of New South Wales that the charter cost the N.S.W. Government £249/19/11.

The East India Company responded that it held itself accountable for £240 for the hire of the *Frolic* and considered that the balance, £54/19/11, was the value of provisions shipped on board the *Frolic* and intended for the Lascars at the wreck. But since the provisions were not applied for this purpose, but were landed at Port Essington and retained there, it was clear that the East India Company was not accountable for them. Earl Gray, who had become Secretary of State, thought that the outstanding £54/19/11 might be considered chargeable to Port Essington.[19]

SUMMARY DETAILS OF *CORINGA PACKET*

Barque
Teak built [probably India, possibly Calcutta, c.1840-41]
Tonnage - 230
Formerly engaged in Opium Trade
Copper sheathed, apparently iron-fastened,
Captain - F. Biggar Chilcott
Sydney Agents - Lyall, Scott & Company
Insurers - Apparently, H.E.I. Co.
Departed Sydney - 26 April 1845 [after a departure on 14 April aborted due to adverse winds]
Destination - Ceylon and Madras via Torres Strait
Wrecked - 7 May 1845, Chilcott Islet, Coringa Islets, Coral Sea
Cargo consigned by J.[?] B. Chilcott [was this a miss-print, or did Captain Chilcott have a relative as a partner?]
- 500 bags flour
- 30 logs cedar
- 20 kegs beef
- 1 case bird skins
- 3 horses
- 9 rams
- 30 sheep
- 25 tons coal

Cargo consigned by John Lord
- 200 bags flour

Cargo consigned by J.C. Lyall
- 12 cases cigars

Mails consisting of 249 letters for London; 400 Sydney, and 118 foreign letters, and 415 newspapers for Calcutta; 124 letters, and 152 papers for Madras; 66 letters and 102 papers for Bombay; 26 letters and 35 papers for Ceylon; 1 letter for Mauritius; and 1 letter for the Cape of Good Hope

Passengers
- Lieutenant Blackhall
- Ensign Bloomfield
- Mr E. Lord [drowned when the gig overturned]
- Mr Henry Van Deerlin [some confusion here. Francis Stewart, Chief Officer of *Hydrabad*, reported that Chilcott, two passengers, and a Miss Beech arrived at Booby Island along with eleven of the ship's hands[20]].

GUANO MINING ON CHILCOTT ISLET

I did not have the opportunity to examine the entire islet during our December 1991 visit. However, Dr Charley reported having seen two prepared blocks of guano on top of the islet near the middle of the southeastern side. The ANPWS *Coringa-Herald National Nature Reserve: Plan of Management* (p.8) briefly states, 'Relics of guano mining during the 1860's remain on Chil-

cott Islet', but does not say what the 'relics' might be. My research indicates that, officially, guano mining did not commence on Chilcott Island until 1877 and that it probably did not continue for very long.

A Mr Gilbert Carver Roberts claimed in a letter to the Earl of Derby (then British Secretary of State for Foreign Affairs), dated 9 March, 1878, that he had been the first discoverer of guano on Chilcott Island during a voyage sometime subsequent to 1871.[21]

The only official license to mine guano at Chilcott was issued to F.E. Beaver of Melbourne by a letter dated 5 February 1877. The license was for a period of seven years and cost Beaver £100. He had initially applied to mine the Willis Islets to the north. This was obviously a speculative application as he shortly afterwards wrote that he had been misinformed as to the potential of the Willis Islets and he wished to change his application to include Chilcott and the Herald Cays.[22] Obviously, he had visited the Willis Islets after his application, and prior to its approval, and had subsequently discovered a potentially richer harvest at Chilcott and the Heralds.

A story, which appeared in the *Cooktown Courier* of 28 February, 1877 entitled 'The Douglas Tragedy' and in the *Cooktown Herald* of the same date entitled 'Most Horrible Murders at Chilcot Island', gives us a graphic description of an incredible occurrence at Chilcott Islet. (Later, the *Courier* story appeared in the *Bundaberg Star* and *Burnett River Times* of 23 March, 1877 from which the following is quoted).

It is interesting to note here that Cooktown was then the centre of government administration in north Queensland due to its proximity to the Palmer goldfields. Cairns had no hospital nor newspaper and its most senior policeman was Sergeant Armstrong who submitted a report to his superior, Inspector Clohesy, at Cooktown. The *Cooktown Courier* journalist writes:

'The *Blackbird* [steamer], which arrived here on Saturday from Cairns, landed three wounded men, who were sent to the [Cook District] Hospital, and who appeared to be hacked and cut in a most terrible manner. The story they tell is one which can hardly be equaled by the most imaginative writer of fiction.'

'It appears that the *Douglas*, schooner, belonging to Messrs. F.E. Beaver and Co., of Melbourne, landed a general cargo in Cairns, and then proceeded on the 18th January to Chilot [sic] Island, lying about 200 miles due east, and worked for guano by that firm.' (Beaver had jumped the gun. He was not informed by Lord Carnarvon's Private Secretary of his successful application for a license to mine guano on Chilcott and Herald Cays until he received a letter dated 5 February 1877[23]).

'In order to obtain a favourable wind the *Douglas* went south as far as Flinders Passage, anchoring on the way under Drink [Dunk] Island, near Cardwell. While there a canoe with three blacks came off and were invited on board. They were supplied with tobacco, pipes, &c, and given to understand that they were wanted to get some companions, and to go with the vessel on her voyage. They apparently agreed, went back and brought another man. The new comer had such a disagreeable appearance that the captain refused to take him, and left with the three first. On arriving at Chilot [7 February], a small detached island, about a mile and a-half long by one broad, they found the *Alexandra*, brig, belonging to the same firm, half loaded. Mr. Beaver, one of the firm, who was on board the *Douglas*, not having enough colored labor to screen the guano fast enough, determined to go back by the *Alexandra*, half loaded as she was, and to fill up with cedar at the Daintree. The brig accordingly left on the morning of the 10th, and - the fact is worth noticing - she took nearly all the firearms of the *Douglas*, and the blacks were present when the transfer was effected.'

'That evening [actually the 14th] night fell with an over-cloudy sky, boisterous wind, and every appearance of rain. Two white men, Cochrane and McIntosh, were on shore in a hut which had been erected, and which was stored with water and rations; two of the blacks were also with them. In the early part of the night, while the white men were sitting in their hut, the blacks seemed to have killed them by simultaneous and treacherous strokes, the attitude of the bodies indicating that they could hardly have been aware of the death-stroke. Then, armed with the half axes which had served for the murder, the two blacks swam through the tempestuous sea off to the vessel.'

'No one on the schooner suspected evil, and all the whites seem to have been asleep; probably the black was waiting for his comrades. Softly they stole about their murderous work. Two white men were asleep on the deck, and both were struck so that they made no sound. One (Shaw) says that he knew nothing till he came to his senses two hours afterwards, waking in a sort of dream finding himself one mass of clotted blood, and chopped all over the head and arm. What saved him was he had wrapped a rug and thick flour bag over his

shoulders as he lay down, and the bag was dinted with the blows of the blunt axes. Thanks to the darkness of the night, he managed to crawl into the forecastle, although a black spying him as he went, aimed a blow at him, which missed. Thinking he was too far wounded to be worth troubling about, the murderers left him, and he managed to crawl aft through the hold and get into the cabin.'

'But I must go back. After the blacks had left the two men, Troy and Shaw, for dead on the deck, they went down into the hold where another sailor, Purcell, was sleeping, and attacked him. He was fearfully chopped on the face, head, and arm, one finger was cut off, and a huge gaping gash made in his back. Him they left for dead, but he subsequently crawled through the hold aft into the cabin. Meanwhile Deasy, the acting second mate, who was asleep in the forecastle, heard Purcell cry out and rushed out on deck. Never suspecting what had happened, he thought that the mooring chain had parted and shouted to that effect. In a moment he saw a blackfellow by his side with an uplifted axe over his head. He dodged the black and sung out "Captain, the blacks are murdering us." Then all rushed on him. How he escaped is a miracle. He has numerous slight flesh wounds and a severe chop on the arm, but only the most wonderful agility and pluck saved him. Once the murderers had him down on his back on the deck, and two paused to let the third get a chop at him. Even this he managed to dodge by shifting his leg, escaping with a flesh wound on the inside of the thigh. While this was going on, the mate awakened by the noise, rushed past and got into the forerigging where another man had escaped. Deasy struggled out of the grasp of the murderers and ran for the forecastle, one black following him. Getting his knife out, which up to that moment he had not been able to draw, he struck at his assailant but missed the stroke, and striking on the axe, lost his knife. Then, picking up a small grindstone lying there, he struck the black and staggered him, thus managing to get into the forecastle. A hurried search showed him there was no weapon to be found, and he came out again to make a rush for the rigging. In his haste and in the darkness, he rushed for the port side, where one of the blacks was part of the way up and another on the bulwark preparing to ascend, with the intention of attacking the mate and Lawrence on the foreyard. Deasy sprung past the black on the bulwark, and grappled the one on the rigging; but before he could wrest the axe out of his hand, the second black wounded Deasy on the heel. Finding that the next moment he would be killed, he scrambled up and reached the foreyard, when he cut blocks with the mate's knife, and the men used them as weapons to keep back the blacks, who, after a while, made no attempt to ascend.'

'During this struggle, which occupied less time than I take in writing about it, the Captain, awakened by the noise, came up, and as he laid his hand on the top of the companion, it was chopped by a blow from an axe. He retreated into the cabin, where he remained with his son, and was subsequently found by the two sorely-wounded men, Shaw and Purcell. They vainly endeavored to load a pistol, striking matches, but not daring to light a lamp. But the flowing blood clogged the pistol and damped the powder [poetic license by the *Bundaberg Star* editor, it was a revolver which fired cartridges], and they could do nothing. The steward had shut himself up in the galley; three men were on the foreyard, Deasy almost fainting, and lashed to prevent falling; and poor Troy lay on the deck near the galley.'

'There was a sort of lull. The men on the foreyard thought that all hands, except themselves, the captain, and his boy, were dead; and the blacks compelled to pause in their active attack, began to look for the bodies of their victims. Shaw, by this time, had crawled away - and, on searching the hold, they found Purcell also gone; there remained only Troy lying motionless near the galley. How long he had recovered his senses no one could tell, but he was not dead. The murderers came to where he lay, and with one blow of an axe chopped off his foot. The steward, trembling in his galley, heard the poor fellow groan, 'Oh God, I'm punished now.' Then they chopped his body and clove his head, till all life - all semblance even of humanity - was battered out of him.'

'So the terrible hours of the night wore on, and day began to dawn; the three blood-stained demons holding the deck - the steward hidden in his galley - the three men on the yard - the captain and his boy in the cabin, with the two poor wounded men weltering in their blood beside him. The grey light of morning made objects visible, and the blacks thought to finish their work. Picking up stones and pieces of coal from the hold, they began to pelt the men on the yard, who dodged the missiles as best they could. These two blacks ascended the rigging with their axes, while the third remained on deck pelting the whites. These, compelled to disregard the stones, confined themselves to keeping the axes at bay with their sling-blocks. Then the blacks found the steward was in the galley; one went to guard the companion while the other burst open the galley door. The steward

jumped through the other door, rushed to the companion, dodged the blow aimed at him by the guard, and tumbled below.'

'Now there was hope for the whites. Daylight was brightening and an un-wounded man had reached the cabin where there was a revolver and ammunition. But deliverance was not for some time. For nearly an hour the men on the foreyard had to keep at bay two of the blacks who were assailing them, while the third kept guard over the companion, cunningly shielding himself from the loaded revolver of the steward. At last an incautious movement of the guard exposed his head, and the next second a bullet went into his brain. The two blacks exchanged a hurried sentence in their own language, and one went to pick up his fallen comrade. The sailors in the foreyard dropped down the rigging. The mate first on deck took up a handspike and staggered the third man with a blow on the head, and the others closed around him. The one who had gone to the dead guard left him, saw the game was up, and jumped overboard. Two of the blacks were now dead, and the steward emptied his revolver at the third one while he swam, but did not succeed in hitting him. They saw him land on a rock, and put off in a boat after him, but he jumped again into the sea, and although they waited for him he was never seen again.'

'Then the survivors went to the Island and found the bodies of their comrades in the hut, and made sail for Cairns with the wounded. Arrived there [18 February], an inquiry was held, and the three worst wounded were sent to our hospital, where, under the skilful treatment of Dr Ahearne, a surgeon of no mean ability, they are progressing as well as could be expected.'

With minor variations, the three newspaper reports agree in the principal details.

How long after this Beaver continued his operations at Chilcott Islet is not known. The editor of the *Cooktown Herald*, with libellous gusto, first attacked the editor of the *Courier* saying that the 'niggers from Dunk Island' were his 'friends' and then accused Captain Harris of kidnapping the three natives and called for a Government inquiry. The whole sequence of unpleasant events may have prompted Beaver to forget guano mining altogether.

From what we can learn from the *Douglas* episode, at least one hut was constructed on the islet. It was furnished with a water tank and supplies, '...and arrangements made for the regular working of the deposits.' Three men, Patrick Troy, Humphrey Coghalin, and Alexander McIntosh, were buried there. Therefore, some evidence of the event may remain on the islet.

CHILCOTT'S LOCATION OF THE *CORINGA PACKET* WRECK

Captain Chilcott was quite specific as to the location of the islet and the position of the wreck. He reported, 'The position of the danger on which the *Coringa Packet* was wrecked is as follows: - Lat. 16°52'30" S., long. by the means of 20 lunar observations 149°55'45" E., the chronometer showing a longitude of 149°55' E., variation of the compass 9 degrees E.; rise of tide at springs 5 feet; the island about 10 feet above the level of the sea, surrounded by a reef dry in some places at low water, the wreck of the vessel bearing N.E. by half a mile; and the whole of this danger does not exceed 4 1/2 miles in circumference. Another small island we observed to the S.W. about four miles [South West Islet].' He also stated that the current was 'running constantly to the north-westward.'[24]

MODERN DESCRIPTION OF CHILCOTT ISLET

Australian Chart *AUS 612* (corrected to 1991) gives a position of 16°56'25"S, 149°59'55"E based upon an 'Observation Spot' at the Eastern end of the islet. Magnetic Variation 8°15'E (1984) increasing about 2' annually.

The islet is described as 'An elongated pear shaped cay with long axis oriented NE-SW. 800m long and 255m wide. Beachrock, piled up at a moderate to steep slope, fringes the S. shore line. Maximum elevation 5m ASL.'[25]

FACTORS AFFECTING SHIPWRECKS IN THE CORAL SEA

In general, isolated islands, reefs and cays obstruct the flow of water resulting in an accelerated current around the reefs and cays. Sometimes an eddy forms on the lee side. (This refers to deflection of the main, deep northwesterly current prevalent throughout the Coral Sea. The northwesterly trend of surface current, which is less affected, is still evident in the reef-top shallows and, combined with the predominant winds and seas from the southeast, generally dictate the distribution of wreck material deposited there). Over the Coral Sea Plateau, the tidal range indicated is 2m.[26]

On average, two or three cyclones per annum

affect the Western Coral Sea, usually between December and April. Although infrequent, tropical cyclones are the greatest hazard in the region. Gales occur infrequently throughout the year. Tropical depressions occur usually two or three times per year. These create conditions similar to cyclones but are less violent.[27]

THE SITES

Two separate sites were located and it is considered highly probable they are both associated with the same wreck.

SITE ONE (Chil.01)

Based upon Chilcott's description of his course,

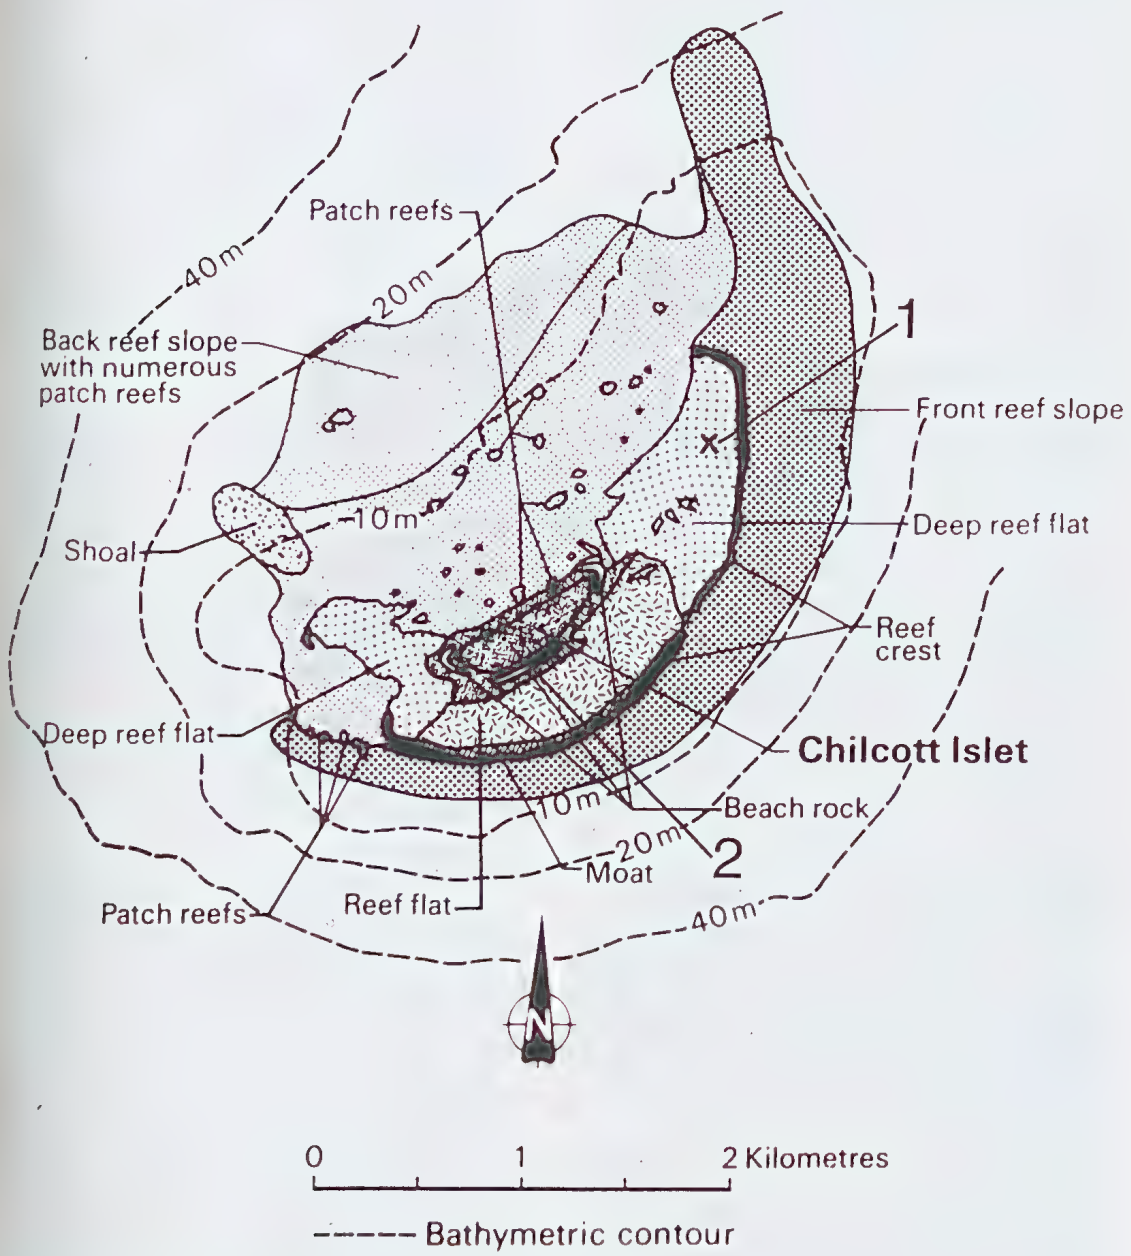

FIG. 6. Chilcott Islet. Approximate positions of sites are numbered.

(NW by W after passing through the Diamond Islets), and the position he gives for the wreck, ($^1/_2$ mile NE of the Islet), we had a good indication of where on the reef to begin our search. Our experience with other wrecks in similar situations led us to confidently expect wreck material on the reef flat scattered in a northwesterly direction from the point of initial impact.

After first exploring the beachrock at the base of the beach on the northeast point of the Islet - where miscellaneous iron remnants, a small piece of coal, and broken bottle glass were found - a 'bottle tree' was constructed on the centre of the beach facing NE as a visual reference point.

Proceeding in the zodiac onto the deep reef flat, a reciprocal back-sight was taken on the 'tree' using a monocular compass. At 225° magnetic, and approximately 30m inside the breakers on the reef crest, a reference buoy was dropped in 2m of water. Immediately, the wreck's anchor chain was seen by a diver some 10m southwest of the reference buoy.

A second flag buoy was attached to the centre of the chain and, bearing in mind the predominant winds and seas from the SE and the northwesterly direction of the current, the first buoy was transferred to the northwestern extreme of the chain to give the surface swimmers a visual reference line of potential material distribution.

The zodiac was anchored over the centre of the chain and *Kanimbla* contacted by hand-held VHF radio. The vessel recorded their own GPS position and by our holding our boat's metal fuel tank overhead as a radar beacon, they were able to record a radar range and bearing on us and the NE end of the Islet as well as its NW and SE sides. From the zodiac, magnetic compass bearings of 218° and 236° were recorded to the centre of the beach slope on the SW and NE sides of the Islet, respectively. With this information, a reasonably accurate GPS latitude and longitude of the site was calculated as 16° 55.650' S. by 150° 00.712' E.

The SE run of the chain was traced as far as the breakers would allow the divers to proceed. A pile of chain was found near that end (which then trended SSE for 7.5m before ending). The anchor deployed by Chilcott was not sighted. It should be found just off the outer edge of the reef crest amidst the breaker build-up.

The line of the chain was recorded with tapes and underwater compass. The greater length of chain lies on an alignment of 300° magnetic or 15° west of due northwest.

It being too dangerous to work on the site at high tide due to the swell and wave chop in the shallow water on the reef flat, and the timing of the lows, being at approximately 0700 and 0800 for the two mornings we had at the Islet (*Kanimbla* was to sail at 1000 the second morning), it was decided not to attempt a regimented area survey due to lack of time and trained personnel. Therefore, our swim search must be considered to be only a cursory examination of the area.

The objectives were to gain an oversight of material quantity, type, and distributional trend. Also it was intended to recover a small number of items which might assist in confirming the site as that of *Coringa Packet* and to assist in the interpretation of the material distribution sequence.

Items located included two rudder pintles (one iron, one bronze from the top of the rudder), a boom ring and goose-neck (possibly from one of the ship's gaff booms), a sandstock brick (a bed of brick was often used beneath ship's galley stoves as insulation for the wooden deck below. Galley stoves were most often placed in the forecastle area of the ship), two large rectangular dressed stones (not recovered, one measured 250×300×550mm having one end cut at an angle), two ballast stones, an iron rigging block strap with hook, a few iron fastening pins (two recovered), broken bottle glass (from base of green case bottle), an abraded piece of timber, a bob-stay plate (mounted on the stem for the attachment of the lower bowsprit brace or bob-stay[28]), a large iron thimble (used to form an eye in a bight of rope), and several unidentified iron objects (not recovered). Six short sections of studded anchor chain averaging 300mm, being loose on the reef, were also recovered for study.

The survey of Site One was curtailed by the necessity to examine and briefly record a second site discovered on the Islet itself.

SITE TWO (Chil.02)

The southeast side of the Islet (normally the weather-side) is almost entirely built of broken slabs of beachrock thrown up by cyclones. The rock extends from water level to the crest of the Islet at a height of approximately 6-8m above low water level.

Mid-way along this side, and at the top of the beachrock, storms have deposited several large ship's timbers.

The timbers are very weathered and the type of timber is not obvious from its surface appearance (although one piece, a bowsprit, has the appearance of conifer). Reference to scantling tables of the period should give us an idea of the size of ship from which they came. A sample was sub-

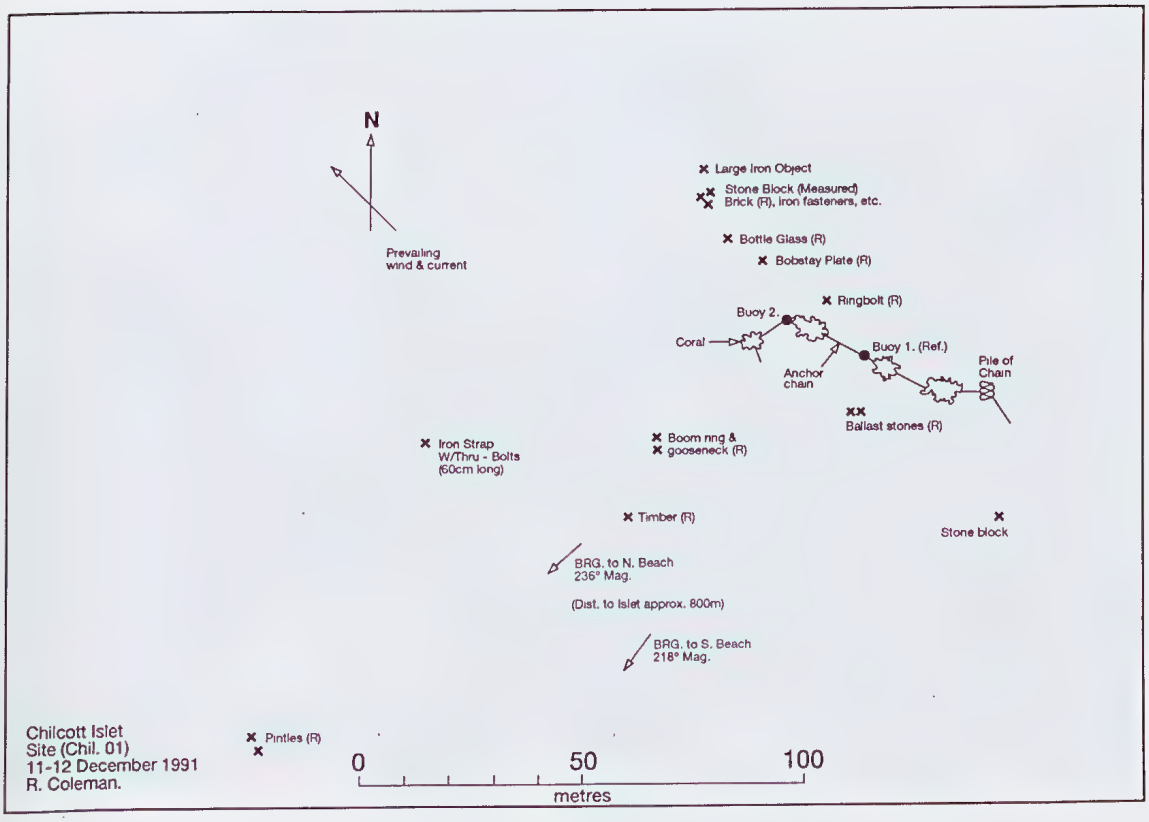

FIG. 7. Plan of Site One.

sequently submitted to the Queensland Forestry Department for positive identification of the timber species to determine where the vessel was built.

All of the material examined indicated that these were the remains of the upper bow section of a reasonable-sized vessel.

There were a number of cant futtocks and top timbers, a bowsprit, fragments of unidentified worked timbers, and a few planks, all of which had been iron-fastened.

Two iron knees (one broken) were located halfway down the beachrock and these also appear to be from the bow section as the upper arms are at an angle, or 'cant' to the flat of the lower arms. The knees were also iron-fastened.

At the water's edge, below the knees, were found two large pieces of tumbled cast iron, possibly parts of hawse pipes (through which the anchor chain passes through the ship's hull at the bow), or chain pipes (through which the anchor chain passes through the deck into the chain locker below). Other unidentified pieces of iron were observed lodged in the lower rocks.

Time did not permit precise recording. However, general measurements were taken of a few timbers and everything was photographed in situ using a photographic scale.

One top timber was recovered so that it could be accurately recorded for comparison with scantling tables and as a sample for timber identification.

DISCUSSION

It seems reasonably safe to assume that Site One is part of the *Coringa Packet*, since it was located where Chilcott said it should be and no other site was located in the general area.

Initial examination of the material from the site indicates that it is consistent with what we should expect from a vessel of *Coringa Packet*'s vintage and size. The recovered piece of timber proved to be *Tectona grandis* (teak) which is further confirmation that the site is that of the 'teak built' *Coringa Packet*.[29]

We have no record of another wreck in the Coringa Islets nor in the Tregrosse Reef/Diamond Islet complex to the southeast from which material might have floated. This lack of recorded wrecks is not to be taken as conclusive. Several ships of

FIG. 8. Site Two. Ship's timbers at top of beachrock.

FIG. 10. Site Two. Iron knees.

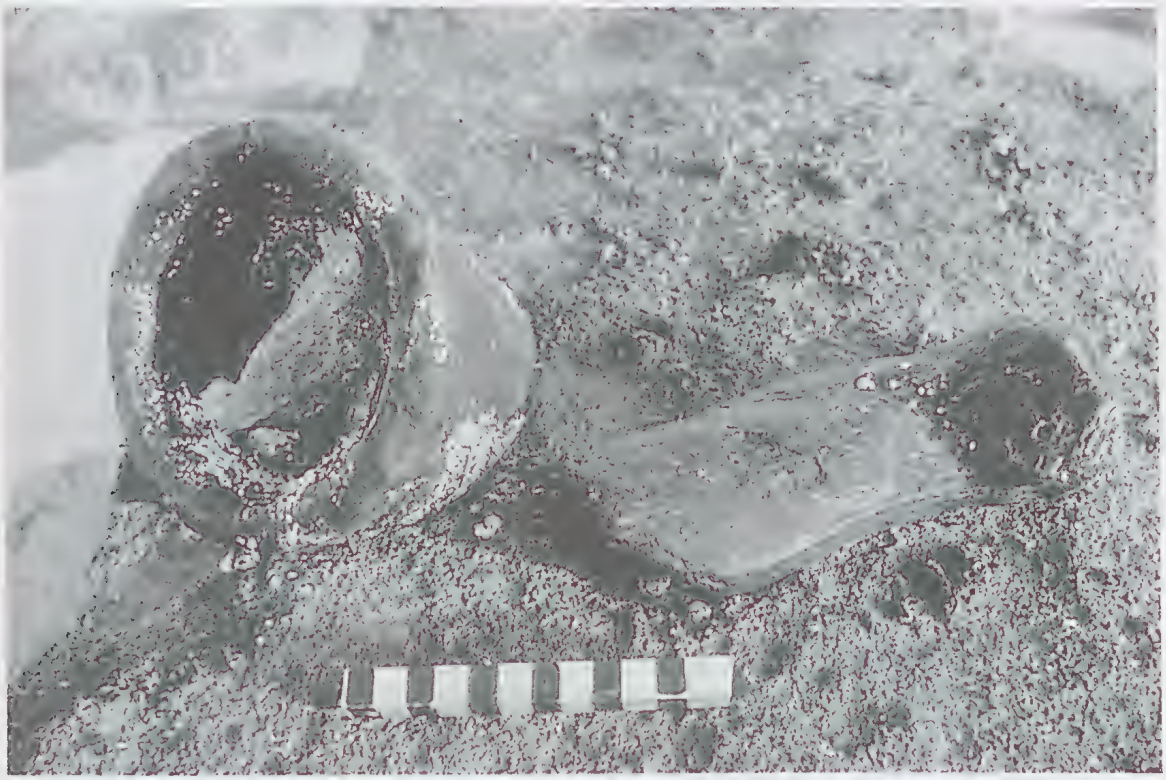

FIG. 11. Site Two. Iron objects found at water level.

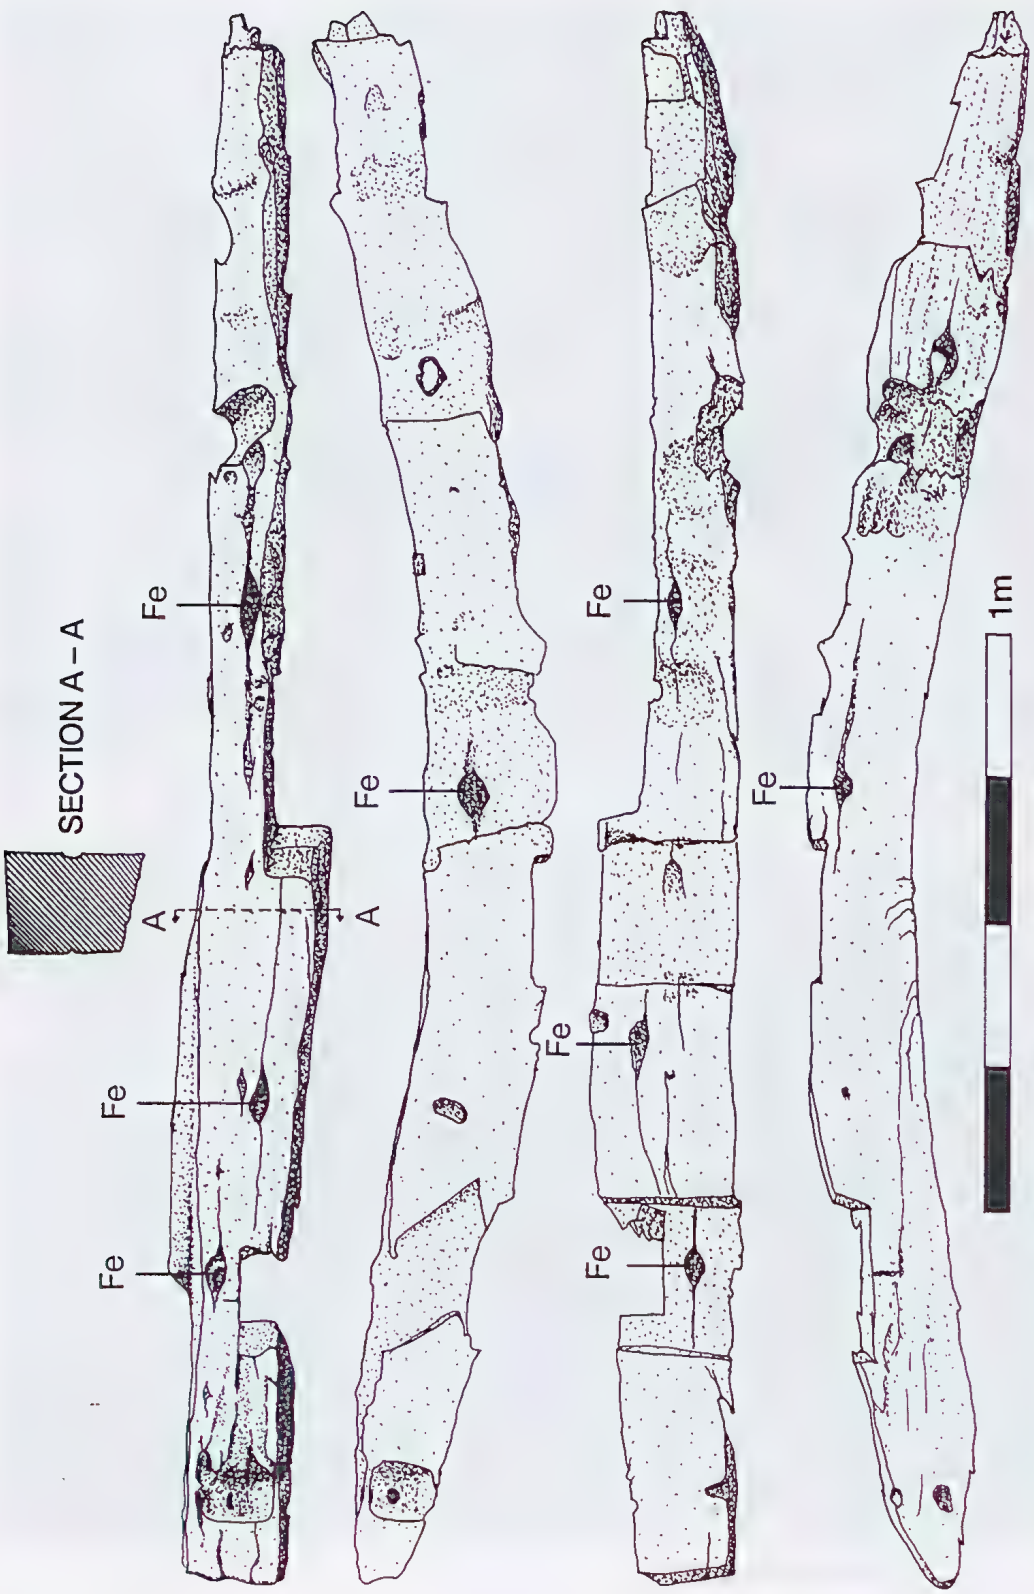

FIG. 12. Site Two. Four views and section of recovered top timber. Length 3.15m (10feet 4inches), sided 280mm (11 inches), moulded at mid-point 315mm (12.5 inches). Iron residue from fastening bolts are indicated 'Fe'.

the period were listed as 'missing' in the Coral Sea with no location given. However, although a number of India-built vessels were engaged in trade with Australia, it would be an extremely unusual coincidence to find two teak-built vessels wrecked in the same location within a few hundred metres of each other.

On first examination of the location of the material at Site Two, it is difficult, but not impossible, to reconcile as being part of the bow section of the Site One wreck.

It would be an unusual storm to carry material from Site One to the southwest and south of the Islet before it had been carried to the north beyond the Islet by winds, seas, and currents that would have generally prevailed for some months after the wreck in May. However, it should be recalled iron, glass, and coal were found on the NE tip and slightly around the north and south sides of the tip of the Islet, in a southwesterly direction from the reeftop site.

A very shallow, smooth, beachrock shelf abuts the tip of the islet extending for a radius to the east and south of some 50- 100m. In normal weather conditions the seas would be rough there. It is very unlikely that material salvaged by Chilcott or MacKenzie or building materials of the guano miners would have been brought ashore in exposed, rough shallows at that point. Rather, they would have landed just around the tip on the sheltered northern beach and opposite to the normally protected anchorage. Therefore, it is conjectured that the material found on the tip of the Islet is indeed flotsam and, at least the iron items, being of little value to any of the groups on the Islet, have been coincidentally transported there while attached to pieces of floating wreckage during a storm from the northeast.

The two rudder pintles found in the water some 200m southwest of the anchor chain are nearly identical in size having an overall length of 53cm (21 inches) and an internal breadth of c. 21cm (8+ inches). The iron pintle was the higher of the two on the rudder, iron being used above the waterline. The bronze pintle, being of similar size, was the next below and just at or below the waterline. The pin of the iron example was c. 5cm longer than that of the bronze to facilitate alignment when installing the rudder. While the overall width of the two pintles appears slightly small for a 230 ton vessel, they tell us something of the shape and style of rudder used and consequently provides some information concerning the shape and construction of the stern of the vessel. The most informative pintle dimension is that of the pin diameter (roughly measured at c. 50mm) which was the more critical in relation to the size of vessel. Steel[30] gives a recommended pin diameter of $1^{7}/_{8}$ inches (47.6mm) for vessels between 201 and 330 tons which would include *Coringa Packet* at 230 tons.

By reference to the location of the pintles on the Site One plan (Fig.7), one will see that at least the top part of the wreck's rudder, with the two uppermost pintles still affixed, became detached from the ship and floated some 200m from the site, to the southwest toward the Islet, before breaking up and a portion sinking from the weight of the metal. Generally, this would indicate that the ship was suffering a major structural break-up. The substantial timber of the rudder tiller was socketed into the upper end of the rudder post. It then passed through the stern of the ship between the large timbers of the transom framing and swung in an arc directly below the main deck beams. For the pintle pins to become disengaged from their mating gudgeons, the horizontal tiller either had to break the transom timbers, virtually destroying the stern of the ship, or snap off itself allowing the rudder to move vertically a minimum distance of 25cm (the length of the pin of the iron, or uppermost pintle). This, combined with the presence of ballast stones and the dressed stone blocks in the immediate vicinity of the stretched anchor chain indicates that the ship was coming apart where it was held by the anchor and chain. Therefore, the odds in favour of the upper bow section, which due to the absence of heavy objects was reasonably buoyant, floating to the southwest and eventually being thrown up on the rocks before it could float to the northwest beyond the islet, are greatly improved.

Again referring to the Site One plan, one will observe that the lie of the majority of chain is SE-NW as is the axis of the majority of loose material. Chilcott states that when the ship struck, she '...slewed broadside on....'[31] There can be little doubt that her head had come about from her sailing course of northwest by west to the northeast and she was then port side to the reef, the edge of which runs to the northeast at that point. Chilcott then cut away the mainmast to lighten ship and to reduce windage and the pendulum effect and dropped an anchor. He says the sea was '...making a breach over all.' Swinging to the anchor at the dictates of the southeast wind and sea and the current from the same direction, and grounding in the shallows of the reef, the ship, for a time rested (according to Pilfold's observations four months after the wreck) with her head to the east. Pilfold's reference to the copper being

removed from her starboard side indicates that she was then heeled onto her port bilges making it difficult to remove copper from that side.[32]

A possible explanation of subsequent events is that, in time, spring tides and associated swells may have lifted her sufficiently for the ship to swing her head to the southeast and her stern to the northwest thus aligning the anchor chain in that direction and allowing time for a concentration of heavy material to be deposited to the northwest of the chain. The chain may have parted (which would explain the jumbled pile of chain at the SE end) and the resultant tremendous force upon the forward-mounted windlass may have contributed to the upper section of bow, or at least pieces of it, being wrenched from the weakened hull. As the remainder of the hull was eventually carried to the northwest, the last of the chain dribbled from the below decks chain locker.

The top timber recovered from Site Two has been identified as *Tectona grandis* (teak).[33]

As it seems that the timbers at Site Two do date from 1845, it is remarkable that the guano miners in the 1870's, who were renown wreck scavengers, had not used them for firewood or to construct their hut and facilities. Perhaps they had an abundant supply of smaller firewood and lighter plank that required less effort to gather. Or, did Beaver & Co. abandon guano mining on the island after the *Douglas* massacre thus occupying the Islet only too briefly to cause much disturbance?

No copper alloy fastenings were observed on either site, which is an unusual coincidence in the case of nineteenth century wrecks; nor for that matter, were any metal sheathing or tacks, which are generally encountered.

The country vessel, *Valetta* (1825), excavated by the author in 1983, was iron fastened but copper sheathed over timber sheathing. Faith in the resistance of teak to the ravages of *Teredo navalis*, plus the fact that almost all metalwork used in Indian shipbuilding was imported from England or Europe[34] (and thus expensive), would seem to have justified the economies of less expensive iron fasteners and the cheaper expediency of using teak sheathing to insulate the iron fasteners from the electrolytic effect of the copper sheet. Phipps made a number of references to India-built vessels being sheathed with copper sheet over teak sheathing boards and implied that copper fastening of country vessels was an exceptional and expensive luxury.

Also, the suggestion is, that 'country' skippers and owners were quite happy with teak sheathing alone. But, in order to procure cargoes from merchants accustomed to the security of their cargo being carried in the generally dry, copper sheathed European-built vessels, they had to make the concession. Captain Pilfold of the *Frolic* pointedly stated that the copper sheathing from the starboard side of the *Coringa Packet* had been removed by the time he arrived. (Obviously by MacKenzie who seems to have salvaged everything possible[35]). Pilfold, by citing witnesses, was ensuring that he would not be accused of breaking his contract by keeping salvaged material for his own profit.

The use of conifer or other straight, reasonably clear softwood for masts and spars, including bowsprits, was normal practice in all shipbuilding. Indeed, pine spars from New Zealand and Australia were a frequent export cargo of northbound ships of the period. However, Phipps[36] states that at least the lower masts and large spars, including the bowsprit, of country vessels were frequently made of teak and sometimes 'poon' from Malacca, the upper masts and lighter spars being made from imported European, American, or Chinese pine.

The identification of the timber of the 'top timber' (the uppermost section of a frame or rib), being an internal structural member, is certainly more conclusive as to the ship's origin. Country vessels' frames were almost always made of either Sissoo (*Dalbergia sissoo* Roxb.) or Saul (*Shorea robusta* Roxb.) both of which were obtained from the forests north of the Ganges.[37] However, Phipps also mentions that, as those timbers became less available in the late 1830's, more vessels were built entirely of teak (*Tectona grandis*).

From the small amount of dimensional data collected on the Site Two timbers and the size and form of the bowsprit (including the unusual manner in which it was stepped), it would seem that the ship was designed to carry an enormous amount of sail (the relatively large crew carried by *Coringa Packet* may lend support to this theory). The rather fine stern indicated by the slightly narrow breadth of the rudder pintles (which reflects the width of the sternpost) also suggests that the ship was built for speed. These were not common features of the ordinary country vessel where speed was sacrificed for cargo volume. Rather, they were essential features of 'Opium Clippers' whose cargo took up less space. Their speed allowed them to make two or more annual round trips to China to the ordinary country vessel's one. Speed was also necessary to avoid Chinese government war-junks wishing to stop

FIG. 13. The Calcutta-built Opium Clipper *Waterwitch* with an exceptionally long bowsprit, jib-boom, and tall, raked masts allowing a tremendous amount of sail to be set.[40]

the illegal trade or pirates attracted either by the valuable opium on the outward voyage or the large amount of specie carried on the return voyage. For this reason, opium clippers were heavily armed.

A high percentage of opium clippers built in India were constructed at Calcutta. Phipps[38] lists seven being built there between 1830 and 1839. Lubbock claims that three were built at Bombay and a half-dozen at Moulmein. Essentially they were built to either of two designs. The first was a copy of a very famous American privateer. The second was specially designed for the trade by Sir Robert Seppings, the Surveyor of the Royal Navy. These were generally barque rigged. Of those built at Moulmein, only one was to the Seppings design. The others were copies of fast Mediterranean 'fruit' schooners.[39] If Phipps' or Lubbock's figures are anywhere near accurate, it can be seen that purpose- built opium clippers were a rare breed indeed.

It is obvious that Site One does not represent the primary site of a wreck. Rather, it is a loose trail of scattered, isolated material. One would expect a concentration of copper sheathing, ballast, coal, and other heavy material such as spare anchors, rudder gudgeons, etc. to be evident. Although it seems that MacKenzie salvaged everything he could from the wreck, it is predicted that much more material will be found to the northwest in the deeper water, (say, 10m), off the back of the deep reef flat where it was carried by floating portions of the ship's hull. Some material, associated with the bow section, may be found to the southwest along the southern shore of the islet.

There are three possible scenarios:

1. Both Sites One and Two are part of the same wreck.
2. Site Two is material from a wreck which floated to Chilcott from elsewhere.
3. Another wreck has occurred on Chilcott reef further to the south and opposite the Islet in an area which was not investigated.

However, it would appear that the presence of *Tectona grandis* at both sites is too consequential to ignore and that the first scenario must be the favoured option.

In the short term, further study of the material and data already collected may resolve a number of questions, but much more remains to be learned from the sites. In the interim, it is important that these preliminary findings be brought to notice and I would strongly recommend that future

private, tourist and scientific visitors and the Royal Australian Navy (frequent visitors) be advised against indiscriminate disturbance of any material remains in the Reserve unless they are conducting authorised archaeological research.

From an archaeological standpoint, there is no question that the *Coringa Packet* wreck and the guano mining aspect of the islet demand further investigation.

Whilst it is difficult to envisage the practical long-term preservation of the timbers and other material of Site Two in situ, it is critical to the study of 'country vessels' that they be precisely recorded and sampled. With this data, it may be possible to reconstruct a portion of the bow section using computer graphics, which will provide us with hitherto unknown details of an even rarer ship style, the 'Country-built Opium Clipper'. Therefore, it is recommended that, **at the first opportunity**, the material at Site Two be mapped and then, as a matter of expediency and economics, removed to a safe place where they can be studied at leisure. It is estimated that an archaeologist with a team of five volunteers assisting could accomplish this in two days if working during the northwest monsoonal period (say, late November-December). Considerable care would have to be exercised in the removal of the timbers because many of them are extremely fragile and vital information may be lost if they are damaged in transport.

In future, a controlled survey of the reef flat, and the discovery and recording of the primary underwater site, may contribute greatly to the meagre information currently known.

It is likely that a recommendation will be made to the Federal Minister, DASET, that, after consultation with ANPWS, a Protected Zone similar to the one at Porpoise Cay (Wreck Reef) be declared under the Commonwealth *Historic Shipwrecks Act 1976*. This would allow protective and management measures, specific to the nature of the resources, to be put into place.

Possible justifications for the declaration of a Protected Zone are as follows:

1. Little is known about the design or construction techniques employed in 'country vessels.' This type of ship played an important role in early Australian maritime history. Moreover, if *Coringa Packet* proves to have been built to one of the rare 'Opium Clipper' designs (of which only a few were built immediately prior to the introduction of steam, iron hulls and thus prior to the consequent decline of Indian shipbuilding) - and the chances are excellent that she was - then the recording and study of her remains are even more important.

2. Historical aspects of both the *Coringa Packet* story and that of the guano miners are of sufficient significance to warrant closer study. The material remains of both episodes can contribute to the interpretation and appreciation of these aspects. Their contribution would be in a physical sense as a part of the Reserve's resources, and in an academic sense as part of Australian and East Indian maritime history.

3. The remains are cultural heritage resources located within an administered Reserve which already has some management mechanisms in place. These unique resources require additional protective and management regimens specific to their nature.

4. Site Two, which has considerable potential to provide new information, is extremely vulnerable to natural attrition and unwitting, casual destruction or disturbance by visitors to the Reserve.

ACKNOWLEDGEMENTS

I wish to express my gratitude to Mr Max Allen of Max Allen Charters, without whose generous assistance the field work would not have been possible. Funding for field work was provided from the Commonwealth Historic Shipwrecks Programme, DASET. I would also like to thank Barry Muldowney for his assistance in the field. ANOMALOPUS PLUTO INGRAM, A POORLY KNOWN SKINK FROM CAPE YORK PENINSULA.

Memoirs of the Queensland Museum 32(1): 54:- The taxon *Anomalopus pluto* Ingram, 1977, a limbless, fossorial skink was based on a specimen collected at McDonnell crossing, Cockatoo Ck, 115km S of Bamaga, Cape York Peninsula (11°33'S, 142°26'E) on 14 July, 1975. Since that time, the species has been encountered infrequently.

In 1980, an Australian Museum (AM) party collected 6 specimens on 16-17 July (AM R94360, McDonnell Ck Crossing, 1 km E of main N/S Peninsula road, 11°33'S, 142°27'E; AMR94361-2, R94484-5, R112004, 15km E of Heathlands settlement on Captain Billy Ck road, 11°45'S, 142°41'E). Eleven years later, 4 specimens of *A. pluto* were collected by officers from the Queensland National Parks and Wildlife Service (QNPWS).One specimen was collected on 6 September on the road edge during road reconstruction, c.12km E of Heathlands ranger base (11°40'06"S, 142°45'30"E). Two days later, 8 to 10 specimens were uncovered in a 30m^2 area at Eliot Ck (11°24'40"S, 142°24'43"E) during earth moving activities. Of these, only the three least damaged specimens were collected. In December 1991, QNPWS (Far Northern Region) approached the Queensland Museum (QM) to assess the Eliot Ck *A. pluto* site, an area of proposed redevelopment. I visited Eliot Ck on 18 January 1992 but found no *A. pluto*. However, four specimens were recorded from 3 other localities: 500m W of Heathlands ranger base (11°45'S,. 142° 35'E), QMJ54050 (17 Jan.), 54082 (19 Jan.); 1km E of Heathlands ranger base (11° 45'S, 142°36'E), QMJ54083, 54213 (19 Jan.); Captain Billy Ck road, 28.25 km from Heathlands ranger base (11°39'S, 142°44'E) (24 Jan.), one seen but not collected.

Habitats

Ingram (1977) recorded QMJ26261 (the holotype) under leaf litter in a small patch of monsoon forest. AMR94360, from 1 km E of the type locality, was found under a piece of wood on the verge of the road bordering a 'vine and scrub thicket' (Greer & Cogger, 1985). Rainforest communities at the type locality are small, isolated patches on grey loamy sand, surrounded by tall open forest dominated by *Eucalyptus tetrodonta* (David Jones, pers. comm.). AMR94361-2, R94484-5 and R112004 were found in low dense heath on white sand: one beneath a lignotuber and the others from a pile of debris beside a track (Greer & Cogger, 1985). The three QNPWS specimens from Eliot Ck came from tall open forest of mainly bloodwood, stringy barks, *Xanthostemon xerophylus*, acacias, scattered livistona palms and pandanus, ironwood with a grassy understory and a moderate scattering of shrubs (Mike Provic, pers. comm.). These were within a few metres of a large termite mound in powdery grey sand. The fourth QNPWS specimen came from thick heath on red/yellow powdery sand in *Melaleuca viridiflora*; *Banksia dentata*; jacksonias; acacias and xanthorrhoeas scrub (Mike Provic, pers. comm.) with abundant large red termite mounds. QMJ54040 and J54082 were collected in a stand of epacrid scrub (*Leucopogon* sp.), 100m from a small stream, from grey loamy-sand beneath a small termite ridden log which supported an active termite mound. QMJ54083, J54213 were in a similar situation but the logs, while termite-ridden, did not support active termite mounds. The specimen from Captain Billy road was in notophyll vine forest (David Jones, pers. comm.) on grey loamy-sand, in association with a termite-ridden log supporting an active termite mound.

Overall, there appears to be no corelation of vegetation types at collection sites. However, *A. pluto* has always been found in sandy substrates.

Notes

A. pluto is known from 15 preserved specimens in the collections of the QM (5), AM (6) and QNPWS (4). These are from 7 localities, all within the Heathlands area of Cape York Peninsula. Following Thomas & McDonald's (1989) classification, McDonald et al. (1991) assigned *A. pluto* a ranking of 3K because of its limited distribution and the lack of information. However, *A. pluto* localities are within a range of less than 100 km; thus, according to their criteria, a rank of 2K is correct. While it is impossible to assess abundance of *A. pluto*, the many specimens encountered at Eliot Ck suggests that it may be common in areas of favourable habitat.

Little information is available on diet. Stomach contents of QMJ54083 contained only termite fragments, not surprising from the close association between *A. pluto* and active termite nests at several localities. Absence of sand particles in the stomach of QMJ54083 may suggest this specimen had been feeding on termites within their burrows (E. Dahms, pers. comm.). Whether *A. pluto* is a specialist termite feeder or a more general feeder is unknown.

A. pluto has an elongate right lung and no right oviduct. Other lizards that have lost the right oviduct produce a brood size of one and *A. pluto* should also follow this pattern (Greer, 1989).

Tissues from QMJ54213 are deposited in the Evolutionary Biology unit, South Australian Museum.

The work was done with a grant from the Royal Geographical Society of Queensland. Kate Couper, Wayne Longmore, Paul Feeney, Martin Cohen, Steve Williams and Trevor McLeod assisted in the field. Ross Sadlier supplied details of Australian Museum specimens. David Jones, Allen Greer and Mike Provic gave helpful advice.

A NEW SPECIES OF SKINK OF *LERISTA* FROM QUEENSLAND AND A RE-APPRAISAL OF *L. ALLANAE* (LONGMAN).

PATRICK J. COUPER AND GLEN J. INGRAM

Couper, P.J. & Ingram, G.J. 1992 06 29: A new species of skink of *Lerista* from Queensland and a re-appraisal of *L. allanae* (Longman). *Memoirs of the Queensland Museum* 32(1): 55-59. Brisbane. ISSN 0079-8835.

L. colliveri sp.nov. is found in NE and Central Queensland. It has been confused with *L. allanae* (Longman) but, besides the strickingly different colour-pattern, it can be readily distinguished by the presence of a nubbin for a foreleg whereas *L. allanae* has no forelegs. With *L. colliveri* separated from *L. allanae*, the range of the latter species is even more restricted than thought. This rare species has only been found between Clermont and Capella, Central Queensland, within the area 22°50-23°06'S and 147°38-147°54'E. It apparently has not been met with since 1960.□*Scincidae, Lerista allanae, Lerista colliveri, new species, Queensland.*

Patrick J. Couper and Glen J. Ingram, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 14 February, 1992.

The status of *Lerista* was clarified by Greer (1967, 1986). Since 1972, the species of the genus have received much attention in the central and western States because of the work of Glen Storr (see Wilson & Knowles, 1988, for references). In that time, however, the species of Queensland have not been as intensely studied.

For Queensland, Storr (1972) clarified the status of *L. muelleri* (Fischer) and Cogger (1975) noted 9 species of *Lerista* from the State. Greer (1979) described a new species *L. ameles* from NE Queensland and Cogger et al. (1983) listed the synonymies for all species. Greer et al. (1983) added three new species - *L. cinerea, L. storri* and *L. vittata* - from NW, NE and Central Queensland and Storr (1986) erected *L. aericeps aericeps* nov., from SW Queensland and the Northern Territory.

In 1988, Wilson & Knowles reviewed all Australian terrestrial reptiles and noted 15 species of *Lerista* from Queensland. However, in 1990, Greer said *L. aericeps aericeps* Storr was a junior synonym of *L. xanthura* Storr. Even so, Storr (1991a) was unconvinced and preferred to retain *L. aericeps* as a valid species. Storr (1991b) also disagreed with Greer's (1990) and Wilson & Knowles's (1988) concept of *L. orientalis* (de Vis); he divided the taxon into three allopatric species, two of which were new: *L. zonulata* and *L. ingrami.*

Recently, Covacevich & Couper (1991b) listed 17 species from Queensland and also provided maps (1991a) of 15 of the species that were represented in the Queensland Museum collection. In this paper, we add a further new species from NE and Central Queensland that has been confused with *L. allanae* (Longman). We also re-appraise the status of the rare skink, *L. allanae.*

Measurements are in millimetres. Specimens prefixed by J are housed in the Queensland Museum, by R are in the Australian Museum. Queensland regions follow Ingram & Raven (1991).

DIAGNOSIS

A large (maximum snout-vent length 84) *Lerista* with a movable eyelid; foreleg reduced and represented by a nubbin; and hindleg with one clawed digit. Most similar to *L. allanae* but distinguished by colour-pattern (continuous, dark, longitudinal lines dorsally and laterally; ventral scales with or without dark flecks vs longitudinal lines of dark spots dorsally and laterally; all ventral scales dark edged).

DESCRIPTION

Snout-vent length (mm): 41-84 (N 12, mean 67.4). Length of appendages etc. (% snout-vent length): hindleg 7-9 (N 12, mean 7.6), tail 111-127 (N 4, mean 118.5), head length 9-13 (N 12, mean 10.0), head width 6-8 (N 12, mean 6.7).

Nasals broadly in contact. Prefrontals widely separated. Frontoparietals narrowly (N 7) to moderately (4) separated but sometimes touching (1). Usually 2 nuchals contacting the parietals, rarely 3 (N 12, mean 2.1). Supraoculars 3, first two in contact with the frontal. Supraciliaries 5 (N 28). Loreals 2, second smaller. Presuboculars 2, second the smaller. Supralabials 6, fourth below eye. Infralabials 6. Midbody scale rows 18 (N 28). Paravertebral scales 81-94 (N 13, mean 87.7). Foreleg almost absent, represented by a nubbin in a dimple. Hindleg with one clawed digit. Lamellae under longest toe 5-7 (N 12, mean 5.9).

Dorsal and lateral ground colour tan with a pattern of more or less continuous, dark, longitudinal lines; the lines are formed by individual scales having a dark central streak; on lower flanks the lines are broken into dark-edged scales. Ventral ground colour cream; chest and belly immaculate to well-marked with dark flecks; underside of tail boldly to obscurely patterned with longitudinal lines of dark flecks. Head shields dark-edged and mottled; lips barred; loreals and temporals marked by a dark streak breaking up posteriorly.

DISTRIBUTION

From just east of Townsville, NEQ, southwest to the Hughenden area, CQ.

ETYMOLOGY

Named for Mr Stanley Colliver OBE (1908-1991) for his generosity and outstanding contributions to the Queensland Museum.

REMARKS

L. colliveri was included in *L. allanae* by Cogger (1983, 1985), Wilson & Knowles (1988) and Covacevich & Couper (1991a). The two species are similar. However, *L. colliveri* has distinct forelegs represented by nubbins while *L. allanae* has no protruding forelegs; they also differ in colour-pattern. The two species are separated by about 400km.

According to the criteria of status in Ingram & Raven (1991: 337), *L. colliveri* should be listed as '3K'.

Lerista allanae (Longman)
(Figs 3-5)

Rhodona allanae Longman, 1937:167. Holotype J6180 from Retro Station, Capella, CQ.

MATERIAL EXAMINED

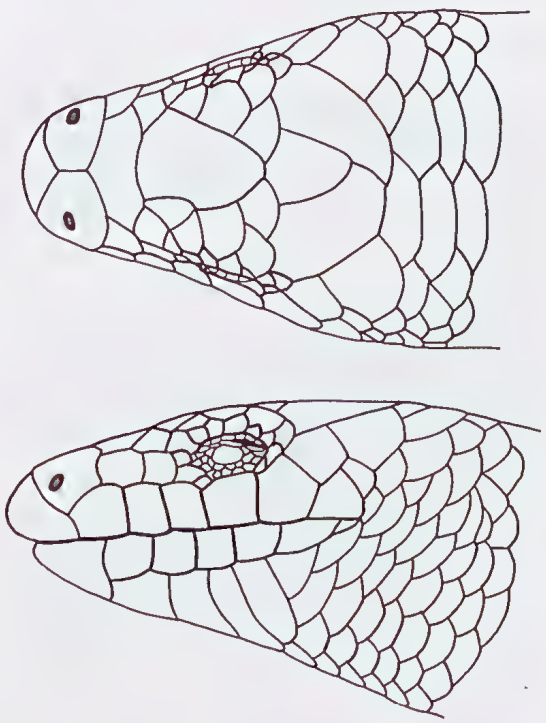

FIG. 4. *Lerista allanae* (holotype J6180). Above: dorsal view of head. Below: lateral view of head.

FIG. 5. *Lerista allanae* (holotype J6180) from Retro Station, Capella, CQ (Garry Cranitch).

Stn, Capella, via Clermont (22°52S', 147°54'E), CQ, P.C. Allan; R13819 20 miles W of Capella (23°06'S, 147°43'E), CQ, J.R. Slevin, Aug 1929.

DIAGNOSIS

A large (maximum snout-vent length 88) *Lerista* with a movable eyelid; foreleg absent (usually represented by a shallow depression); and hindleg with one, clawed digit. See diagnosis of *L. colliveri* for further differences from that species.

DESCRIPTION

Snout-vent length (mm): 61-88 (N 7, mean 76.3). Length of appendages etc. (% snout-vent length): hindleg 6-10 (N 7, mean 7.7), tail 100-104 (N 2, mean 102), head length 9-10 (N 7, mean 9.0), head width 6-8 (N 7, mean 6.4).

Nasals broadly in contact. Prefrontals widely separated. Frontoparietals narrowly (N 4) to moderately (2) separated but rarely touching (1). 2-4 nuchals contacting the parietals (N 7, mean 2.4). Supraoculars 3, first two in contact with the frontal. Supraciliaries 4 or 5 (N 8, mean 4.5). Loreals 2, second smaller. Presuboculars 2, second the smaller. Supralabials 6, fourth below eye. Infralabials 6. Midbody scale rows 18, rarely 20 (N 8, mean 18.3). Paravertebral scales 78-89 (N 7, mean 85.1). Foreleg absent, represented usually by a shallow depression. Hindleg with one, clawed digit. Lamellae under longest toe 8-9 (N 8, mean 8.6).

Dorsal and lateral ground colour tan to gray-brown; back and flanks marked by longitudinal lines of dark spots. Ventral ground colour pale with chest and belly strongly marked by dark edged scales; dark edging particularly prominent under tail. Head shields dark-edged, obscure mottled; lips barred; loreals and temporals marked by dark streak breaking up posteriorly.

DISTRIBUTION

Between Clermont and Capella, CQ, within the area 22°50-23°06'S and 147°38-147°54'E.

REMARKS

Longman (1937) described *Rhodona allanae* from three specimens. He designated J6180 as holotype but left unwritten the registration numbers of the two paratypes. Covacevich (1971) said the paratypes were J6040 and J6238 and that J6308 was a questionable alternative to J6238. However, while there is no doubt about J6040, both the dates of registration of J6238 and J6308 (28 June 1937 and 30 November, 1937 respectively) are after the date of publication of Longman's paper (24 June 1937) and thus unlikely to have been examined for the paper. Actually, the second paratype must be J6179, which was registered with the holotype and is noted as 'paratype' in the register.

According to the criteria of status in Ingram & Raven (1991: 337), *L. allanae* should be listed as '2E'. McDonald et al. (1991) rated it as '3R'. However, they included specimens of *L. colliveri* in their concept of *L. allanae*. With *L. colliveri* removed, the species is only known from over a restricted range of about 60km and has been collected only in the years 1929 by J.R. Slevin (see Slevin, 1955), 1936-1938 by Mrs P.C. Allan (inferred from the same dates of registration in the Queensland Museum register) and 1960 by C. Vallis. In the last 25 years, despite intensive searching between Clermont and Capella by many collectors, *L. allanae* has not been found again.

L. allanae is apparently sympatric with two other *Lerista*: *L. punctatovittata* (J46739-41) has been taken from c.8-10km E of Capella at Gregory Mine turnoff (23°05'S, 148°06'E) and *L. fragilis* has been collected nearby (J6181-3, 6231 Retro Stn, Capella, via Clermont; J46742-3, 46746 c.8-10km E of Capella at Gregory Mine turnoff).

ACKNOWLEDGEMENTS

We thank Steve Wilson, Gregory Czechura and David Nebauer (Queensland Museum) and Allen Greer (Australian Museum) for their advice and help; Ross Sadlier (Australian Museum) for the loan of specimens in his care; and Glenn Shea (University of Sydney) and Garry Cranitch (Queensland Museum) for their photography.

A NESTING RECORD FOR *COERANOSCINCUS RETICULATUS* (GÜNTHER). *Memoirs of the Queensland Museum 32(1): 60. 1992:-* On 5 March, 1992, a *Coeranoscincus reticulatus* nest containing 8 eggs was found in moist soil beneath a rotten rainforest log in the Mistake Mountains, SEQ (27°58'S, 152°22'E). The log measured 107×20cm (length×width) and was in broad contact with the ground surface and situated in full sunlight (12.25pm). The eggs, just visible below the ground surface, were buried in loose soil in a 2.5cm deep depression. The substrate consisted of a soft, loamy, basaltic soil with a pH of 6.37. Surface air temperature was 27.6°C and the soil temperature within the nest was a cooler 20.0°C.

The eggs varied in length from 23.71-28.94mm (mean 27.22mm) and width from 14.0-18.55mm (mean 16.59mm). The size of the eggs seemed surprisingly large for a species with a maximum snout-vent length (SVL) of 195mm. Only one egg was accurately weighed. It measured 26.05×16.88mm and weighed 3.85gm. Six of the eggs were regular, oval shaped; one was slightly irregular oval; and one was distinctly bean shaped. Seven of the eggs appeared to be predominantly cream with black crossbands; the back and tail had an obscure, chequered effect of cream, black and brown; the pale venter scales were strongly marked with black edges producing a series of dark longitudinal lines running along the flanks, belly and under-surface of the tail.

Greer & Cogger (1985) examined shell thickness of oviducal eggs in *C. reticulatus* and suggested the species was oviparous. Our record confirms their hypothesis and the *C. reticulatus* eggs from Mistake Mountains represent the first nesting record for the species.

However, it is not possible to determine whether or not the 8 eggs found were a single clutch. From preserved museum specimens of *C. reticulatus*, McDonald (1977) recorded 3-6 oviducal eggs(N=4) in the months October-December. Thus, 8 eggs might be a single clutch but it is also possible that the nesting site was shared by more than one female. Communal nesting is well known in scincid lizards and is summarised by Greer (1989).

The fieldwork on which this paper was based is part of a study on the rainforests of SE Queensland funded by the National Rainforest Conservation Programme.

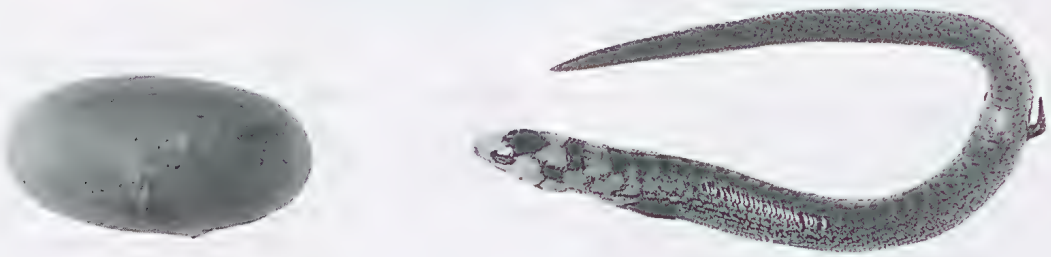

FIG. 1. *Coeranoscincus reticulatus* egg (QM J54649) and hatchling (QM J54647).

healthy; the eighth egg had a small patch of fungus on the shell.

Four eggs were carefully removed from the nest and returned to the laboratory for incubation in vermiculite. Two of these developed fungus and were preserved in 10% formalin (registered as Queensland Museum (QM) J54649 (Fig. 1) and 54650). When opened QM J54650 contained a well-developed, cream coloured embryo (SVL 39.2mm, total length 71.52mm) with conspicuous dark crossbands on the anterior half of the body.

The two eggs left incubating hatched on 2 April, 1992 (QM J54647) and 5 April, 1992 (QM J54648). Hatchling QM J54647 (Fig. 1) (SVL 59.86mm, total length 113.34mm) emerged from an egg measuring 28.07×18.55mm. Hatchling QM J54648 (SVL 58.24mm, total length 111.98mm) emerged from an egg measuring 26.05×16.88mm. Both hatchlings were similarly patterned: the head and neck regions were

JALIJBANG 2 AND THE DISTRIBUTION OF PECKED FACES IN AUSTRALIA

BRUNO DAVID, DAVID CHANT AND JOSEPHINE FLOOD

David, B., Chant, D. & Flood, J. 1992 06 29: Jalijbang 2 and the distribution of pecked faces in Australia. *Memoirs of the Queensland Museum* **32**(1): 61-77. Brisbane. ISSN 0079-8835.

Archaeological excavations at the Jalijbang 2 rockshelter, near Katherine, Northern Territory, show that in this area pecked faces and Panaramitee type peckings are unlikely to pre-date the mid-Holocene. These results, however, are unlikely to shed light on the antiquity of pecked faces elsewhere in arid and semi-arid Australia, for the Cleland Hills, Durba Hills, Dampier, Sturt Creek, and Jalijbang pecked faces appear to be regionally distinctive. It does, however, show that the so-called *Panaramitee* artistic style consists of a broad, highly generalised set of conventions which cannot be purely understood as of having great antiquity.□ *rock art, Wardaman, Northern Territory, Australian prehistory.*

In a secluded sandstone gorge, 150km south-west of Katherine, N.T. (Fig. 1), are found a series of highly unusual engraved figures. When they were first observed by archaeologists during the mid 1980s, the figures were described as a minor but striking component of a broader regional body of rock art dominated by non-figurative and track peckings and figurative paintings (Lewis & McCausland, 1987). The figures themselves consist of four large anthropomorphs pecked into a near-vertical sandstone wall, three of which have their faces depicted (Figs 2-4). A further three pecked faces are located on nearby boulders (Figs 5 & 6). The site in which these occur is known as Jalijbang (spelled 'Jalikpany' by Lewis & McCausland, 1987) by the local Wardaman Aboriginal people. The pecked faces on the wall and boulders are all depicted in frontal view, and are reminiscent of the pecked faces from Cleland Hills (1000km to the south), which are commonly believed to be of great antiquity (Edwards, 1968). Lewis & McCausland (1987: 78), entertaining the idea of prehistoric inter-regional contacts between people from the Jalijbang region, Cleland Hills, and from other regions containing similar engravings, concluded that:

> 'whether or not there is any relationship between the Jalikpany figures and the complex anthropomorphic figures and/or face engravings elsewhere cannot, at this time, be determined.'

This paper is an attempt to address this issue and to investigate the antiquity of the Jalijbang figures. Furthermore, if the Jalijbang engravings can be shown to be closely related stylistically to the Cleland Hills engravings, then the antiquity of the former may shed light on the antiquity of the latter.

INVESTIGATING THE ANTIQUITY OF THE JALIJBANG PECKINGS

Jalijbang 2 is a small rockshelter with a high ceiling near the downstream end of a small gorge. The site itself has a curious setting in that it is bounded to the east by a vertical sandstone rock face, to the south by massive sandstone boulders (evidence of past roof-falls), and to the west and north by a seasonal creek. The creek bed itself consists of high quality ochre pebbles and quartzite and sandstone blocks. A small pocket of soft sediments has been preserved in the area bounded by the creek, the rock wall and the boulders, and this was made possible only because the boulders themselves protected it from the creek's northward waterflow during the wet season. Water rushes past the soft deposits at Jalijbang 2 during the wet season, detouring around the massive boulders, and flooding the pocket of soft sediments with quiet waters which deposit new silts during times of flood. It is in this protected pocket that archaeological sediments are found, preserved by the periodic addition of silts (Fig. 7) .

The large boulders near the soft sediment contain numerous engravings. Most of these consist of abraded grooves and pecked bird tracks. But

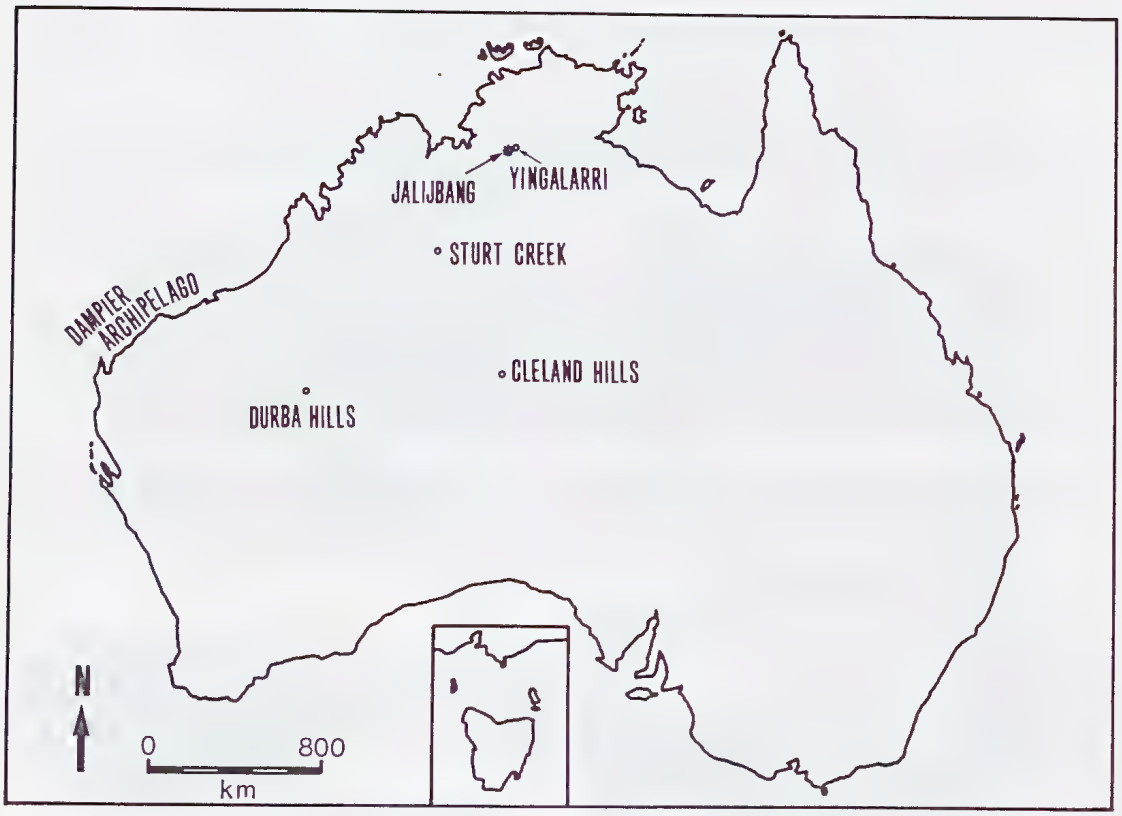

FIG. 1. Australia showing locations mentioned in text.

near the soft deposits, where the boulders meet the creek bed, lies a medium-sized boulder with a pecked face (Fig. 5). Two other pecked faces, as well as peckings of dingo-forms, occur on boulders in a rockshelter 20m upstream (Fig. 6). These boulders appear to be part of the massive sandstone boulder scree which begins at the upstream rockshelter, and end at the downstream end of Jalijbang 2. They are likely to have been deposited as a result of either instantaneous or prolonged roof-fall events.

The peckings on these boulders all occur on the boulder's upper or side surfaces (Fig. 8). None have been found on underlying boulders. Consequently, all of the boulder engravings are likely to post-date the roof-fall. Further, if the roof-fall itself was a prolonged event, then the engravings themselves were likely to have been undertaken after the *latest* episode of roof-fall, given that engravings only occur on the uppermost boulders. In excavating at Jalijbang 2, we therefore aimed at dating the roof- fall in order to obtain a maximum antiquity for the boulder engravings, which include three pecked faces (two of which occur in the upper rockshelter) reminiscent of the Cleland Hills pecked faces.

In July and August 1989, one of us (B.D.) undertook a small excavation at Jalijbang 2, immediately beneath the four pecked anthropomorphs which adorn the sandstone wall (Fig. 7). Sixteen juxtaposed 50cm × 50cm squares were excavated until compact sediments were reached, after which excavation of only four squares continued[1]. All materials were excavated in bucket spits following the natural stratigraphy (Johnson, 1979). Stone artefacts and other cultural materials greater than 2cm maximum dimension were recorded in three dimensions and bagged separately, as were all hearth stones.

Although the Jalijbang 2 sediments were well stratified, most of the individual stratigraphic laminations resulting from the alluvial deposition of silt could not be identified in situ, as variations in texture and colour were minimal.

[1]The surface sediments from the other 12 squares were excavated so that loose surface sediments would not fall into the main pit and contaminate older materials.

FIG. 2. Pecked anthropomorph located on a wall at Jalijbang 2.

FIG. 3. Pecked anthropomorph located on a wall at Jalijbang 2.

Five stratigraphic units were revealed from the excavation (Fig. 9):

Stratum 1: loose surface sediments. Fine tan-brown silts, extremely loose, containing small amounts of organic materials. Sediments are uniformly very fine.

Stratum 2: immediately underlies Stratum (SU) 1. SU 2 consists of a number of ashy and/or charcoal-rich lenses within a broader silt layer. These lenses are given separate identification (SU 2b, 2c and 2f), and most are spatially discontinuous across the excavation. SU 2 proper is a fine, silty sediment, finely laminated in some places, but the lamination was too indistinct to record except for sub-stratum 2a. The silts contain very small amounts of organic matter (including charcoal). Sediments are light tan-brown in colour. The separate sub-strata are:
SU 2a, being a 2mm thick lens of slightly darker silt;
SU 2b, a fairly well defined layer of grey ashy silt (poor in charcoal);
SU 2c, an extremely well defined charcoal concentration, containing burnt stones. It is very well defined in square E6 especially. In this layer were found the first evidence of pebbles (all burnt), many of which are fire cracked. SU 2c is black in colour, and is almost pure charcoal;
SU 2d, a fine gravel lens, with silty matrix around it. It is present in square E6, but it is ill-defined elsewhere;
SU 2e, a greyish orange silt;
SU 2f, an extremely well defined charcoal lens. It is very ashy and black in colour.

Stratum 3: extremely compact gravel and pebble layer, orange-brown in colour. Pebbles range in size from small (<1cm) to approximately 25cm maximum size. The pebbles and gravel making up SU 3 appear similar to the materials which currently make up the adjacent creek bed. The boundary between SU 2 and SU 3 is well defined.

Stratum 4: decomposing sandstone, mottled reddish yellow. Intersection with overlying SU 3 is ill-defined, spanning approximately 3cm.

Stratum 5: solid sandstone. This is the basal stratigraphic unit consisting of large boulders with relatively flat surfaces. Excavation could not proceed into or below Stratum 5 because of the size of the boulders.

Radiocarbon Dates

Two radiocarbon dates were obtained:

FIG. 4. Pecked anthropomorph located on a wall at Jalijbang 2.

a. 260± 60BP (New Age; Conventional Age is 250±60BP) (Wk-1551). This date is from a good charcoal sample from Square E6, XU 6, and dates the uppermost hearth excavated (SU 2c) (^{13}C permil = -26.6). This hearth is a well-defined charcoal and hearth stone lens which is assumed to have been created as an archaeologically instantaneous event.

b. 1040±60BP (New Age; Conventional Age is 1010±60BP) (Wk-1550). This dates the lowermost hearth (SU 2f), and comes from a good quality charcoal sample from Square F6, XU 10 (^{13}C permil = -26.0).

Occupation at Jalijbang 2

Human occupation at Jalijbang 2 began sometime before 1040±60BP. Low density deposition rates of stone artefacts are found throughout the deposits, although peak rates occur in association with the two hearths (around 260BP and 1040BP) (Table 1). Only two small fragments of bone were found (both in post-260BP times), whilst hearth stones and heat-shattered burnt rocks are associated with the uppermost hearth. Ochre occurs, but it is difficult to associate its presence with artistic activities, as the creek bed itself contains vast numbers of ochre pebbles, and periodic floods can be expected to deposit very small fragments of ochre with the deposited silts. Ochre pebbles were also used as hearth stones during use of the uppermost hearth. No in situ ochre fragments exhibit any signs of use wear (Appendix 1).

Although stone artefacts occur below the bottom hearth (1040±60BP), their numbers are very low. These low rates are associated with SU 3 and 4, the gravel and sandstone layers below the alluvial silts and hearths. The gravels themselves indicate the presence of creek flow in this section of the site sometime in the past (in pre-1040BP times), although the large boulders were present to the immediate south during that time (as indicated by the underlying SU 5 boulders in the excavations). An extension of the depth-age curve dates the uppermost surface of the in situ sandstone boulders (SU 5) to 2880BP, although the presence of a different stratigraphic unit between it and the dated silts (SU 2) means that this date is likely to be a very general indication only of the age of the roof-fall which resulted in the boulder deposit. Consequently, this extrapolated date should be used with caution, and is presented here as a very general indication only of the order of magnitude which we can expect the age of the roof-fall underlying the cultural deposits to be. It is not known if cultural materials occur below the boulders, as excavation could not proceed below them.

Other Dates

Two other independent sources indicate a mid- to late-Holocene antiquity for the end of the roof-fall expressed stratigraphically as SU 5:

1. On boulders located in a rockshelter 20m upstream from Jalijbang 2 (at Mennye-ya), a large, exfoliated boulder contains pecked dingoforms on its upper surface. These boulders were likely to have been deposited during the same roof-fall event(s) which resulted in the creation of the scree-slope at Jalijbang 2, and dated to approximately pre-2880BP by reference to the depth- age curve. As dingoes first arrived in Australia around 3500 years ago (Solomon & David, 1991), the peckings must have been undertaken sometime after that time. This does not mean that the boulders were necessarily deposited after this time, but does indicate that at least some of the art on them were done in mid-

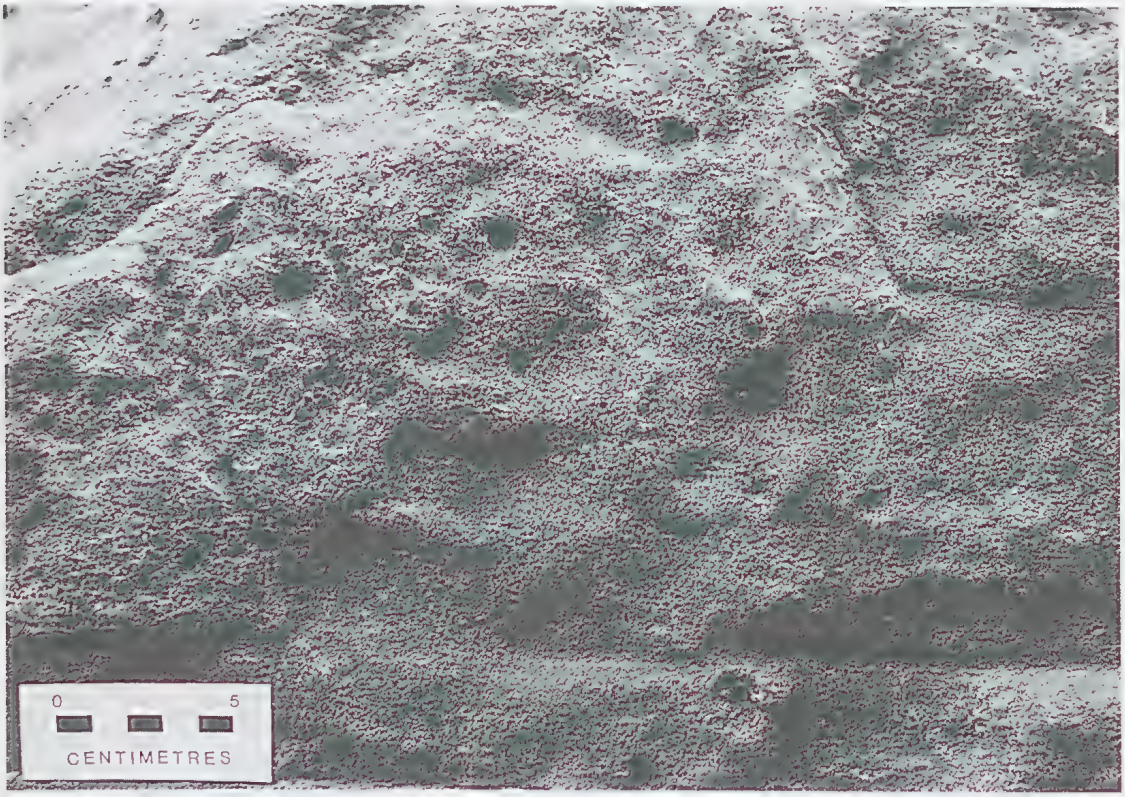

FIG. 5. Weathered pecked face from creek-bed boulder, Jalijbang 2 (see Fig. 7 for location of boulder).

TABLE 1. Deposition of materials, Squares E6 and F6. All rates are per m^2 per 100 years.

to late-Holocene times. The other peckings on this and nearby boulders show a similar degree of patination (moderate to heavy) as the dingo peckings, indicating probable comtemporaneity.

2. A cortex sample was extracted from a nearby boulder by Alan Watchman (pers. comm., 1988). The cortex was examined by Watchman (1990), who found a thin, microscopic layer of organic-rich materials at its base. The organic materials were extracted and dated through AMS, where a date of 4010±300 was obtained (Watchman, 1990). As the sample came from near the base of the cortex, it dates the beginnings of cortex development, and hence when

FIG. 6. Pecked faces. A, I-N=Dampier. B-C=Jalijbang boulders. D-G=Cleland Hills. H=Durba Hills. After Dix (1977) and Lewis & McCausland (1987).

FIG. 7. Plan of Jalijbang 2. Fine-dashed area is large boulder scree.

the boulder probably became exposed to the elements. 4010±300BP is therefore likely to represent the antiquity of the boulder's deposition to its current position.

Discussion of Antiquity of Boulders at Jalijbang 2

Three independent investigations all point to a mid- to late- Holocene antiquity for the end of the roof-fall which resulted in the massive boulder scree at Jalijbang 2. The in situ sandstone boulders located in the excavation were themselves tentatively dated to around 2880BP by extension of the depth-age curve. A major problem with this dating is that it assumes a steady sedimentation rate below the lowest radiocarbon date, and hence, by itself, the resultant chronology can only be taken as a general approximation at best. When compared to the cortex date (4010±300BP) and the presence of pecked dingo-forms on boulders from the adjacent scree deposits (post-3500BP), however, the depth-age calculation appears to be of the correct order of magnitude. The roof-fall at Jalijbang 2 appears to have ended around 3000 to 4000 years ago.

Antiquity of Pecked Faces

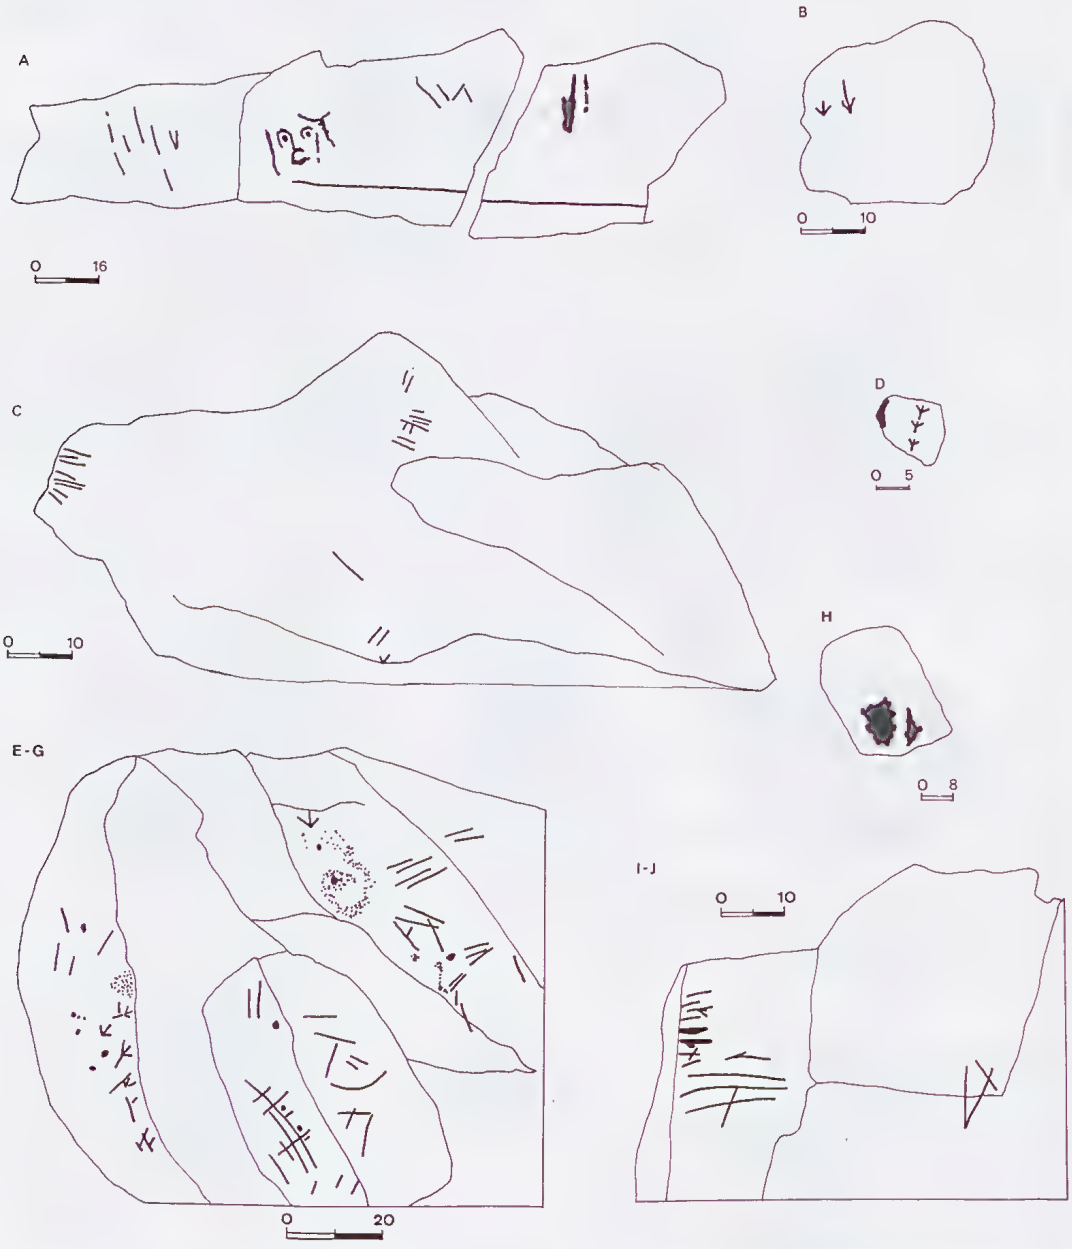
Given a likely mid- to late-Holocene antiquity for the end of the roof-fall at Jalijbang 2, it is also likely that the pecked faces and other engravings on the boulders are of a similar antiquity. The pecked face in the creek bed at the base of the boulder scree (Fig. 5) is also unlikely to pre-date the mid-Holocene as the annual waterflow in the creek can be expected to have obliterated the pecking were it to have greater antiquity. It is notable that during pre-3000BP times precipitation was significantly higher than at present, making it even more unlikely that this pecking would have survived (Chappell & Grindrod, 1983).

As all of the boulder engravings at Jalijbang 2 are located on the upper and side surfaces of the uppermost boulders only, it is also likely that all engravings post-date the *latest* episode of roof-fall (3000 to 4000BP). These engravings include pecked faces and bird tracks and abraded grooves.

The peckings on the rock wall, however, are much more difficult to date. It is possible that the roof-fall which terminated around 3000 to 4000 years ago resulted in the creation of the rock wall itself (and hence the peckings postdate this time), but it is also possible that the current rock wall existed before the roof-fall. If the former was the case, the peckings on the wall would be roughly contemporaneous with the boulder engravings. It is possible, however, that the wall engravings are older, although they possess similar patination to the adjacent boulder peckings (supporting general contemporaneity, although degree of patination can vary widely even within localised areas). In any case as will be shown below the boulder pecked faces are stylistically different from the wall ones, and therefore the antiquity of the former cannot be used to date the latter on stylistic grounds. In short, the boulder engravings probably date to the mid- to late-Holocene, whilst the antiquity of the wall engravings is unknown.

We investigate below the possiblity of determining the antiquity of other pecked faces from arid and semi-arid Australia by investigating stylistic distributions of pecked faces. We specifically ask the question, are the dated (boulder) pecked faces at Jalijbang 2 of a purely

FIG. 8. All of the abraded and pecked figures located on the boulders at Jalijbang 2. All scales are in centimetres. Continued on next page



local style, or are such faces found elsewhere also; if the latter, can the antiquity of the Jalijbang 2 faces reveal information on the antiquity of pecked faces elsewhere?

To address these questions, we undertake preliminary analysis of all published pecked faces from Australia which have a basic resemblance to those of Jalijbang.

THE REGIONAL OCCURRENCE OF PECKED FACES

Wardaman Country (Jalijbang and Yingalarri)

The pecked faces from Jalijbang can be divided into two groups, those on boulders and those on the wall. The three faces found on the

FIG. 8. Continued from previous page. All of the abraded and pecked figures located on the boulders at Jalijbang 2. All scales are in centimetres.

rock wall are very similar to each other: they all have concentric circles for the eyes, ears, noses, and broadly cylindrical outlined faces. They also have full or partial bodies. The faces pecked on boulders, however, exhibit neither bodies nor ears, and consist only of non-concentric eyes. Only one of the boulder pecked faces has a nose. The boulder faces are generally smaller than those located on the wall, and were created by a small number of separate, pecked lines (6, 7 and 7 for the boulder faces, compared to the 14, 20 and 26 lines that make up the pecked faces on the wall[2]). In short, the Jalijbang pecked faces can be divided into two distinct stylistic groups, the structurally complex wall faces, and the more generalised boulder ones.

A pecked face was also recently rediscovered by the authors at Yingalarri, 20km east of Jalijbang (and still within Wardaman country). This pecking (see Flood et al., in press), like the Jalijbang boulder ones, lacks the structural complexity of the Jalijbang wall peckings (see Table 2 for traits present).

Cleland Hills

Edwards (1968) reported on the occurrance of fifteen pecked faces from the Cleland Hills, 1000km south of Jalijbang. Of these, five figures are illustrated in his and subsequent reports (Edwards, 1968; Dix, 1977) (many of the others are badly weathered and difficult to distinguish). The Cleland Hills faces have been linked stylis-

[2] These numbers refer to the separate lines that make up the *faces* of each figure only.

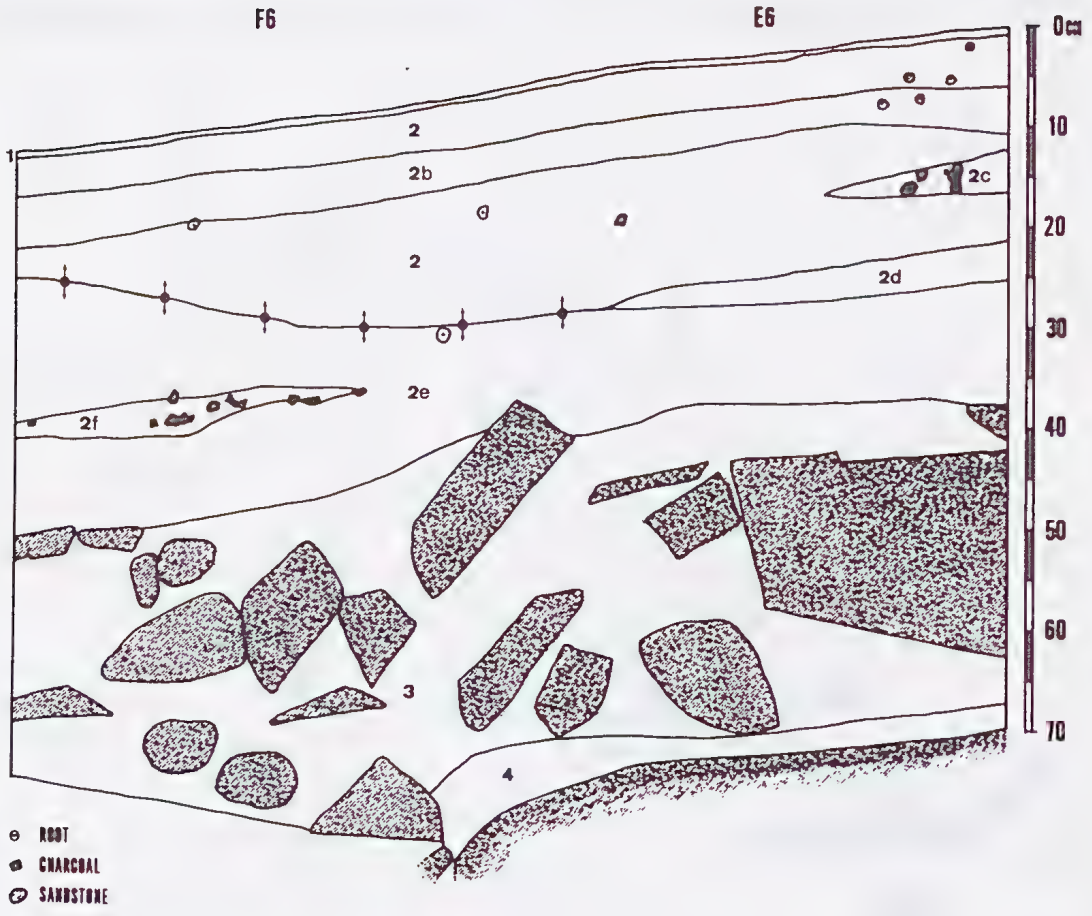


FIG. 9. Section drawing, Jalijbang 2.

tically to those from Jalijbang, Dampier, Sturt Creek and elsewhere (e.g. Dix, 1972, 1977; Lewis & McCausland, 1987), and have been considered to have considerable antiquity by virtue of their advanced state of patination. Yet the Cleland Hills faces contain a suite of characteristics not found in pecked faces elsewhere. These faces are generally pear- shaped or heart-shaped with noses depicted whilst their mouths are shown as straight or curved lines (at Jalijbang mouths on the wall faces are represented as single dots). Eyes consist of concentric circles, but unlike the Jalijbang wall faces, they were executed by a small number of separate pecked lines only (7, 8, 9, 10 and 10 for the five faces illustrated in Edwards, 1968 & Dix, 1977). We will return to these points below.

Dampier

The pecked faces from the Dampier region of Western Australia are relatively varied in style. One of their dominant features is the representation of hair on many figures, although this is not always so. Other characteristics are concentric circle eyes, and the enclosure of the head in an outline. The nose is sometimes represented, but ears are not and heads are never pear-shaped. The Dampier faces include figures created by numerous separate lines (up to 32) as well as some created by a few lines only (as few as seven). The former are more common.

Durba Hills

The Durba Hills (W.A.) face reported by Dix (1977) exhibits hair and concentric circle eyes, but nose, ears, body, and head enclosure are missing. It is reminiscent of the Dampier faces, and this is especially so of the hair and of the parallel lines below the eyes.

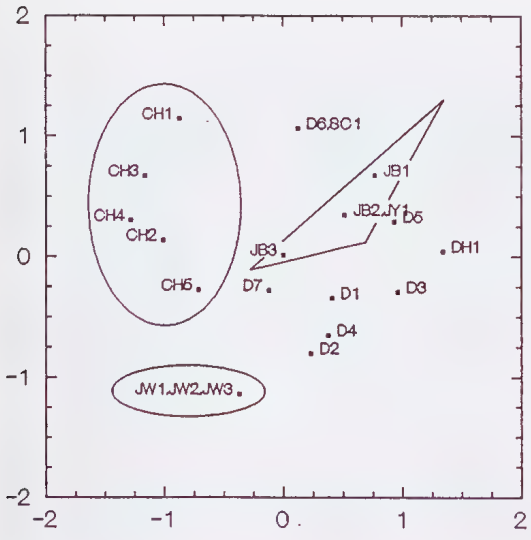

FIG. 10. MDS map based on eight qualitative variables.

Sturt Creek

The Sturt Creek pecking has, like the Cleland Hills faces, a linear mouth. The head is enclosed and attached to a full body (Crawford, 1968; Walsh, 1989). It is in this way reminiscent of the Jalijbang 2 wall peckings, although unlike the latter, it does not have concentric circle eyes, ears or nose.

Regional Variability

The Jalijbang 2 boulder and wall pecked faces are stylistically different from each other, especially with respect to the presence or absence of concentric circle eyes, nose, ears, and associated bodies. Similarly, whilst the wall faces are composed of many separate pecked lines, the boulder faces contain considerably fewer lines (Table 3). The pecked face located on an exposed boulder at Yingalarri is stylistically similar to the boulder faces from Jalijbang 2.

To the south and southwest of Jalijbang, however, are found a number of pecked faces which, although superficially resembling the Jalijbang faces, are regional variations of the same theme (pecked faces). Such peckings are characteristic, although minor, components of some arid and semi-arid zone pecked assemblages. Since they are not found in more humid zones, their shared presence in arid Australia has often entertained the possibility of inter-regional interactions linking the places where they are found in a vast desert social network. But before this idea can be properly entertained, the presence of shared stylistic traits should be demonstrated. The presence of pecked faces in different areas, by itself, cannot be taken to signify a single artistic convention - pecked faces are not necessarily structurally complex endeavours, and only a limited number of traits (e.g. presence of eyes and head outline) are needed to make a picture resemble a face. In other words, the presence of non-essential lines (e.g. ears are not needed to make a face-form), and/or of particular combinations of features, are needed to be shared before two geographically separate bodies of pecked faces can be deemed to be represented by a single stylistic convention.

In examining the similarities and differences between the known pecked faces of Jalijbang, Yingalarri, Cleland Hills, Durba Hills, Dampier and Sturt Creek, we began by identifying whether certain traits were present or not. These traits are:

1. hair or head-dress;
2. nose;
3. ears;
4. linear mouth (as opposed to a dot or an enclosed area);
5. concentric circle eyes (a circle around a dot is not considered a concentric circle);
6. pear or heart shaped head;
7. head enclosed by an outline;
8. associated body.

The traits themselves were chosen to highlight stylistic variation. It was noticed that some traits were present in all pecked faces (e.g. eyes), whilst others were present in some only. The traits chosen specifically represent the major traits present in a number of peckings but not all of them. A Multi- Dimensional Scaling (MDS) statistic was subsequently undertaken to reveal how the separate faces cluster stylistically with each other, on the basis of the combination of the eight identified traits. Our main aim was to determine whether or not the faces from each region clustered together and, if so, did these clusters separate out conspicuously from the other regions.

The variables used in the MDS were the eight traits enumerated in Table 2. MDS is a set of mathematical techniques which enables the mapping of units (pecked faces) as points in geometrical space, reducing the number of dimensions (eight in our case) to two. It enables the user to locate the units in a spatial configuration - a 'map' (Fig. 10) (Alvey et al., 1982: 122). Ulsaner (1978: 5) writes: 'Once we have located the ... points in (multi-dimensional) space, we

seek to determine the hidden structure, or theoretical meaning of this spatial configuration'.

The importance of MDS is that it provides a way of reducing the data to two dimensions. These two dimensions represent the 'hidden structure' of the data. Identification of key differences between the pecked faces was determined by identifying those that stand out or cluster together on the MDS map. To do this, statistical proximity values between units (pecked faces) are computed. 'The larger the dissimilarity (or the smaller the similarity) between two objects, as shown by their proximity values, the further apart they should be in the spatial map' (Kruskal & Wish, 1978: 7).

The results of the MDS shows a high level of regional clustering. As expected, the Jalijbang 2 wall and boulder peckings separate out. The Yingalarri figure, also located within Wardaman country, cluster with the Jalijbang 2 boulder faces. The Cleland Hills faces separate out well, as do the Dampier and Durba Hills faces. The Sturt Creek figure is similar to one of the Dampier figures, but all other pecked faces-are regionally discrete (Fig. 10). In short, the arid and semi-arid zone pecked faces consist of a series of regionally specific figures, differentiated by the presence or absence of particular traits. It is the combination of such traits which gives each region its stylistic particularity. Unfortunately, the published information and illustrations of these pecked figures do not reveal enough information to determine whether or not there are also regionally specific metrical differences. We have nevertheless briefly attempted to gather information on this question by quantifying the following:

a. the ratio of the distance between the eyes (taken from centre of eyes) to width of face at that plane;

b. the maximum width to height ratio (the former being at a parrallel to the eye plane, and the latter perpendicular to width);

c. the number of separate pecked lines making

up the faces (if a body is present, it is not included in the quantification).

The MDS undertaken on this data set does not reveal the distinct regional character revealed by the previous analysis (Table 3, Fig. 11). Nevertheless, the Cleland Hills faces separate out well from the other peckings, accentuating their regional specificity. Detailed quantitative analysis will have to await the availability of further quantitative data from each of the pecked figures.

DISCUSSION

The rock art located in Wardaman country, Northern Territory, is widespread and stylistically diverse. A very small component of the Wardaman rock art assemblage consists of pecked faces, some of which also have associated torsos. Within Wardaman country, the Jalijbang and Yingalarri pecked faces are superficially reminiscent of the Cleland Hills faces. These have often been infered to have considerable antiquity because of their stated advanced state of patination. Published photographs, however, show that some of these peckings are moderately patinated only (e.g. Edwards, 1968). In any case patination, especially of peckings in open sites, is not necessarily an indication of great age, as is testified by the existence of patinated post-contact graffiti. Similarly, the Jalijbang pecked faces have been claimed to be of considerable antiquity, but there is no strong reason to believe this is necessarily the case. On the contrary, the pecked faces found on boulders in Jalijbang 2 and in a nearby rockshelter (Mennye-ya) are likely to date to the last 3000-4000 years. Because these figures are stylistically distinct from pecked faces from other parts of arid and semi-arid Australia, however, their antiquity cannot in this way be used to infer the ages of pecked faces elsewhere.

Furthermore, the engravings found on the Jalijbang 2 boulders also include pecked bird tracks and linear designs and abraded grooves. Such peckings have often been characterised as typical components of the so-called Panaramitee engraving tradition. Such engravings are often believed to have considerable antiquity (e.g. Maynard, 1977), but at Jalijbang 2 they appear to have a maximum age of 3000-4000 years BP. Abraded grooves and pecked bird tracks, however, have also been found at the Yingalarri 1 excavations (Mulvaney, 1975), where they were dated to at least 5000BP. Abraded grooves are also known to have been created in the Jalijbang and Yingalarri areas during recent times (Flood

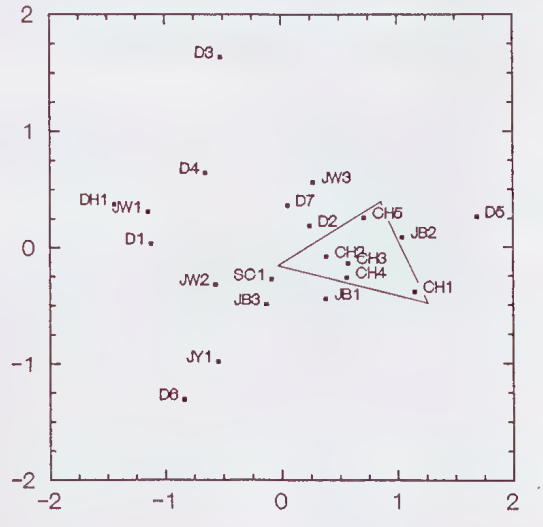

FIG. 11. MDS map based on three quantitative variables.

et al., in press). It is therefore likely that peckings and abraded grooves were part of a long artistic tradition in Wardaman country, spanning the period from pre-5000BP times to the ethnohistoric present. This pattern appears to be similar to that found by Nobbs & Dorn (1990) in the Olary region to the south, where cation-ratio dates revealed a broad range of non-figurative and track peckings spanning approximately 30 000 years of prehistory (but see Watchman, in prep.). In the Wardaman and Olary regions at least, the 'Panaramitee' (as defined stylistically by Maynard, 1977) has had a long history, broken only in recent times by the White intruders who constrained the local people access to the lands in which they engraved and painted.

In short, although some of the engravings found in Wardaman country have been dated to pre-5000BP times by Mulvaney (1975), there is no evidence that the pecked faces from Jalijbang 2 have any great age. Although their precise antiquity remains a matter for speculation, excavations at the site point towards a likely mid- to late-Holocene antiquity. We say this through circumstantial evidence only:

1. the occurrence of extensive roof-fall predating approximately 3000BP *may* indicate that the main, pecked wall at Jalijbang 2 did not exist before that time;

2. boulder peckings occur only on the upper and side surfaces of boulders believed to have been deposited in their current positions during the mid- to late-Holocene. Given the absence of peckings from the underneath surfaces, the peckings are likely to have been undertaken only after the boulders were deposited in their current positions;

3. the pecked face on the boulder in the creek bed at Jalijbang 2 has not been totally obliterated by water action, implying that it may not be of great antiquity;

4. other nearby peckings, also associated with the roof-fall boulders relating to points 1 and 2 above, contain peckings of dingoes, which because of their known antiquity in Australia must post-date approximately 3500 to 4000 years BP;

5. analysis of cortex on a boulder near Jalijbang 2 indicates that cortex development began approximately 4000 years ago. Because of its proximity to Jalijbang 2, it is likely that this boulder resulted from the same roof-fall activity as the boulders currently forming the scree-slope into the site itself (points 1 and 2 above), in support of a similar antiquity for the roof-fall itself (creation of the boulder surface where cortex development ensued).

Although the Jalijbang 2 boulder peckings (and wall peckings to a lesser extent) are more likely to be of mid- to late-Holocene age, it has not been possible to gain information on the antiquity of other, similar engravings from the Northern Territory and Western Australia. The latter are stylistically distinct from the pecked faces found in Wardaman country, with each area possessing regionally-distinctive pecked faces. These findings question the previously widely-stated belief that pecked faces from many parts of the Australian arid and semi-arid zones were similar and presenting material evidence for a broad, interactive social network which linked central Australia into a more or less unified 'desert culture'. On the contrary, this is nowhere reflected in the distribution of pecked faces which emphasise the regional specificity of artistic traditions in Australia's arid core.

ACKNOWLEDGEMENTS

We would like to thank the Wardaman people for allowing us to excavate at Jalijbang, Earthwatch for financial support and fieldwork assistance, and A.I.A.T.S.I.S. for funding the carbon dates. Bryce Barker, Ian McNiven, Philip Jones and an anonymous referee made useful comments on an earlier draft.

REVISION OF *SARMATIUM* DANA (CRUSTACEA:BRACHYURA: SESARMINAE) WITH DESCRIPTIONS OF THREE NEW SPECIES

P.J.F. DAVIE

Davie, P.J.F. 1992 06 29: Revision of *Sarmatium* Dana (Crustacea:Brachyura: Sesarminae) with descriptions of three new species. *Memoirs of the Queensland Museum* **32**(1): 79-97. Brisbane. ISSN 0079-8835.

Sarmatium Dana, 1851, is revised and re-diagnosed. Crabs of this genus are primarily characterised by: carapace deeply vaulted; ocular peduncle swollen basally, cornea constricted and reduced; upper surface of palm of male cheliped bearing a series of transverse grooves separating transverse swollen ridges. *Sarmatium* is now considered to contain five species: *S. crassum* Dana, 1851; *S. germaini* (A. Milne Edwards, 1869); *S. striaticarpus* sp.nov.; *S. hegerli* sp.nov.; and *S. unidentatus* sp.nov. They are easily separated by the different patterns of ridges and grooves on the upper surfaces of the palm and carpus of the male cheliped. □*Crustacea, Brachyura, Grapsidae, Sesarminae, mangroves, Indo-West Pacific, new species.*

Peter J.F. Davie, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 3 February, 1992.

Sarmatium Dana, 1851, has a very confused history. Established for a single species *S. crassum* Dana, 1851, it was enlarged considerably by Tesch (1917) who included six other Indo-West Pacific species and two Atlantic species. Serène & Soh (1970: 398) pointed out that the two Atlantic species, *S. curvatus* H. Milne Edwards, 1837, and *S. pectinatus* H. Milne Edwards, 1853, are rightfully placed into the genus *Metagrapsus* H. Milne Edwards, 1853. Tesch (1917) had previously considered *Metagrapsus* as a junior synonym of *Sarmatium*. Features to separate the two genera were given by Serène & Soh (1970). The six Indo-West Pacific species placed in *Sarmatium* by Tesch: *S. integrum* A. Milne Edwards, 1873; *S. inermis* de Man, 1887; *S. indicum* A. Milne Edwards, 1868; *S. punctatum* A. Milne Edwards, 1873; *S. biroi* Nobili, 1905; and *S. fryatti* Tesch, 1917 (=*rotundifrons* A. Milne Edwards, 1869), are now all included in *Neosarmatium* Serène & Soh, 1970. Tesch (1917), following de Man (1891), considered *Sarmatium germaini* (A. Milne Edwards, 1869) to be a junior synonym of *S. crassum* but *S. germaini* was later shown to be a valid species by Serène & Soh (1971).

Serène & Soh (1971) considered *Sarmatium* to consist of two species, *S. crassum* and *S. germaini*. It is apparent however, after examining the larger amount of material available for the present study, that what Serène & Soh (1971) thought to be *S. crassum* from Singapore is in fact a new species. In addition, field work carried out in northern Australia has revealed two hitherto unknown species. With the five species here recognised, the genus concept for *Sarmatium* can now be much better understood.

Abbreviations used in the text are: AM, Australian Museum, Sydney; MNHN, Muséum national d'Histoire naturelle, Paris; ZRC, Zoological Reference Collection, National Museum of Singapore; NNM, National Natural History Museum, Leiden; QM, Queensland Museum, Brisbane; SMF, Senckenberg Museum, Frankfurt; USNM, United States National Museum, Washington; ZMG, Zoological Museum of Goetingen (collection housed at SMF); ZMH, Zoological Museum of Hamburg; ZMK, Zoological Museum Copenhagen. The descriptions for this paper were prepared using the DELTA computer system for generating taxonomic descriptions (Dallwitz & Paine, 1986).

Measurements given in the text are of the carapace breadth (measured at the widest point including lateral spines) followed by length. Leg segments were measured in a straight line to give maximum dorsal length and so are not always the maximum possible length, and this should be borne in mind when using the ratios. The exact limits of the width of the hind margin are also sometimes difficult to determine and in this work they were defined by the point at which the lateral carapace suture meets the rear margin. Gonopod terminology follows that of Sakai & Yatsuzuka (1979).

TYPE SPECIES

Sarmatium crassum Dana, 1851.

DIAGNOSIS

Carapace sub-quadrate, slightly wider than long; greatest width behind exorbital angles; deeply vaulted, depth c.0.8- 0.9 × carapace width in males; regions moderately defined; anterolateral margins regularly convex; with 1-3 teeth behind the exorbital angle; front deflexed, c.0.35- 0.4 × carapace width, 0.5 × fronto-orbital width, pre-orbital teeth obsolete. Ocular peduncle swollen basally, cornea constricted and reduced. Basal segment of antennal peduncle with a well developed outer rounded tongue; antennal flagellum small and entering orbit. Basal antennular segment swollen. Inter-antennular septum narrow, 0.2- 0.3 × width of front. Median post-frontal lobes distinct, very broad, lateral lobes not clearly differentiated. Third maxilliped merus 0.7- 0.8 × length of ischium; merus longer than wide; outer margin convex; antero-external angle not produced; exopod narrow, barely visible in frontal view. Chelipeds subequal; upper surface of palm with a series of transverse grooves separating swollen ridges; outer surface of palm without median longitudinal row; dorsal surface of dactyl in males with at least one large, broad, chitinous tubercle, and some small pointed chitinous tubercles. Legs: merus anterior margin with an acute sub-distal spine, unarmed terminally; carpus with accessory carinae on upper surface. G1 long, reaching just past suture between sternites 2/3; moderately stout; completely calcified; palp obvious but not separated from stem, rounded, calcified; apical process corneous, strongly produced, straight; gonopore terminal or slightly displaced towards the dorsal surface. G2 short, relatively narrow, tapering, twisted, tip blunt. Male abdomen relatively narrow, third segment slightly the wider or sub-equal to first; first segment does not cover entire width of sternum between 4th pereiopods. Base of penis slightly calcified, just visible beneath setae adjacent to margin of third segment.

REMARKS

Sarmatium is separated from the two closest genera *Neosarmatium* and *Metagrapsus* by two major characters: 1, ocular peduncle swollen basally, cornea constricted and reduced; 2, upper surface of palm of male cheliped with a series of transverse grooves separating swollen ridges.

KEY TO THE SPECIES OF *SARMATIUM*

1. Outer ventral border of cheliped palm with a marked longitudinal ridge extending onto fixed-finger (even on juveniles and females); male cheliped with superior outer surface of palm bearing 7-8 relatively evenly spaced transverse grooves; dactylus with three large, strong chitinous tubercles on proximal half, followed by 17-18 small acute chitinous tubercles; carpus with a finely granular area distally, without trace of oblique fine striations. Maximum size c.28mm..... ..... *germaini* A. Milne Edwards, 1869

   Outer ventral border of cheliped palm and fixed-finger without a longitudinal ridge; male cheliped with superior outer surface of palm bearing less than 7 strong transverse grooves; dactylus variously armed, but not as above; upper face of carpus sometimes with oblique fine striations. Maximum size 28mm 2

2. Palm of male cheliped with 4 major transverse grooves on upper outer surface. Dactylus with four strong chitinous tubercles on proximal half. Maximum size c.25mm.....3

   Palm of male cheliped with transverse grooves not as conspicuous, but with a large, smooth or granular swelling occupying most of upper outer surface. Dactylus with only one major chitinous tubercle on proximal half. Maximum size 13-20mm.....4

3. Upper surface of carpus of cheliped with large patch of tiny, flattened, squamous granules behind articulation distally; these may be aligned into short fine rows near outer edge but never appear as transverse striations. Ridges and grooves on upper surface of palm all subparallel. First proximal tooth on dactyl of cheliped placed slightly distally from articulation.....*crassum* Dana, 1851

   Upper surface of carpus of cheliped with broad patch of c.25 long, fine, transverse striations

between articulation and spine of inner angle. Upper surface of palm with proximal most corrugated ridge separated from next broad groove by a triangular space. First proximal tooth on dactyl of cheliped placed almost on edge of proximal end .....*striaticarpus* sp.nov.

4. Male cheliped has dorsal margin of dactyl, with 1 large forwardly directed, chitinous tubercle on outer edge, proximally. Superior outer face of palm with 2-3 narrow, smooth grooves distally, followed by a deep concavity, and a large swelling back to the posterior margin, the distal slope of which is long and covered in well separated, medium sized, low round granules. Upper surface of carpus with 9 prominent transverse ridges distolaterally. Maximum size c.20mm.....*hegerli* sp.nov.

Male cheliped has dorsal margin of dactyl bearing a single, large, elongate, slightly oblique, medial tooth, proximally. Superior outer face of palm with very broad, deep, smooth, oblique depression, a very large rounded medial transverse swelling, and a narrow proximal band of seven very fine, long transverse ridges. Upper surface of carpus without transverse ridges. Maximum size c.13mm .....*unidentatus* sp.nov.

DESCRIPTION

Carapace: c.1.1×broader than long in males, 1.2 in females. Fronto-orbital width c.0.75-0.85×carapace length. Carapace deeply vaulted; convex in both directions but only slightly from side to side. Depth c.0.8×carapace width (c.0.7 in females). Regions moderately defined; mesogastric well defined; cardiac distinct; intestinal distinct. Lateral margins subparallel; slightly concave. Anterolateral margins regularly convex; with two blunt teeth behind the exorbital angle; exorbital angle blunt, only slightly projecting. First anterolateral tooth similar in size to exorbital angle but with longer margin; second anterolateral tooth blunt; minute, almost obsolete. Front c.0.36-0.39×carapace width; c.0.5× fronto-orbital width; moderately deflexed; with shallow median emargination and bilobed; lateral

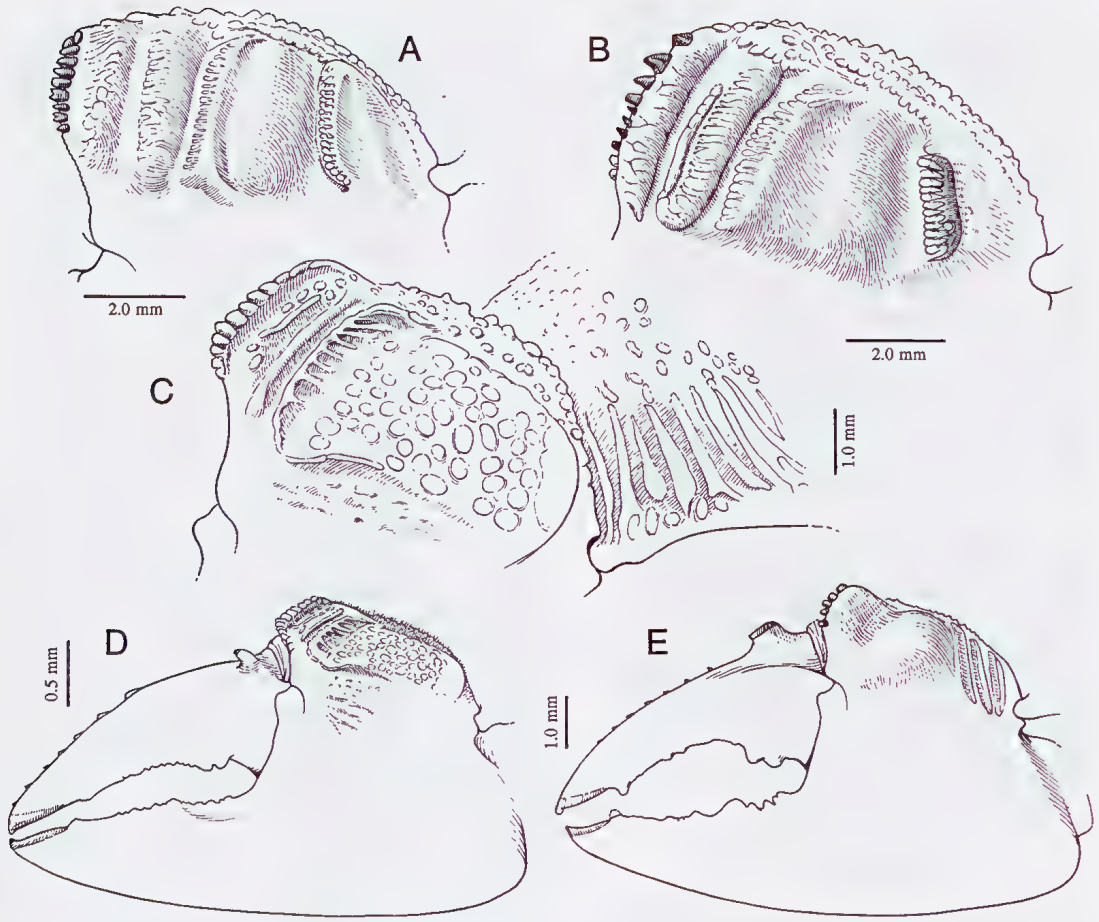

FIG. 1. A, *Sarmatium crassum* Dana, upper face of palm of♂ chela (QM W15228). B, *S. striaticarpus* sp.nov., upper face of palm of♂ chela (holotype, ZRC 1970.1.23.14). C,D, *S. hegerli* sp.nov., upper and outer faces of♂ chela (holotype, QM W9698). E, *S. unidentatus* sp.nov., outer face of male chela (holotype, AM P31822).

angles obtuse, blunt; pre-orbital teeth obsolete; lateral margins slightly diverging posteriorly. Post-frontal lobes distinct; median lobes distinctly broader than laterals; lateral lobes not clearly differentiated. Branchial ridges prominent forming a series of short broken granular striations; last continuous, parallel with posterolateral margin, and finishing over coxa of fourth walking leg. Posterior margin c.0.45-0.5 × carapace width. Carapace surface smooth, shining, punctate; setae arranged sparsely on branchial lines. Upper orbital border minutely granular; straight; inner angle rounded. Lower orbital border straight; evenly granular. Inner orbital tooth present; well developed; equilateral triangular, ocular peduncle swollen basally, cornea constricted and reduced. Basal segment of antennal peduncle with a well developed outer lobe in form of rounded tongue. Inter-antennular septum narrow; 0.22-0.24 × width of front.

Third maxilliped: Merus 0.7-0.8 × length of ischium. Suture between merus and ischium slightly sloping inward. Ischium inner margin microscopically granular. Palp articulates medially on distal margin of merus. Exopod narrow, barely visible in frontal view; flagellum normal.

Chelipeds: Subequal; large and robust. Merus posterior border with minutely granular striations; distinct subdistal spine; lower border granulate; anterior border convex, coarsely granulate; carpus with a small spine at inner angle; inner margin unarmed, striated, rounded, ventral-

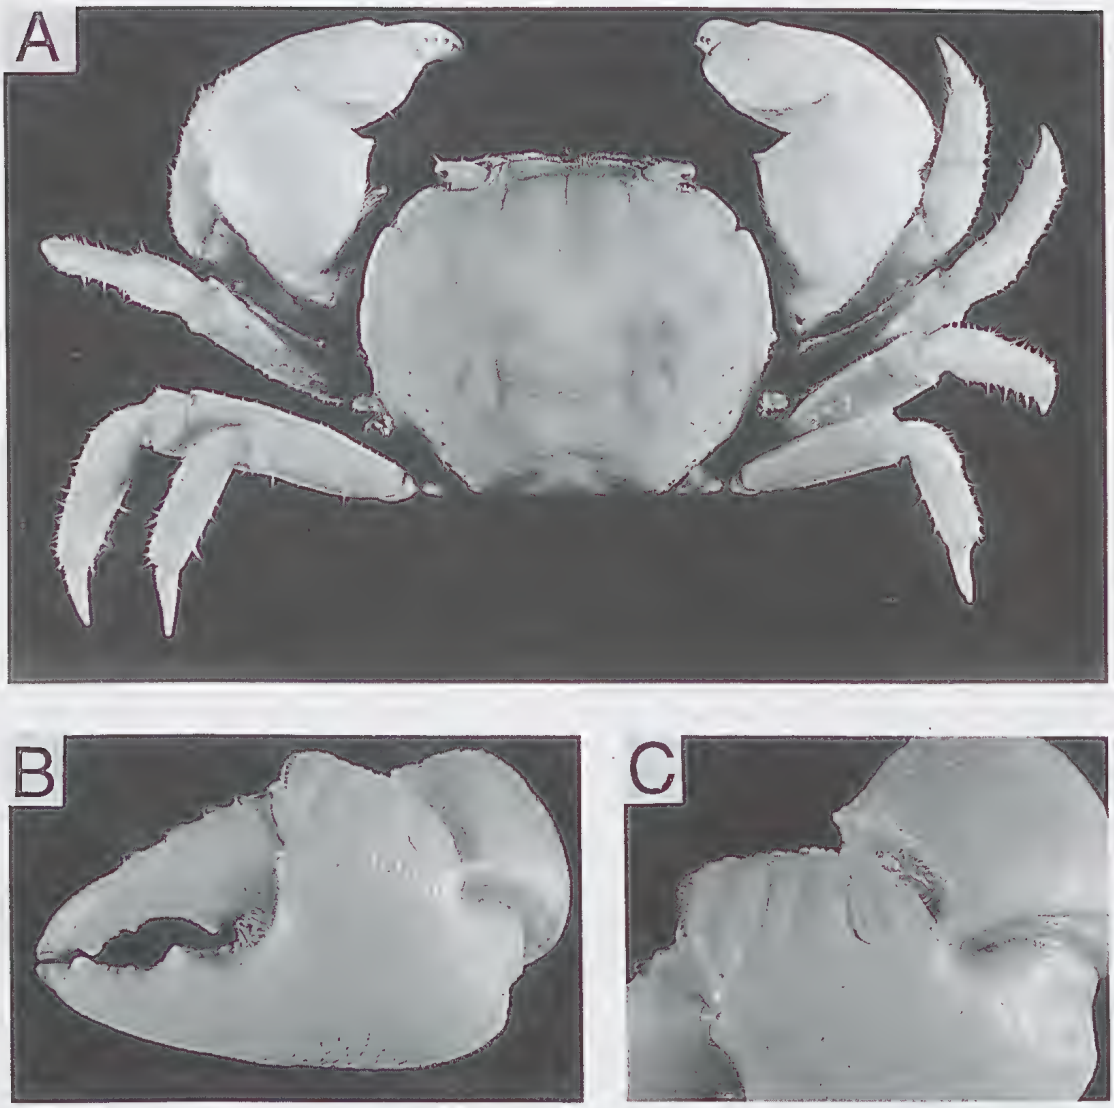

FIG. 2. *Sarmatium crassum*, ♂ (QM W15228). A, dorsal view. B, chela. C, upper surface of palm of chela. Scale line in mm.

ly with row of small granules and short proximal oblique crest bearing row of long setae; granules present on inner face of carpus just below inner angle; outer margin striated, with narrow patch of sparse, very short setae; upper surface microscopically striated proximally, smooth and wrinkled medially, behind articulation distally a large patch of tiny, flattened, squamous granules which become aligned into fine rows near outer edge. Palm upper surface with a series of transverse grooves separating swollen ridges, distal margin of upper surface of palm bearing row of 10-13 pectinated teeth along edge of articulation, proximal to this is a series of 6 broad, swollen, rounded ridges, relatively evenly separated, ridges 3/4 and 5/6 joined by low rim top and bottom; fourth ridge broader than others; fifth ridge low and with row of 15-20 granules along its lower distal edge; superior margin with a series of moderately large granules, but without conspicuous setation. Outer surface of palm smooth and punctate; without median longitudinal row; without a ventral ridge. Outer surface of palm naked, small patch of setae at base of fingers, fringe of setae at insertion of dactyl. Inner surface of palm with sparse large flat smooth granules,

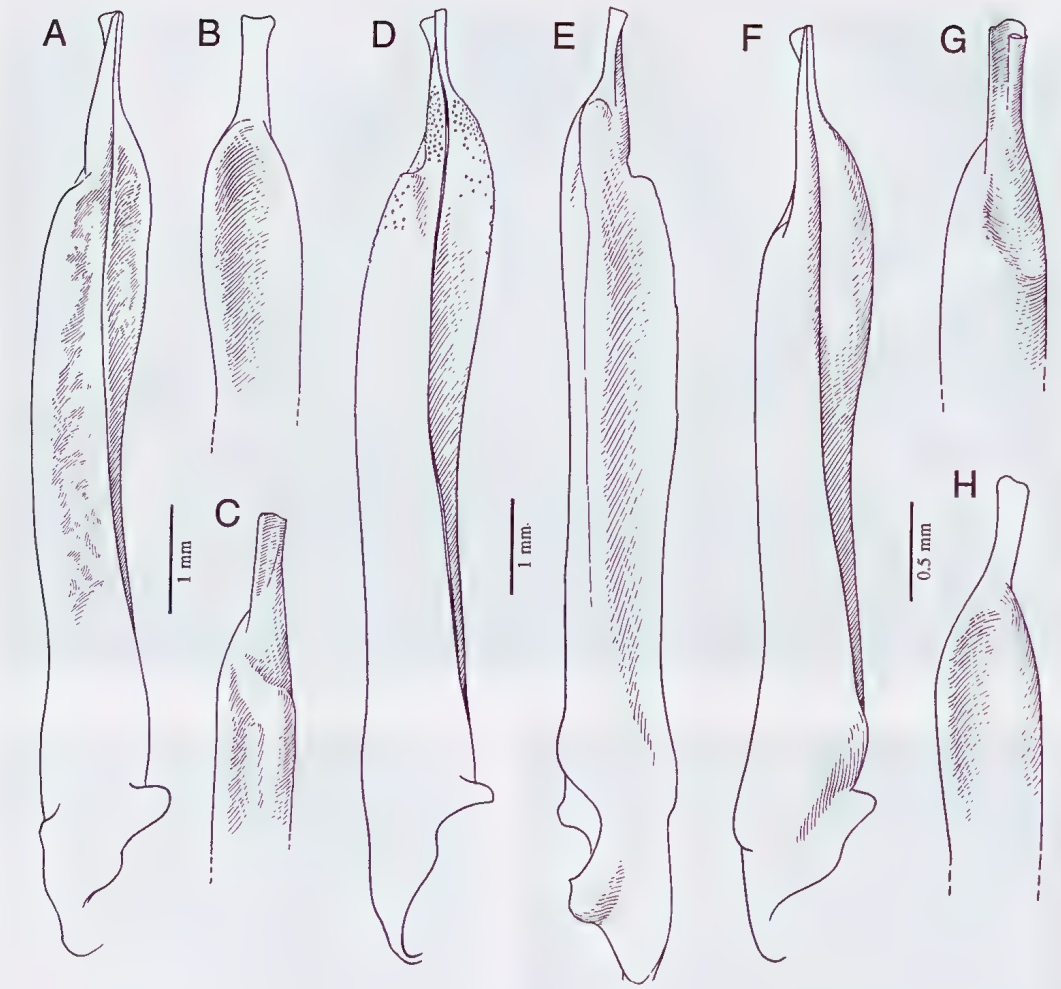

FIG. 3. Male first gonopods (setae removed). *Sarmatium crassum* Dana. A, abdominal view. B, C, lateral views of apex. *S. striaticarpus* sp.nov. D, abdominal view. E, sternal view. *S. hegerli* sp.nov. F, abdominal view. G, H, lateral views of apex.

largest and most conspicuous near gape, but not forming a strong vertical crest. Immovable finger slightly flattened on outer surface; moderately long. Length cutting edge c.0.45×length propodus in males (0.5 in females). Ventral border of chela straight, or slightly convex. Dorsal surface of dactyl of males bearing 4 large, broad, chitinous tubercles in proximal three-fifths, first set away from joint about same distance as to following tooth, a small patch of setae in the space; second tooth larger than first; third and fourth teeth largest, similar sized; teeth 1-4 set increasingly obliquely, highest towards outer face; followed in distal quarter by a row of 12-14 small closely set chitinous tubercles of even size. Fingers pointed; curved slightly inwards; a moderate gape between cutting margins in males.

Walking legs: Medium length; compressed and flattened; second pair slightly the longest, c.1.5-1.7×maximum carapace width. Third leg: merus c.2.4-2.6×as long as wide; carpus c.2.6-2.8×as long as wide; propodus c.2.3- 2.6×as long as wide. Dactyli about equal to length of propodi; slender and almost straight; terminating in acute chitinous tips. Propodus with an accessory carina on inferior proximal portion of upper surface. Meri of legs 1-3 with scattering of small distally directed prickles; dorsal and ventral borders of meri granulate. Setae short, predominantly on upper distal face of carpi, and on upper half of propodi, and continuing onto dactyli in thin rows.

Male abdomen: Relatively narrow; third segment slightly the widest. Slightly calcified base of penis adjacent to margin of third segment. Segments three-five slightly tapering. Width segment three 4.1-4.7 × length (relatively narrower in smaller males). Segment six not elongated; 1.45-1.6 × wider than long. Telson nearly subequal in length to segment 6; 1.25-1.5 × longer than wide (relatively longer in large males); evenly rounded.

Gonopods: G1 moderately stout; slightly curved. Inner-dorsal margin distally curved inward. Dorsal surface of stem flattened; completely calcified. Palp poorly developed, not separated from stem, large, broad, rounded, calcified. Outer dorsal margin of stem convex. Distal part of the stem broad but narrowing. Apical process present; corneous; strongly produced; straight. Gonopore slightly displaced towards the dorsal surface. Setae long, simple, dense, obscuring structural detail. G2 short, relatively narrow, tapering, twisted, tip blunt.

COLOURATION

Fawn-brown, chelipeds and legs biscuit-coloured with orange tinge (Barnard, 1955); carapace purple in life with yellow patches, thoracic legs yellow with purple patches (Crosnier, 1965).

DISTRIBUTION

With certainty from only the following localities: Samoa (Dana, 1851b, 1852); Durban Bay, South Africa (Barnard, 1955); Madagascar (Crosnier, 1965); Dar es Salaam, Tanzania (Hartnoll, 1975); Eritrea, Red Sea (Fishelson, 1971; Holthuis, 1977); Sulu Archipelago, Indonesia (present record); eastern Queensland, from Brisbane north to 11 50'S on Cape York (McNeill, 1968; and present records); New Caledonia (Serène, 1973); Tahiti (present record).

Questionably from: Sumatra (Nobili, 1906 - no diagnostic characters were given, so may also be atributable to *S. striaticarpus* sp.nov.); Nicobars (Alcock, 1900, single ♀ specimen); 'Pacific' (Tesch, 1917, single ♀ specimen).

HABITAT

In the mangroves (Crosnier, 1965; McNeill, 1968). 'An uncommon species in creek mangrove, where specimens were collected from the *Ceriops* and mixed zones' (Hartnoll, 1975). Mangroves; mouth of river in mudbank at low water; mud in *Rhizophora*; mud in *Avicennia* (present records).

REMARKS

Serène & Soh (1970) presented data and figures separating what they believed to be *Sarmatium crassum* from *S. germaini*. Unfortunately their *S. crassum* specimens represent a new species very closely allied to *S. crassum*, but differing in a number of distinctive characters (see later). The accurate identity of *S. crassum* is slightly problematic as, being a Dana species, the type was destroyed in the Chicago fire of 1871. This means that it is difficult to be absolutely certain what is the true *S. crassum*. After considering Dana's description, I consider the Asian specimens previously attributed to *S. crassum* to be the new species, and it is here named *S. striaticarpus*. *Sarmatium crassum* differs from *S. striaticarpus* on the following grounds:

1. The shape and disposition of the ridges and grooves on the upper surface of the palm are different. In *S. crassum* the ridges are all subparallel and this is evident in Dana's Fig. 1d; whereas in *S. striaticarpus* the proximal most corrugated ridge is separated from the next broad groove by a triangular space. Also there is a slight groove separating the distal row of pectinatious teeth in Dana's figure which is also true of my *S. crassum* material but not present in *S. striaticarpus*.

2. The first proximal tooth on the dactyl of the cheliped is placed slightly distally from the articulation in *S. crassum* and this also seems true of Dana's figure although it is not clear; in *S. striaticarpus* it is placed almost on the very edge of the proximal end.

3. So far, *S. striaticarpus* is only known for certain from vicinities north of the equator. To remove all doubt over the identity of *S. crassum* the erection of a neotype would be necessary. I am reluctant to do this because I have not seen specimens from the type-locality (Samoa). Although the Asian specimens certainly represent a new species (*S. striaticarpus*), slight reservations must remain about the identity of the specimens here referred to *S. crassum*. The shape of the male abdomen in Dana's figure differs a little from that of the present material, and it is difficult to ascertain if this difference is due to growth changes (Dana's specimen was quite small), inaccuracies in the figure, or if it does in fact represent a real difference at the species level. In this last case a new name would be required for the material here identified as *S. crassum*.

Sarmatium striaticarpus sp.nov. can further be separated from *S. crassum* on the following grounds: the small chitinous tubercles on the dis-

tal half of the dactyl of the cheliped are greater in number and more closely spaced in *S. crassum*; *S. striaticarpus* has a broad patch of c.25 long, fine, transverse striations, mostly continuous but some subdivided, on the upper surface of the cheliped carpus between the articulation and the spine of the inner angle, in *S. crassum* the upper surface is microscopically striated proximally, smooth and wrinkled medially, and with a large patch of tiny, flattened, squamous granules behind the distal joint, which become aligned into fine rows near outer edge.

MATERIAL EXAMINED
HOLOTYPE: ZRC 1970.1.23.14, 1♂ (24.3×23.0mm), Johore Straits, C.L. Soh, 21.1.1970.
PARATYPES: USNM 73213, 1♀ (16.2×14.0mm), Iloilo, Panay I., Philippines, H.C. Kellers, U.S. Navy, April 1929, Ilo Ilo Eclipse Exped.

DESCRIPTION
Carapace: c.1.1×broader than long. Fronto-orbital width c.0.75×carapace length. Carapace deeply vaulted; evenly convex longitudinally, flat from side to side. Depth c.0.8-0.9×carapace width. Regions well defined; mesogastric well defined; cardiac distinct; intestinal indistinct, defined laterally by branchio-intestinal grooves. Posterolateral margins divergent posteriorly; moderately concave. Anterolateral margins regularly convex; cristate; with three blunt, forwardly directed teeth behind the exorbital angle (third reduced to trace only). Front c.0.36×carapace width; 0.5×fronto-orbital width; moderately deflexed; with a broad median emargination; lateral angles obtuse; pre-orbital teeth obsolete; lateral margins slightly diverging posteriorly. Medial post-frontal lobes very broad, well defined, laterals almost obsolete; without clumps of setae. No short ridge on first epibranchial tooth. Branchial ridges not prominent; relatively short. Posterior margin c.0.5×carapace width. Carapace surface smooth, shining, punctate; setae arranged sparsely on branchial lines. Upper orbital border evenly granular; straight and slightly oblique; inner angle rounded. Lower orbital border straight; smooth. Inner orbital tooth present; well developed; equilateral triangular. Antennal flagellum very small, entering orbit. Orbital hiatus open. Basal segment of antennal peduncle with an elongate, rounded outer lobe. Basal antennular segment moderately swollen. Inter- antennular septum c.0.23×width of front.

Third maxilliped: Merus c.0.7×length of ischium. Suture between merus and ischium slightly sloping inward. Ischium sub-triangular; inner margin smooth. Palp articulates near outer distal margin of merus. Exopod narrow, barely visible in frontal view; c.0.3×width of ischium; flagellum normal.

Chelipeds: Subequal; large and robust. Merus of male without stridulatory ridge; posterior border minutely granulate; distinct subdistal spine; lower border granulate; anterior border coarsely granulate medially. Carpus with a spine at inner angle; inner margin with narrow granular bead; granules present on inner face of carpus just below inner angle; outer margin with a series of smooth granular striations; between articulation and spine of inner angle is a broad patch of c.25 long, fine, transverse striations, mostly continuous but some subdivided. Palm upper surface with a series of transverse grooves separating swollen ridges; a distally swollen margin bearing row of 10-12 pectinated teeth along edge of articulation, largest near superior margin, minute distally; behind this a wide groove; then a ridge, itself subdivided by a narrow groove into a very narrow distal ridge and a wide proximal ridge; behind this a series of two very wide swollen ridges separated by a broad concavity, but both ridges connected by a narrow margin top and bottom; behind this a triangular depression with its apex dorsally, and then a pair of short, closely-set comb-like ridges. Outer surface of palm smooth and punctate; with slight depression at base of fixed finger; without ventral ridge. Outer surface of palm naked; with small patch of setae at base of fingers just fringing articulation. Inner surface of palm with a low granular vertical crest of 5-6 granules largest ventrally; and an oblique crest of about 6 large granules running from below vertical crest to upper part of fixed finger. Immovable finger slightly flattened on outer surface; moderately long; length cutting edge c.0.45×length propodus. Ventral border of chela slightly convex. Dorsal surface of male dactyl with 15-17 chitinous tubercles; 4 large, widely spaced tubercles, set obliquely, on the proximal half, becoming longer but no higher distally; in

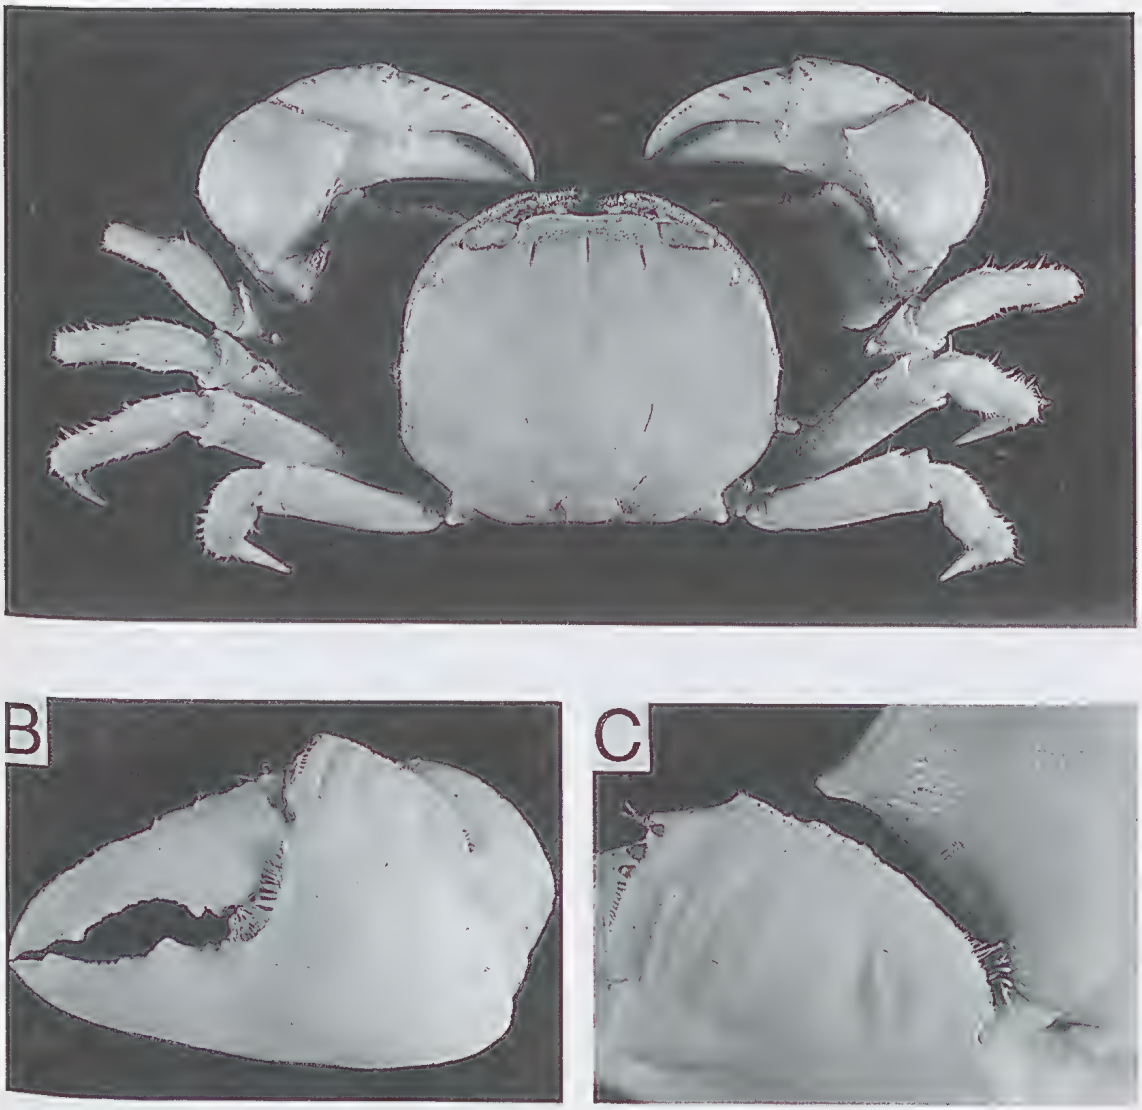

FIG. 4. *Sarmatium striaticarpus* sp.nov., ♂ (holotype, ZRC 1970.1.23.14). A, dorsal view. B, chela. C, upper surface of palm of chela. Scale line in mm.

distal half a row of 12 small closely set sharp tubercles, forwardly pointed, becoming minute distally; proximal portion of inner edge without distinct granules. Fingers pointed; curved inwards; a moderate gape between cutting margins.

Walking legs: Medium length; compressed; slender; first three pairs all of similar length but third pair slightly longest (c.1.7 × maximum carapace width). Third leg: merus c.2.8 × as long as wide; carpus c.2.6 × as long as wide; propodus c.2.6 × as long as wide; dactylus c.0.8 × length of propodus. Dactyli slender and slightly recurved; terminating in acute chitinous tips. Propodus with an accessory carina on inferior proximal portion of upper surface. Leg segments smooth, anterior margins minutely granular; fringed with short, soft, setae, also arranged in thin tufts in rows on anterior and posterior faces.

Male abdomen: Relatively narrow; third segment widest. First segment broad, only slightly narrower than third segment. Segments 3-5 slightly tapering. Width segment three c.4.3 × length. Telson longer than preceding segments, only slightly longer than sixth segment; c.1.4 × longer than wide; evenly rounded.

Gonopods: G1 moderately stout; slightly curved. Inner-dorsal margin evenly curved onto palp. Dorsal surface of stem flattened; completely

calcified. Palp well developed, separated from stem, large, narrow, rounded, calcified. Outer dorsal margin of stem convex. Distal part of stem broad but narrowing. Apical process present; corneous; strongly produced; straight. Gonopore displaced towards the dorsal surface. Setae long, simple, lying around corneous tip and apical part of stem obscuring structural detail. G2 short, evenly tapering, moderately twisted, apically pointed.

COLOURATION

Palm of the cheliped brownish red (Serène & Soh, 1971).

DISTRIBUTION

Singapore (Tweedie, 1936; Serène & Soh, 1971; present records); Southern Okinawa, Japan (Sakai, 1936, 1976); Philippines (present record). Relatively common in the mangroves of Singapore and Malaysia (Serène, 1973, referring to this species as *S. crassum*).

HABITAT

Mangrove swamp (Serène, 1973; Sakai, 1976; present records).

ETYMOLOGY

Named in reference to the characteristic striations on the upper surface of the carpus of the cheliped.

REMARKS

See 'Remarks' for *S. crassum*.

Sarmatium germaini (A. Milne Edwards, 1869)
(Figs 5, 6A-C)

Sesarma germani A. Milne Edwards, 1869: 28; De Man, 1887: 651; 1891: 51.

Sarmatium germaini: Serène & Soh, 1970: 397, 405; 1971: 238, fig. 1, pl. 1 (1-4); Soh, 1978: 11, pl. 4a.

MATERIAL EXAMINED

LECTOTYPE. MP-B3668 (Dry), 1♀ (15.0×16.6mm), Poulo Condore, South China Sea, coll. M. Germain.

PARALECTOTYPES. MP-B10472 (Dry), 1♂ (13.3×12.4mm), Poulo Condore, South China Sea, coll. M. Germain. (On the posterior portion of the carapace is written '428' and below this 'GS' in faded black ink - specimen is dry, carapace intact but left cheliped, various legs and abdomen are detached.) MP-B10473, 1♂, same collection data as B10472, badly broken.

OTHER MATERIAL. ZRC 1970.2.20.3, 1♂ (27.8×25.6mm), Johore Straits, Singapore, C.L. Soh, Feb. 1970. MP-B10471, 1♂ (26.0×24.4mm), Port Swettenham, Malaysia, coll. Sasekumar, 22.10.1968. DESCRIPTION

Carapace: c.1.1×broader than long. Fronto-orbital width c.0.8×carapace length. Carapace deeply vaulted; evenly convex longitudinally, flat from side to side. Depth c.0.9×carapace width. Regions moderately defined; mesogastric well defined; cardiac distinct; intestinal indistinct, defined laterally by branchio-intestinal grooves. Lateral margins slightly divergent posteriorly; slightly concave. Anterolateral margins regularly convex; usually with two blunt, forwardly

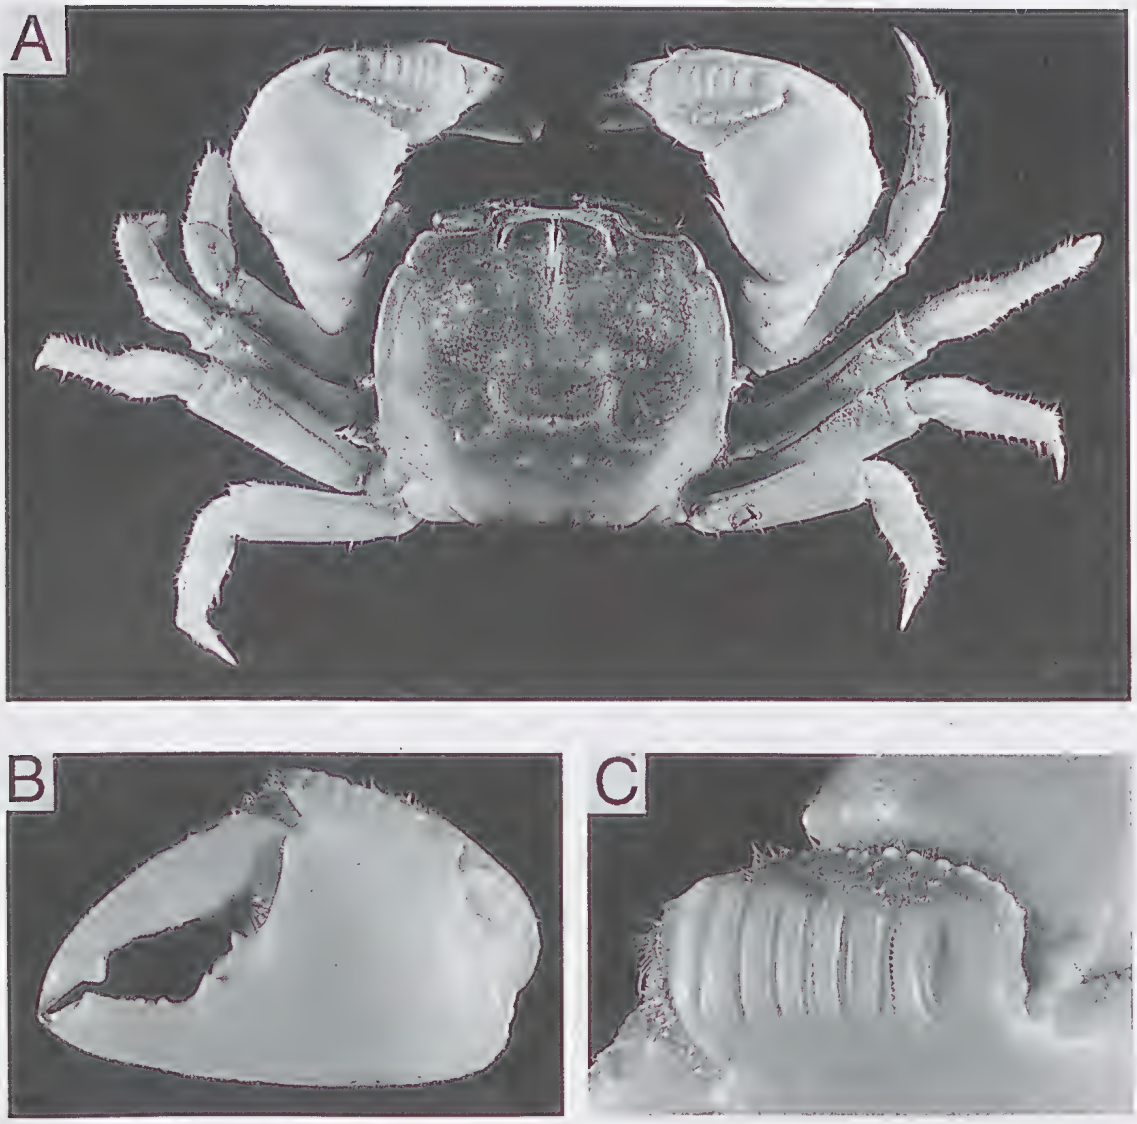

FIG. 5. *Sarmatium germaini* (A. Milne Edwards), ♂ (QM W14858). A, dorsal view. B, chela. C, upper surface of palm of chela. Scale line in mm.

directed teeth behind exorbital angle, a third tooth sometimes noticeable. Front c.0.4 × carapace width; 0.5 × fronto-orbital width; moderately deflexed; with broad median concavity; lateral angles obtuse; pre-orbital teeth obsolete; lateral margins slightly diverging posteriorly. Post- frontal lobes medially well defined, laterally indistinct; without clumps of setae. Branchial ridges moderately prominent; relatively short. Posterior margin c.0.5 × carapace width. Carapace surface smooth, shining; wrinkled and punctate posteriorly; setae arranged sparsely on branchial lines. Upper orbital border evenly granular; with slight median convexity; inner angle rounded. Lower orbital border straight; evenly granular. Inner orbital tooth present; well developed; equilateral triangular. Basal segment of antennal peduncle with broad and rounded outer lobe. Inter-antennular septum narrow; 0.25-0.3 × width of front.

Third maxilliped: Merus c.0.8 × length of ischium. Suture between merus and ischium horizontal. Ischium sub- triangular; inner margin smooth. Palp articulates near outer distal margin of merus. Exopod narrow; 0.4 × width of ischium; flagellum normal.

Chelipeds: Subequal; large and robust; merus

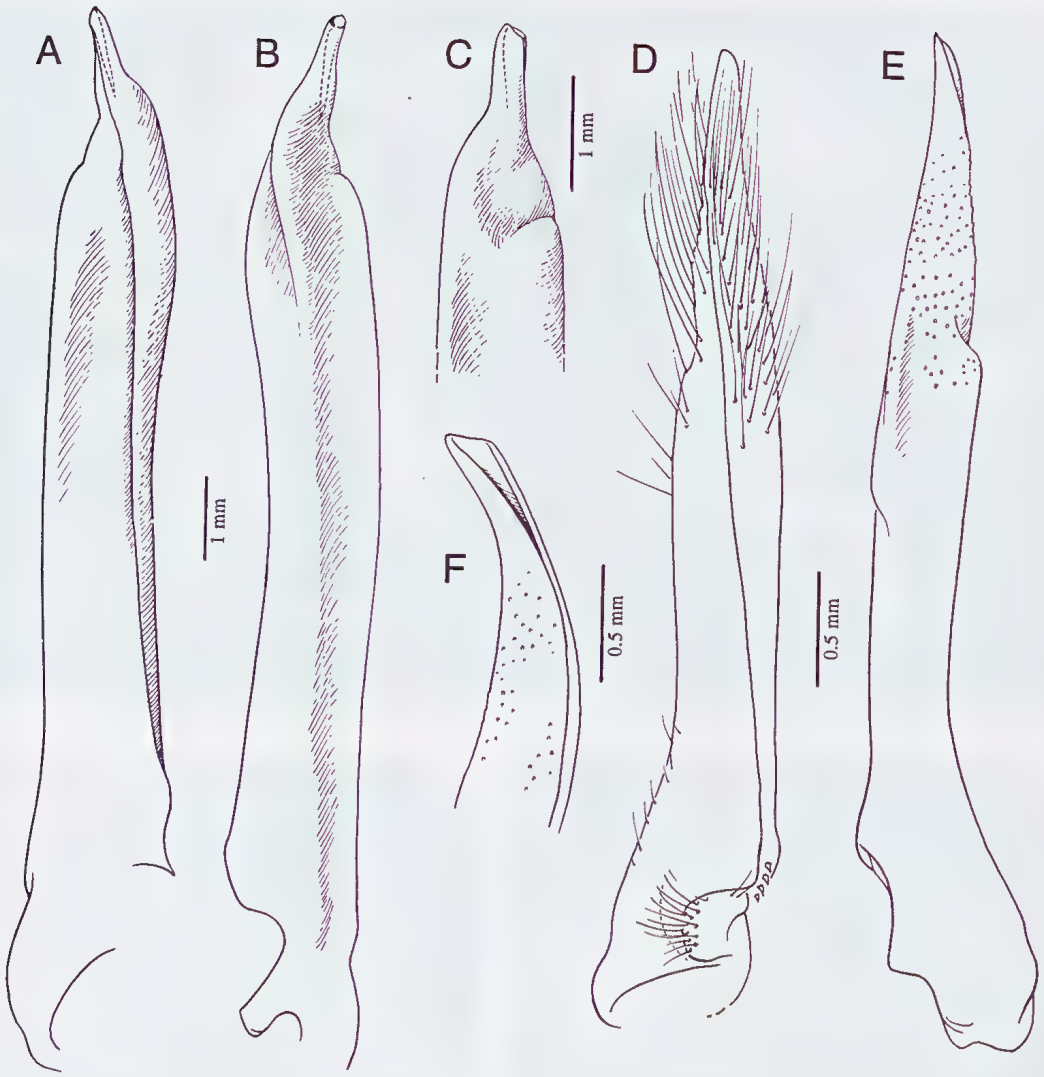

FIG. 6. Male first gonopods (setae removed, except for D). *Sarmatium germaini* (A. Milne Edwards) (QM W14858). A, abdominal view. B, sternal view. C, lateral view of apex. *S. unidentatus* sp.nov. (holotype, AM P31819). D, abdominal view. E, sternal view. F, lateral view of apex.

with posterior border minutely granulate; without distinct subdistal spine; lower border granulate; anterior border sparsely granulate, slightly coarser medially; carpus with a broad tooth at inner angle; tubercles present on inner face of carpus just below inner angle, 1 or 2 ventrally on vertical crest; outer margin smooth, wrinkled, upper medial surface behind articulation with a broad patch of small flattened vesicular tubercles. Palm upper surface with a series of transverse grooves separating swollen ridges: upper distal margin behind articulation with a row of 14-17 blunt chitinous tubercles, slightly larger towards inner end; behind this a series of 8 transverse swollen ridges, first 7 of similar shape evenly spaced, third to seventh subequal in width, slightly narrower than first and second; behind seventh, a much broader sulcus separating a much broader, proximal transverse swelling; ridges 3/4, 5/6, 7/8 narrowly connected top and bottom, more-or-less obviously; ridges 3,5, and 7 with a line of punctations on distal edge, deeper on 5, very deep on 7 so as to form a series of gutters with a prominent granule at the base of each gutter; behind transverse ridges superior border with large rounded granules. Outer surface of palm smooth

and punctate; without median longitudinal row. Ventral ridge extends to tip of fixed finger, less distinct distally, very prominent behind fixed finger, extends less than halfway towards proximal end. Outer surface of palm naked except for fringe of short setae around dactyl articulation; with a patch of 'fur' on superior margin behind transverse ridges. Inner surface of palm smooth; without a vertical crest. Immovable finger slightly flattened on outer surface; moderately long. Length cutting edge c.0.4-0.5×length propodus. Ventral border of chela convex, straight in small specimens. Dorsal surface of dactyl bearing 3 large chitinous tubercles in proximal half, set obliquely; followed immediately by 17-18 small acute chitinous tubercles. Fingers pointed; slightly curved inwards; a wide gape between cutting margins.

Walking legs: Medium length; cylindrical; slender; second pair slightly the longest, c.1.7×maximum carapace width. Third leg: merus c.2.3-2.5×as long as wide; carpus c.2.6-2.7×as long as wide; propodus c.2.2- 2.3×as long as wide; dactylus c.0.95×length of propodus. Dactyli slender and slightly recurved; terminating in acute chitinous tips. Propodus without short accessory carina on inferior proximal portion of upper surface. Meri of legs 1-3 with a scattering of small sharp prickles on outer surface; leg segments fringed with short setae, setae arranged in thin tufts in rows on anterior and posterior faces.

Male abdomen: Relatively narrow; third segment the widest. First segment broad, only slightly narrower than third segment. Segments three-five slightly tapering, each with slightly concave margins. Width segment three c.4.3×length. Telson length subequal to sixth segment; c.1.4×longer than wide; evenly rounded.

Gonopods: G1 moderately stout; curved. Inner-dorsal margin evenly curved onto palp. Dorsal surface of stem flattened; completely calcified. Palp poorly developed, not separated from stem, large, narrow, rounded, calcified. Outer dorsal margin of stem convex. Distal part of the stem narrow. Apical process present; corneous; strongly produced; straight. Gonopore terminal. Setae long, simple, lying around corneous tip and apical part of stem obscuring structural detail. G2 short, evenly tapering, moderately twisted, apically pointed.

Colouration

Greenish brown with reddish tinge on legs (A. Milne Edwards, 1869); palm of the cheliped yellowish light brown (Serène & Soh, 1971).

Distribution

Poulo Condore Island, Vietnam, South China Sea (type locality, A. Milne Edwards, 1869); Singapore and Malaysia (Serène & Soh, 1971, and present record); Hong Kong (Soh, 1978); Philippines (present record); northern Australia - from Brisbane to Darwin (present records).

Habitat

In the mangroves and nearly always out of the water (A. Milne Edwards, 1869). Mangrove lined creek at mean low water; *Rhizophora* mudbank; at burrow entrance at night 10m inland from creek bank (present records).

Remarks

A. Milne Edwards (1869) did not specifically designate a holotype but he gives the measurements for only a single specimen of 17×16mm, and does not mention its sex. From his description of the 'six ou sept très-petits bourrelets obliques et parallèles' on the chela, one might think that he examined a male, but these ridges are also present, albeit indistinctly, on the female. His note on habitat - that this species was collected almost always out of the water - does suggest that he was given more than one specimen to examine. De Man (1891) says, 'I was enabled to study a typical male specimen of *Ses. Germani* of the Paris Museum', but he does not give measurements. Serène & Soh (1971) state, 'The senior author ... was able to re-examine the holotype of *S. germaini* in the Paris Museum (April 1970); it is a dry female and not a male as indicated by De Man (1891).' The decision is taken here to designate the female as the lectotype - its measurements do not precisely conform to those given by A. Milne Edwards, but they are very near. There are also two dry male specimens at the Paris Museum, MP-B10472-3, and one of these was presumably the specimen examined by De Man. A relatively modern label identifies them as being collected by M. Germain from Poulo Condor, but no original labelling has been preserved. The specimens (one is little more than a series of fragments) are indeed *S. germaini* as defined here, and by Serène & Soh (1971), however they are both much smaller than the measurements given by A. Milne Edwards. They are considered, along with the female discussed above, to have been syntypes, and are thus designated here as paralectotypes.

The spelling of the species name was justifiably emended by Serène & Soh (1971) as the species was clearly intended to be named after its collector, R. Germain, and can thus be considered an 'incorrect original spelling' under Article 32(c) of the International Code of Zoological Nomenclature (1989, Third Edition).

DESCRIPTION

Carapace: c.1.1×broader than long in males, c.1.2 in females. Fronto-orbital width c.0.8×carapace length (0.9 in females). Carapace deeply vaulted; convex anteriorly, almost flat from side to side. Depth c.0.8×carapace width. Regions moderately defined; mesogastric well defined; cardiac distinct; intestinal indistinct, defined laterally by branchio-intestinal grooves. Lateral margins subparallel; slightly concave. Anterolateral margins regularly convex; with three blunt teeth behind the exorbital angle; second small but obvious, third minute almost obsolete. Exorbital angle blunt, rounded, not projecting. First anterolateral similar in size to exorbital angle but with longer margin. Front c.0.36- 0.39×carapace width; c.0.5×fronto-orbital width; moderately deflexed; with shallow median emargination; lateral angles rounded; pre-orbital teeth obsolete; lateral margins slightly diverging posteriorly. Median post-frontal lobes distinct, distinctly broader than laterals which are not clearly differentiated. Branchial ridges prominent as a series of short broken granular striations; last continuous, parallel with posterolateral margin, and finishing over coxa of fourth walking leg. Posterior margin c.0.5×carapace width. Carapace surface smooth, shining, punctate. Setae in short tufts over entire surface, less prominent on cardiac and intestinal regions. Upper orbital border minutely granular; straight; inner angle rounded. Lower orbital border straight; evenly granular. Inner orbital tooth present; well developed; acute equilateral triangular. Basal segment of antennal peduncle with well developed, elongate, rounded outer lobe. Inter-antennular septum narrow; 0.22-0.24×width of front.

Third maxilliped: Merus c.1.4×length of ischium. Ischium inner margin microscopically granular. Palp articulates medially on distal margin of merus. Exopod narrow, barely visible in frontal view; flagellum normal.

Chelipeds: Subequal; large and robust; merus with posterior border minutely granulate; with distinct subdistal spine; lower border minutely granulate; anterior border sparsely granulate, with a few large rounded granules medially on convexity; carpus with a spine at inner angle; inner margin minutely granular, rounded, ventrally with minutely granulate crest and a long proximal oblique ridge bearing row of long setae; granules present on inner face of carpus just below inner angle; outer margin striated, bearing thick band of short setae; upper surface smooth and sparsely granulate, with distinctive area of 9 prominent ridges and 8 grooves, running transversely along outer distal half behind joint. Palm upper surface with a series of transverse grooves separating swollen ridges: distal margin of upper surface of palm raised, with a series of 4-8 short, broad, truncated, chitinous teeth; proximal to this a series of 3 ridges separating 3 narrow smooth grooves, or sometimes the first ridge low and uneven and followed by area of small smooth granules, and then the other two arced ridges; on proximal slope of last ridge is a series of short ridges and grooves, longest towards upper mar-

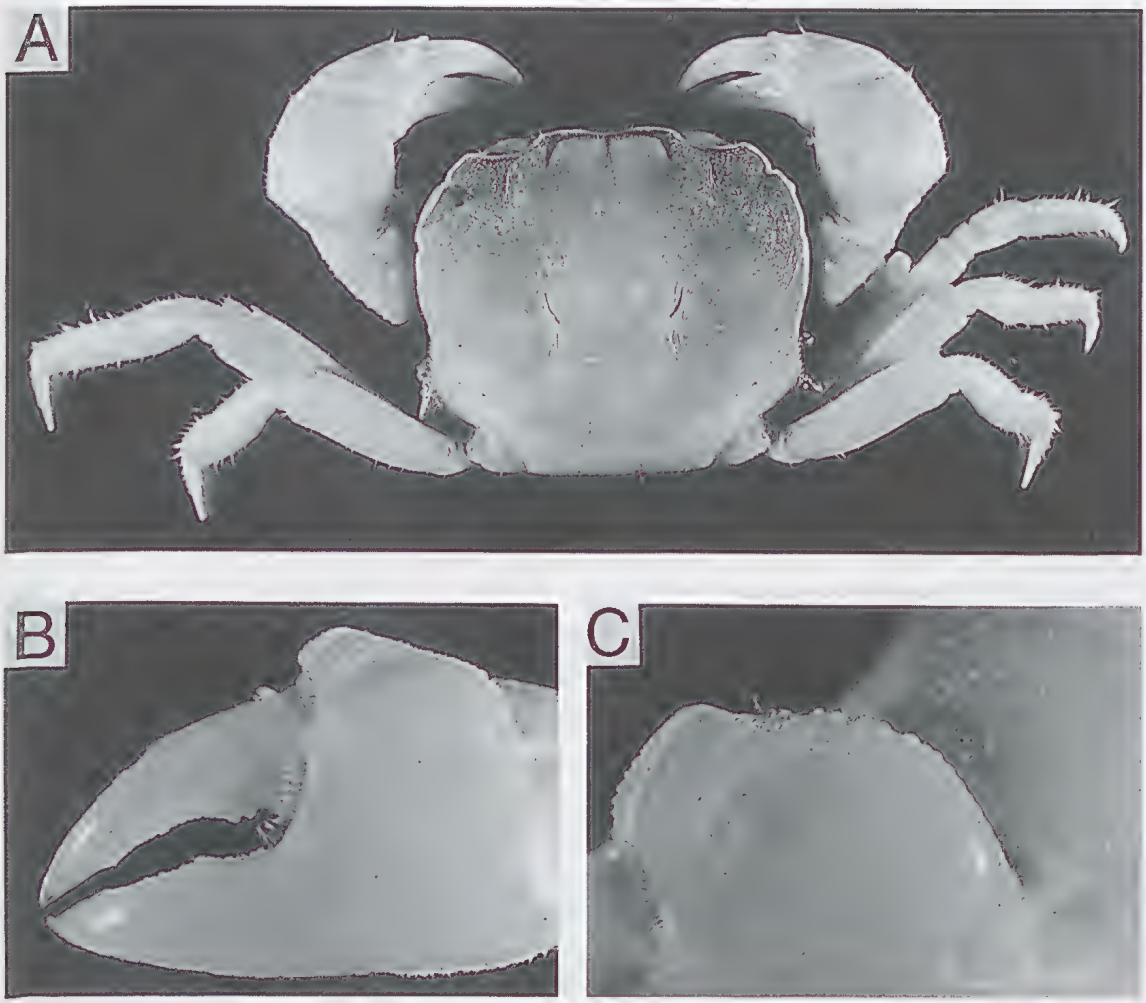

FIG. 7. *Sarmatium hegerli* sp.nov., ♂ (holotype, QM W9698). A, dorsal view. B, chela. C, upper surface of palm of chela. Scale line in mm.

gin; behind this a very broad deep concavity, and then a large swelling back to posterior margin, the distal slope of which is long and covered in well separated, medium sized, low round granules; superior margin with large rounded granules and short setae. Outer surface of palm smooth; without median longitudinal row; without a ventral ridge. Outer surface of palm naked except for fringe of setae at insertion of dactyl, and a small patch ventro-proximally behind joint and as a triangular patch proximally on ventral face. Inner surface of palm smooth; without vertical crest but with a few very low rounded tubercles, almost indistinguishable. Immovable finger rounded on outer surface; without ventral ridge; moderately long. Length cutting edge c.0.45-0.49× length propodus. Ventral border of chela straight, or slightly convex. Dorsal surface of dactyl with 1 large forwardly directed, bluntly pointed, chitinous tubercle proximally near joint on outer edge of superior margin; 5-6 additional chitinous tubercles commencing c.two-fifths distance towards tip; first large, oblique, truncate; second smaller of same form; third also similar but very small, distal 2-3 minute and reducing distally, last tubercle situated well before tip; thick triangular patch of setae proximally on upper surface near joint. Fingers pointed; slightly curved inwards; a narrow gape between cutting margins in largest male, no gape in smaller males.

Walking legs: Medium length; compressed; second pair slightly the longest, c.1.3-1.5× maximum carapace width. Third leg: merus c.2.4-2.7× as long as wide; carpus c.2.5- 2.7× as long

as wide; propodus c.2.3 × as long as wide. Dactyli about equal to length of propodi; slender and slightly recurved; terminating in acute chitinous tips. Propodus with an indistinct accessory carina on inferior proximal portion of upper surface. Meri of legs 1-3 with scattering of small distally directed prickles; dorsal and ventral borders of meri granulate. Setae short, covering anterior and posterior faces of carpi and propodi, and distal upper margins of meri; continue on to proximal half of dactyli in thin rows.

Male abdomen: Relatively narrow; third segment the widest, subequal with first. Segments three-five tapering. Width segment three c.4.25-4.9 × length, relatively narrower in smaller males. Segment six not elongated; 1.25-1.35 × wider than long. Telson longer than preceding segments, only slightly longer than segment 6; 1.4- 1.5 × longer than wide; evenly rounded.

Gonopods: G1 moderately stout; slightly curved. Inner-dorsal margin distally curved inward. Dorsal surface of stem flattened; completely calcified. Palp poorly developed, not separated from stem, large, broad, triangular, calcified. Outer dorsal margin of stem convex. Distal part of the stem broad but narrowing. G1 apical process corneous; strongly produced; straight. Gonopore slightly displaced towards the dorsal surface. Setae short, simple, obscuring structural detail. G2 short, relatively narrow, tapering, twisted, tip blunt.

Sternum: Thick covering of setae between insertion of telson and mouth frame.

Habitat

Mangroves; burrows in riverbanks and banks of drainage channels; moist to very sloppy mud; not restricted to a particular mangrove zone. One burrow, apparently belonging to this species had a raised entrance, but this does not seem typical.

Distribution

Only known from Northern Territory, Australia.

Etymology

Named for Mr Ed Hegerl, director of the Australian Littoral Society, and one of Australia's leading marine conservationists. Someone I have followed into very many, very muddy places.

Remarks

The key provided here separates *Sarmatium hegerli* sp.nov. from all other known species of *Sarmatium*. The pattern of grooves and ridges on the upper surface of the palm of the cheliped; the shape, number and position of the cheliped dactylar tubercles; and the male first gonopod are distinctive.

Sarmatium unidentatus sp.nov.
(Figs 1E, 6D-F, 8)

Material Examined

Holotype: AM P31822, 1♂ (12.5 × 10.9mm), Nungbalgarri Ck, N.T., 2.5km upstream, west bank, D. Grace, 27.7.1976.

Paratype: AM P31819, 1♂ (11.7 × 10.4mm), Liverpool R., N.T., 14.3km upstream, amongst debris on mud floor in *Rhizophora* mangrove forest, D. Grace, 30.1.1975.

Description

Carapace: c.1.15 × broader than long. Fronto-orbital width c.0.85 × carapace length. Carapace deeply vaulted; convex in both directions, only slightly from side to side. Depth c.0.8 × carapace width. Regions moderately defined; mesogastric well defined; cardiac distinct; intestinal distinct. Lateral margins slightly divergent posteriorly; slightly concave. Anterolateral margins regularly convex; with two blunt teeth behind the exorbital angle. Exorbital angle blunt, rounded not projecting. First anterolateral tooth similar in size to exorbital angle but with longer margin. Second anterolateral tooth minute. Front c.0.4 × carapace width; c.0.5 × fronto-orbital width; moderately deflexed; with shallow median emargination; lateral angles quadrate, rounded; pre-orbital teeth obsolete; lateral margins sub-parallel. Median post-frontal lobes distinct, distinctly broader than laterals; lateral lobes not clearly differentiated. A series of short broken granular branchial striations; last continuous, parallel with posterolateral margin, and finishing over coxa of fourth walking leg. Posterior margin c.0.5 × carapace width. Carapace surface smooth, shining, punctate. Setae arranged sparsely on branchial lines. Upper orbital border minutely granular; straight; inner angle rounded. Lower orbital border straight; evenly granular. Inner orbital tooth present; well developed; bluntly triangular. Basal segment of antennal peduncle with a well developed elongate, rounded outer lobe. Basal antennular segment swollen. Inter- antennular septum narrow; 0.22-0.24 × width of front.

Third maxilliped: Merus c.1.35 × length of ischium. Ischium inner margin granular. Palp articulates medially on distal margin of merus.

FIG. 8. *Sarmatium unidentatus* sp.nov., ♂ (holotype, AM P31819). A, dorsal view. B, chela. Scale line in mm.

Exopod narrow, visible proximally and distally in frontal view but mostly hidden; flagellum normal.

Chelipeds: Subequal; large and robust; merus with posterior border minutely striated; without distinct subdistal spine; lower border granulate; anterior border convex, coarsely granulate; carpus with inner angle granular; inner margin rounded, ventrally with row of minute granules and short proximal crest bearing row of long setae; granules present on inner face of carpus just below inner angle; outer margin striated, bearing rows of short dark setae; upper surface smooth and shiny distally, microscopically striated proximally. Palm upper surface with a series of transverse grooves separating swollen ridges: distal border of upper surface of palm with prominent crest bearing 5-6 short, broad, truncated, chitinous teeth; proximal to this a very broad, deep, smooth, oblique depression; then a very large medial transverse swelling; then a series of seven very fine, long transverse ridges ending near proximal margin of upper border; first six ridges joined top and bottom to form 3 pairs; superior margin distinctly granular, and lacking setation. Outer surface of palm smooth; without median longitudinal row; without a ventral ridge. Outer surface of palm naked except for fringe of setae at insertion of dactyl. Inner surface of palm sparsely granular, mostly smooth; with a low vertical crest of c.3 granules. Immovable finger rounded on outer surface, or slightly flattened on outer surface proximally; without ventral ridge; moderately long. Length cutting edge c.0.45 × length propodus. Ventral border of chela concave at base of fixed finger, bearing a shallow longitudinal depression. Dorsal surface

of dactyl tuberculate, bearing a pronounced slightly oblique, elongate proximal tooth, truncated and capped with chitin; a small patch of setae proximal to this tooth; distally followed by a broad gap and then a series of evenly spaced very small, acute, forwardly directed, chitinous tubercles, becoming minute distally and finishing at about three-quarters length of finger. Fingers pointed; curved inwards; a wide gape between cutting margins.

Walking legs: Medium length; compressed; second pair the longest, c.1.6-1.7 × maximum carapace width. Third leg: merus c.2.7 × as long as wide; carpus c.2.4- 2.5 × as long as wide; propodus c.2.5 × as long as wide. Dactyli about equal to length of propodi; slender and recurved; terminating in acute chitinous tips. Propodus without distinct accessory carina on inferior proximal portion of upper surface. Meri of legs 1-3 with scattering of small distally directed prickles; meri granular on superior margins; minutely striated over upper half. Setae very short and sparse on anterior halves of meri; thicker on upper halves of carpi, particularly along accessory ridges; also present on propodi on superior border and on both anterior and posterior faces, but disappearing distally; most obvious on anterior legs.

Male abdomen: First 3 sements subequal in width in holotype but third segment the widest in paratype. Segments three-five tapering, markedly from 3-4, then moderately. Width segment three c.4.6-4.8 × length. Segment six not elongated; c.1.8 × wider than long. Telson longer than preceding segments; c.1.3 × longer than wide; evenly rounded.

Gonopods: G1 moderately stout; slightly sigmoid. Inner-dorsal margin distally curved inward. Dorsal surface of stem flattened; completely calcified. Palp poorly developed, not separated from stem, small, narrow, rounded, calcified, situated c.two-thirds distance towards tip. Outer dorsal margin of stem convex. Distal part of the stem narrow. G1 apical process present; corneous; strongly produced; stout not markedly narrower than distal part of stem; straight. Gonopore terminal. Setae long, simple, lie around tip, mostly distal to palp. G2 short, relatively narrow, tapering, tip blunt.

Sternum: Thick covering of setae between insertion of telson and mouth frame.

HABITAT

Amongst debris on mud floor in *Rhizophora* mangrove forest.

DISTRIBUTION

Only known from Nungbalgarri Ck and Liverpool R., Northern Territory, Australia.

ETYMOLOGY

Named for the single pronounced slightly oblique, elongate, proximal tooth on the dactyl of the cheliped which is diagnostic.

REMARKS

The key provided here separates *Sarmatium unidentatus* sp.nov. from all other known species of *Sarmatium*. The pattern of grooves and ridges on the upper surface of the palm of the cheliped; the shape, number and position of the cheliped dactylar tubercles; and the male first gonopod are distinctive.

ACKNOWLEDGEMENTS

I am indebted to Dr Alain Crosnier of ORSTOM for his assistance in helping me to undertake this study, and for his encouragement; and the Board of Trustees of the Queensland Museum for support and travel assistance. A large part of the work was undertaken while at the Laboratoire de Zoologie (Arthropodes), Muséum national d'Histoire Naturelle, Paris, under a grant from the Institut française de Recherche Scientifique pour le Développement en Coopération (ORSTOM). Dr Danièle Guinot kindly arranged the loan of comparative specimens. Dr Charles Fransen of the Nationaal Natuurhistorisch Museum, Leiden, and Dr Michael Türkay of the Forschungsinstitut Senckenberg, Frankfurt, are both sincerely thanked for their generosity and kindness whilst I was visiting their laboratories. John Short is thanked for his assistance with photography and help with preparation of plates. M. Maurice Gaillard executed the excellent illustrations. I thank too my wife Kathleen for her support and all manner of practical assistance.

THE RARE SHRIMP, *PHYLLOGNATHIA CERATOPHTHALMA* (BALSS), DISCOVERED IN MORETON BAY. *Memoirs of the Queensland Museum 32(1): 98:-* A collection of Crustacea was made by SCUBA diving at Myora, North Stradbroke Island, Moreton Bay. One particularly striking species excited interest, and proved to be the rare shrimp *Phyllognathia ceratophthalma* Balss. The Myora coral community occurs as a shallow (1-3m), narrow reef, with six coral species (Lovell, 1989). It is unusual within Moreton Bay in having large plates of *Acropora digitifera* (Dana). These grow attached to loose rubble on a muddy-sand substrate, which means they are easily overturned to sample the associated fauna. This small reef has a high diversity of invertebrates, including species which are more typically expected on outside reefs. This is possibly because during times of flooding when the rest of the Bay is subject to severe freshwater dilution, circulation patterns within the Bay cause a pooling of undiluted seawater along the northern side of Stradbroke Island. The reef also lies just to the side of the main channel leading in and out of the Bay, so recruitment from open coastal waters, and the warm southerly flowing East Australian Current, can be expected. See Bruce (1991) for full synonomy.

Phyllognathia ceratophthalma (Balss, 1913)

Hymenocera (?) *ceratophthalma* Balss, 1913: 236.
Phyllognathia ceratophthalma: Borradaile, 1915: 206; Bruce, 1991: 267-269, fig. 28.

Material Examined: QM W17487, 1 ♂ (8.0 mm cl (including rostrum)) & 1 ♀ (11.0 mm cl), Myora, Moreton Bay, 2m, in hole in base of *Acropora digitifera* plate, 14.4.1992, P. Davie.
Remarks: Bruce (1991) provided a modern figure and description of this apparently rare shrimp. The present specimens have an identical colour pattern to that described by Bruce (1991) but differ in having a translucent white/cream, rather than yellow-brown, background colour. Despite being known since 1913, and despite widespread use of SCUBA for underwater collecting over the past 25 years, this strikingly coloured shrimp is known from only four previous records: Satsuma, Japan, the type locality (Balss, 1913); Maldive Islands (Borradaile, 1915); Lizard Is., northern Great Barrier Reef; New Caledonia (Bruce, 1991). The present record is a significant southerly range extension.

On the tenth day after capture, the female was seen to release larvae from under her abdomen although her ovigerous state had not been previously apparent from casual observation. 25 first stage zoeae were released, and a further 16 were found in a 'brood pouch' formed by the broad, overlapping pleopods. This species is reproductively a K-strategist, with a small number of large eggs. It probably can maintain a breeding population at this southerly, subtropical locality. The first zoeae will be described elsewhere. Facilities were not available to rear them to later stages.

CYMBASTELA, A NEW GENUS OF LAMELLATE CORAL REEF SPONGES

JOHN N.A. HOOPER AND PATRICIA R. BERGQUIST

Hooper, J.N.A. & Bergquist, P.R. 1992 06 29: *Cymbastela*, a new genus of lamellate coral reef sponges. *Memoirs of the Queensland Museum* **32**(1): 99-137. Brisbane. ISSN 0079-8835.

Seven species of lamellate, stalked sponges from Australasian waters are referred to a new genus, *Cymbastela* gen.nov. Six species from tropical, predominantly coral reef habitats: *C. stipitata* (Bergquist & Tizard) (type species) and *C. vespertina* sp.nov., both from NW Australia, *C. concentrica* (Lendenfeld) and *C. coralliophila* sp.nov. both from the Great Barrier Reef, Queensland, *C. marshae* sp.nov. from the Houtman-Abrolhos Is, Western Australia, and *C. cantharella* (Lévi) from New Caledonia). Another species is recorded from temperate South Australian waters (*C. notiaina* sp.nov. from the Gulf of St Vincent). All the species conformed to the existing interpretation of *Pseudaxinyssa* Burton, but they are referred here to *Cymbastela* since all are substantially different from the type species of *Pseudaxinyssa, A. tethyoides* Kirkpatrick. *Pseudaxinyssa* is synonymized with *Axinyssa* Lendenfeld. The seven species of *Cymbastela* are primarily differentiated by their spicule length and geometry, axial and extra-axial skeletal development, growth form, lamella thickness and live colouration. Four species are sympatric over part of their range in tropical Australia, whereas three species have more restricted, allopatric distributions in temperate Australia and the western Pacific Ocean. ☐ *Pseudaxinyssa, Axinyssa, Cymbastela, new genus, new species, Porifera, Axinellidae, taxonomy, biogeography, Australasia.*

John N.A. Hooper, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; Patricia R. Bergquist, Department of Zoology, University of Auckland, Private Bag, Auckland, New Zealand; 29 January, 1992.

No formal revision of the complete order Axinellida has yet been published, even though for many years it has been recognized these marine sponges were polyphyletic (Bergquist & Hartman, 1969). Recent work on several families within the Axinellida, using a phylogenetic framework, has gone some way towards redistributing some of these taxa amongst other existing orders. Families considered so far (with their affinities as suggested by particular authors), are Axinellidae (Halichondrida; Van Soest et al., 1990), Desmacellidae (Poecilosclerida; Van Soest, 1984), Hemiasterellidae (Hadromerida; Hooper, 1986; Voultsiadou-Koukoura & Van Soest, 1991), Rhabderemiidae (Poecilosclerida; Hooper, 1990), and Raspailiidae (Poecilosclerida; Hooper, 1991). However, it is not yet clear whether the concept of an order Axinellida should be abandoned completely, or retained and restricted to one or few families. Additional, non-morphological data is required to confirm or refute these ideas (discussion in Hooper et al., 1992), and until such is available none of the above assignments can be completely endorsed.

Axinellidae is undoubtedly the most difficult of all the families of Axinellida to interpret. The original conception of the family, basically corresponding to the old subfamily Axinellinae of Lendenfeld (1889), with major additions by Hallmann (1916) and de Laubenfels (1936), included genera with an 'axinellid skeletal plan' consisting of a condensed axial core with diverging plumose or plumo-reticulate extra-axial branches. This definition stands today (e.g. Hartman, 1982), even though nearly half of the 50 nominal genera included in the family have skeletal structures other than axinellid (e.g. evenly reticulate - *Reniochalina*; sinuous - *Rhaphoxya*; dendritic - *Acanthella*; thickly encrusting/leptoclathrid - *Fasubera*). In such cases, genera with atypical skeletal structures were included in Axinellidae because their spicule geometries were similar to those with axinellid skeletons. However, recent biochemical evidence indicates that the family contains several distinctly heterogenous groups of genera (Bergquist & Hartman, 1969; Hooper et al., 1992).

A recent revision of halichondriids by Van Soest et al. (1990), based primarly on morphological characters, suggested that genera of Axinellidae could be redistributed into three existing families (Axinellidae, Desmoxyidae and Halichondriidae) and a new family (Dictyonellidae). Van Soest et al. (1990) referred these four families to the order Halichondrida, and although we do not presently support or refute this ordinal placement, we agree that for the Axinellidae at least, there is a pressing

need for a re-evaluation of the major morphological characters used to distinguish taxa within the Axinellidae, including the relative importance of these characters as reliable indicators of phylogenetic affinity.

It is difficult in many cases to assign species of Axinellidae to genera with complete assurance, as there are few morphological characters with clear importance at the supraspecific level. Unlike most groups within Poecilosclerida, for example, Axinellidae lack any unique or diverse spicule geometries, and lack microscleres which could provide clues on affinities between genera. Thus, the major problem preventing resolution of the supraspecific taxonomy of Axinellidae is the difficulty or inability to define autapomorphies and, furthermore, there is disagreement in the interpretation of the relative importance of the few existing morphological characters that do occur in the group - in particular spicule shape and skeletal organization. Biochemical evidence may provide more objective information on the affinities of the numerous genera presently included in the family, but the few data available are not entirely clear (Hooper et al. 1992): there are, in many cases, no obvious morphometric characters that correlate consistently with generic groupings based on chemotaxonomic data (see Hooper et al., 1992). The 'axinellids' are one group of Porifera that require rigorous genetic study.

The existing subdivision within Axinellidae, resting solely on morphological features, concerns the skeletal architecture, presence or absence of a specialised ectosomal skeleton, and morphology and diversity of structural megascleres. The curvature and geometry of megascleres, however, is thought to vary considerably within a particular species groups, and confuse the interpretation of interrelationships between species even further. This problem was first identified by Dendy (1905), who noted that oxeas may become strongyles or even styles, and curved or sinuous strongyles, once considered apomorphic for genera such as *Acanthella*, reappear throughout the family.

Consequently, it is not surprising that there are many genera of Axinellidae that presently contain heterogenous assemblages of species, particularly the large groups of *Phakellia*, *Acanthella*, *Axinella*, to each of which numerous species have been assigned. A similar situation exists for *Pseudaxinyssa*, and although it contains only eight nominal species - prior to the present work - some of these are obviously quite different from the type species. Lévi (1983) first stated that *Pseudaxinyssa* was probably polyphyletic, and this was recently reiterated by Van Soest et al. (1990). The present paper re-evaluates *Pseudaxinyssa*, returns its type species and several other described species to *Axinyssa*, and creates a new genus to receive several described species and a number of new species mainly from tropical Australian coral reef habitats.

METHODS

Preparation of material for light microscopy and scanning electron microscopy (SEM) is described elsewhere (Hooper, 1991). Abbreviations used in the text are as follows: AM, Australian Museum, Sydney; BMNH, The Natural History Museum, London; CMNZ, Canterbury Museum, Marine Invertebrate collection, Christchurch; MNHN LBIM, Muséum National d'Histoire Naturelle, Laboratoire de Biologie des Invertébrés Marins et Malacologie, Paris; NCI Q66C-, US National Cancer Institute shallow water collection program (Australian Institute of Marine Science, Townsville, contract) - primary material in USNM, duplicates/fragments in NTM and QM; NTM, Northern Territory Museum, Darwin; ORSTOM, Institute Français de Recherche Scientifique pour le Developpement en Cooperation, Noumea; PIBOC, Pacific Institute of Bio-organic Chemistry, Far Eastern Scientific Centre, Academy of Sciences of the USSR, Vladivostok; QM, Queensland Museum, Brisbane; SMF, Natur-Museum und Forschungsinstitut Senckenberg, Frankfurt; USNM, United States National Museum of Natural History, Smithsonian Institution, Washington; ZMB, Zoologisches Museum für Naturkunde an der Humboldt-Universität, Berlin.

SYSTEMATICS

Family AXINELLIDAE Ridley & Dendy

Axinyssa Lendenfeld, 1897

Axinyssa Lendenfeld, 1897:116; Burton, 1931:349; Van Soest et al., 1990:25.

Axinomimus de Laubenfels, 1936:163; Van Soest et al., 1990:27 (type species *Axinella paradoxa* Ridley & Dendy, 1886:482 [by monotypy]; holotype BMNH 1887.5.2.68).

Pseudaxinyssa Burton, 1931:350; Van Soest et al., 1990:27 (type species *Axinyssa tethyoides* Kirkpatrick, 1903:245 [by original designation]; holotype BMNH 1902.11.16.25, schizotype MNHN LBIM DCL298).

Not *Pseudaxinyssa*, sensu Bergquist & Tizard, 1967: 190; Lévi, 1983:719.

TYPE SPECIES

Axinyssa topsenti Lendenfeld, 1897:116 (by monotypy) (holotype ZMB 2971, schizotype BMNH 1908.9.24.145).

DIAGNOSIS (emended)

Massive, frequently subspherical, sometimes lobate or lobate-digitate growth forms, often with an apical cloacal cavity or fistulose surface conules; surface with prominent, regularly spaced conules; choanosomal axial skeleton open plumose, dendritic or vaguely radiating tracts of larger oxeas, without axial compression, with poorly developed spongin fibres; fibres cored by larger oxeote megascleres; subectosomal extra-axial skeleton plumose, plumo-reticulate, ascending to surface, without obvious spongin fibre component; mesohyl usually with abundant collagenous spongin; specialised ectosomal skeleton may be present in the type species, or absent, consisting of tufts of smaller oxeas perched on peripheral choanosomal skeleton, protruding through surface, forming surface conules; megascleres oxeas or modified oxeas, one or two sizes.

REMARKS

Lendenfeld (1897:116) created the genus *Axinyssa* for a single species, *A. topsenti* Lendenfeld, which had a vaguely plumose, ascending choanosomal skeleton composed of multispicular tracts of large oxeas, with smaller stylote oxeote spicules in brushes on the surface. These choanosomal spicule tracts and smaller ectosomal brushes protrude through the surface for a short distance, producing characteristic microconules. There is no distinctive, compressed core in the skeleton (termed 'axial condensation'), although there is differentiation between the axial and extra-axial regions. Several other species were subsequently described and included in *Axinyssa* (Kirkpatrick, 1903; Topsent, 1906; Wilson, 1925).

Burton (1931) created *Pseudaxinyssa* for two species previously assigned to *Axinyssa* - the type species *A. tethyoides* Kirkpatrick (1903), and *A. gravieri* Topsent (1906). He also included a previously undescribed species, *P. tenuispicula* Burton (1931) from Natal. All three species differed from *Axinyssa* sensu stricto in lacking a specialised ectosomal skeleton of smaller styloid oxeas. They were closer to *Axinella* in their skelatal structure, but had only oxeas as megascleres (*Axinella* usually has styles and oxeas, or only styles, although at least one anomolous oxea-bearing species is also known [see below]). Van Soest et al. (1990) noted that a specialised ectosomal skeleton, such as that seen in *A. topsenti*, commonly occurs within many axinellids and, as such, it may not be a reliable or even valid taxonomic character when used above the species level. We provide further evidence to support this conclusion in the present work, (i.e. *Cymbastela coralliophila* sp.nov. having a specialised ectosomal skeleton), supporting the proposal that *Axinyssa* and *Pseudaxinyssa* (s.s.) should be merged.

Pseudaxinyssa, as defined by Burton (1931), were massive sponges, without strong differentiation between the axial and extra-axial skeletons, and without any evidence of axial condensation. The type species *Axinyssa tethyoides* (Kirkpatrick) is subspherical, with fistulose, usually blind surface papillae, with large oxeas between 530-790μm long scattered between skeletal tracts and forming a branching reticulate, non-compressed, undifferentiated skeletal architecture (i.e. no distinct axial and extra-axial components). However, the subsequent addition of two stalked, cup-shaped sponges from the Indo-west Pacific, *Pseudaxinyssa stipitata* Berquist & Tizard (1967) and *P. cantharella* Lévi (1983), did not fit at all with the original conception of the genus. These two species had compressed-reticulate axial skeletons, with diverging plumose (or plumo-reticulate) extra-axial skeletons, and spongin fibres were reasonably well developed. Both groups of species were similar to *A. tethyoides* only in having diverging tracts of oxeas near the periphery of the skeleton, whereas in other features they were quite different. Therefore, it is proposed here to include these anomolous stalked, predominantly cup shaped species in a new genus.

Following from Van Soest et al.'s (1990) revision of *Axinyssa* and our own observations on various museum specimens, 13 species may be referred to the genus, most from the tropical oceans (also indicating known geographic distributions, and material we have examined):

A. aculeata Wilson (1925:445) (Philippines; none).

A. ambrosia (de Laubenfels, 1934:14) (Puerto Rico; none).

A. aplysinoides (Dendy, 1922:39) (Cargados Carajos, Amirante, Seychelles; none).

A. digitata (Cabioch, 1968:229) (Roscoff; none).

A. fenestratus (Ridley, 1884:464) (Arafura Sea; holotype BMNH 1882.2.23.255).

A. gravieri Topsent (1906:563) (Red Sea; specimen of Lévi (1965:15), MNHN LBIM DCL327L).

A. paradoxa (Ridley & Dendy, 1886:482) (Tristan de Cunha Is; none).

A. pitys (de Laubenfels, 1954:178) (Palau Islands; holotype USNM 23103).

A. radiata (Lévi & Lévi, 1983:968) (New Caledonia; paratype MNHN LBIM DCL 2955).

A. tenuispicula (Burton, 1931:350) (Natal; none).

A. tethyoides Kirkpatrick (Natal; holotype BMNH 1902.11.16.25).

A. topsenti Lendenfeld (Adriatic; holotype ZMB 2971).

A. valida (Thiele, 1899:12) (Moluccas; ? paratype SMF 1821).

Another species exists in the MNHN collections, identified as a new species of *Pseudaxinyssa* by Claude Lévi (pers.comm.) ('holotype' MNHN LBIM DCL1497) from Anborombe, Africa (M. A. Crosnier stn CRO 69), and it too should be included in *Axinyssa*. The affinities of the remaining species which have been included in *Pseudaxinyssa* at one time or another are as follows:

P. cantharella Lévi (1983:719) (New Caledonia) belongs to the new genus described below.

P. stipitata Bergquist and Tizard (1967:189) (northern Australia) also belongs to the new genus described below.

P. tricalyciformis (Bergquist, 1970:15) (holotype CMNZ Mar. Inv. 3/63), a replacement name for *Axinella lamellata* Bergquist (1961:188) (preoccupied), from the Chatham Islands, was referred to *Pseudaxinyssa* by Bergquist & Tizard (1967:190). It has oxeas, some with styloid modifications, forming a condensed axial skeleton and plumose extra-axial skeleton, and is returned to *Axinella*. Discrepancies in dates of referral and description of that species are a consequence of delayed publication of the 1970 paper, which was completed in 1966 (Bergquist, 1970:4).

Following Van Soest et al.'s (1990) revision of the 'halichondrid' axinellids *Axinyssa* was referred to the family Halichondriidae Vosmaer, as emended by them, in having vague, ill-defined spicule tracts, with a high ratio of spicules to spongin. By comparison, 'true' members of the Axinellidae have ordered, axially condensed, extra-axially plumo-reticulate skeletons. The type species of *Pseudaxinyssa*, *A. tethyoides* fits well with the emended definition of Halichondriidae (see Figs 1-2), and a redescription of *A. tethyoides* is provided here for comparative purposes with the new genus described below.

Axinyssa tethyoides Kirkpatrick
(Figs 1-2)

Axinyssa tethyoides Kirkpatrick, 1903: 245-6, pl. 5, fig.12, pl.6, fig.8a,b.; Van Soest et al., 1990:27, fig.18.

Pseudaxinyssa tethyoides; Burton, 1931:350.

Material Examined
Holotype: BMNH 1902.11.16.25: Cone Point, Natal, South Africa, 68m depth. Schizotype: MNHN LBIM DCL298.

Substrate and Depth Range
Broken shell substrate.

Geographical Distribution
Known only from the type locality.

Description
Shape: Subspherical, massive growth form, 64mm diameter, with slightly flattened basal region (point of attachment) (Fig. 1A).

Surface features: Detachable, relatively fragile skin, covered with numerous small papillae, 2-5mm long, 1-2.5mm diameter, most erect, fistulose, but few open at the apex. When open, diameter of oscule approximately 1mm.

Colour: Live colouration unknown, mottled black and dark brown in ethanol.

Texture: Firm, barely compressible consistency, easily crumbled.

Ectosome: Membraneous, without specialised skeleton, with moderate quantities of detritus within heavy organic matrix, occasionally with spicules from peripheral choanosomal skeleton protruding through surface, corresponding to surface papillae (Fig. 2B).

Choanosome: Skeleton branching reticulate, open-meshed (mesh diameter 140-320μm), without trace of axial condensation or differentiation between axial or extra-axial regions. Skeletal tracts pauci- or multispicular, 80-170μm wide, composed of tightly bound oxeas, without spongin fibres, bound together within heavy collagenous mesohyl (Fig. 1B). Near periphery skeletal tracts diverge to surface, protruding through ectosome slightly or not at all.

Spicules: Oxeas of single size class, long, robust, symmetrical, slightly curved at centre,

FIG. 1. *Axinyssa tethyoides*, holotype (BMNH 1902.11.16.25). A,whole specimen (scale=30mm). B,SEM of skeleton (scale=1mm). C,spicule (scale=250μm).

tapering to sharp points (Fig. 2A) (length 533-648.4-789μm, width 18-29.6-43μm).

REMARKS

The large size of spicules, undifferentiated axial and extra-axial skeletons, lack of a condensed axial skeleton, absence of spongin fibres, presence of heavy collagen in the mesohyl, and a spherical fistulose growth form distinguish this species from all the Australian '*Pseudaxinyssa*' species. For reasons discussed above we consider that this distinction is at the generic level.

Cymbastela gen.nov.

Pseudaxinyssa, in part, Bergquist & Tizard, 1967: 190; Lévi, 1983:719.

TYPE SPECIES

Pseudaxinyssa stipitata Bergquist & Tizard, 1967:189 (holotype AM Z3101).

DIAGNOSIS

Typically stalked, cup-shaped, thinly lamellate growth form. Ectosome with or without

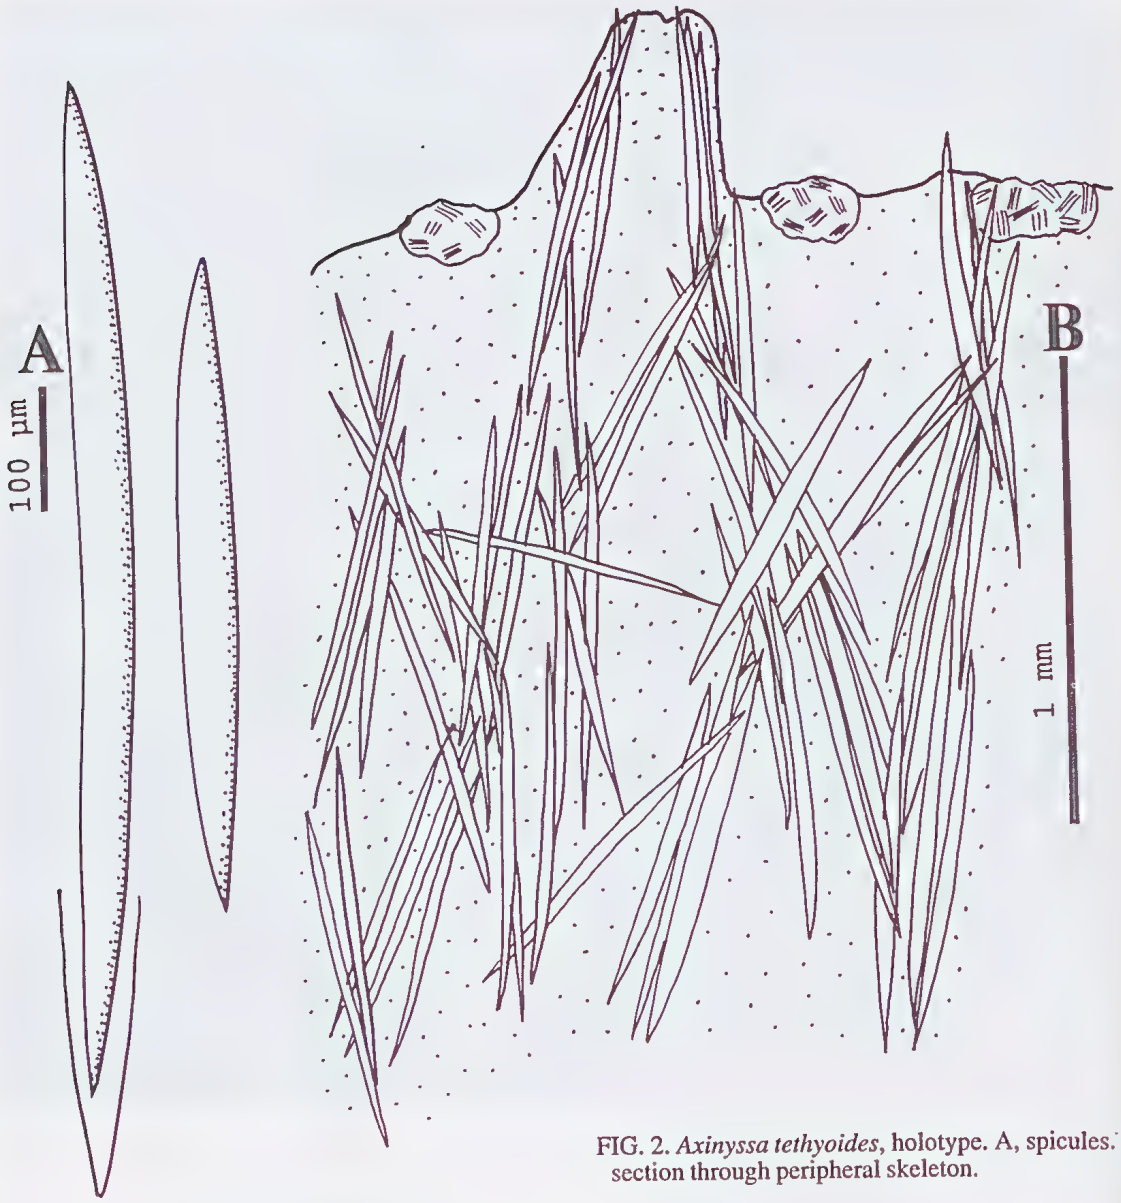

FIG. 2. *Axinyssa tethyoides*, holotype. A, spicules. B, section through peripheral skeleton.

specialised skeleton of smaller oxeas. Choanosomal skeleton with compressed reticulate axial region, in which major tracts run longitudinally through lamellae, and with gradually ascending, diverging, radial, plumose or plumoreticulate extra-axial region, in which tracts become plumose and project through surface. Spongin fibres well developed, cored by oxeas, frequently with telescoped points. Predominantly autotrophic, most species containing symbiotic cyanobacteria. Oviparous.

ETYMOLOGY

Latin, *cymba* - cup, *stela* - column (f.); *Cymbastela*, for the predominantly stalked, cup-shape growth forms.

REMARKS

Cymbastela is an unusual axinellid in its growth form, although this morphology is also repeated in several Haplosclerida, such as some *Haliclona* and *Amphimedon*. Typically the genus has a reticulated, compressed axial skeleton and a plumose extra-axial skeleton, both composed of

TABLE 1. Comparison in spicule dimensions between described species of *Cymbastela*. All measurements given in micrometres, and expressed as minimum - mean - maximum range of measurement. N=number of specimens examined.

well formed spongin fibres. In the extra-axial region there are always fewer paucispicular, reticulate fibres interconnecting the multispicular, radial or plumose, ascending fibres. This structure shows some similarities to the skeletons found in *Axinella* Schmidt (i.e. *A. polypoides* Schmidt, sensu Vosmaer, 1912), in which there is a condensed, reticulate axis and plumose-branching and reticulated extra-axis, and *Phakellia* Bowerbank (i.e. *P. ventilabra* Linnaeus, sensu Vosmaer, 1912), in which there is a condensed, reticulate axis, and a plumose, radial, non-branching or poorly-branching extra-axial skeleton. Both *Axinella* and *Phakellia* have spicules consisting of styles, strongyles and oxeas, in all combinations, whereas in *Cymbastela* spicules are only oxeas, usually with telescoped ends. *Cymbastela* is superficially most similar to *Phakellia* (sensu Vosmaer), due to the emphasis of the extra-axial skeleton over other structures, but it is probably most closely related to *Axinella* in all other features.

It is difficult to define any particular character which may serve as a synapomorphy for *Cymbastela*, clearly differentiating it from its sister group *Axinella*, in particular. Virtually no single feature is unique; levels of homoplasy are comparatively high within the Axinellidae. The lamellate growth form is characteristic and consistent, but not unique to *Cymbastela*: two species of *Axinella*, *A. vaceletia* (Pansini) and *A. shoemakeri* de Laubenfels, are also lamellate. Similarly, *Axinella polycapella* de Laubenfels has a reduced spicule complement, with mostly only oxea megascleres, although in *Cymbastela* many of the oxeas have telescoped ends, and it is probably this feature that is most important in defining the genus. Therefore, all three characters in combination - growth form, spiculation and skeletal architecture - are considered to be valid discriminatory characters defining the new genus.

Seven species are referred here to *Cymbastela*, only three of which have been previously described. The genus is most common in the tropical Australian - western Pacific region, although one temperate species is also known.

KEY TO THE SPECIES OF *CYMBASTELA*

Characters found in both preserved material [and live specimens] are indicated.

1. Oxeas mostly with telescoped ends ..... 3.

   Oxeas mostly with tapering ends ..... 2.

2. Thicker lamellate, cup-shaped growth form, often with external buttresses, concentric lamellae, and lateral projections [typically pigmented olive-green and mauve]) ..... *C. stipitata* (Bergquist & Tizard).

   Thinly lamellate, usually simple, concentric or asymmetrical cup-shaped growth forms, without exterior projections [dark maroon-brown, evenly pigmented] .... *C. vespertina* sp.nov.

3. Oxeas well silicified ..... 4.

   Oxeas poorly silicified, vestigial, thin, with strongyloid-rounded telescoped ends [small symmetrical vase-shaped, thin lamellae, even surface, live colouration unknown] .....*C. notiaina* sp.nov.

4. Specialised ectosomal skeleton of smaller oxeas present, overlaying projecting subdermal skeleton of larger oxeas [wide cups or thickly lamellate lobes attached directly to substrate, usually with convoluted external surface, mot-

tled olive-green and olive-brown colouration] ..... *C. coralliophila* sp.nov.

Without specialised ectosomal skeleton ..... 5.

5. Axial skeleton not compressed, predominantly plumo-reticulate, extra-axial skeleton radial, not plumose, ectosomal skeleton with plumose projecting spicules [concentric cups, usually buttressed or with other sorts of external projections, thin lamellae, convoluted margins, with obvious differences between interior (porous, inhalant) and exterior (smooth, exhalant) surfaces, pale orange] ..... *C. cantharella* (Lévi).

Axial skeleton compressed, predominantly reticulate, extra-axial skeleton predominantly reticulate, ectosomal skeleton with plumose projecting spicules [concentric or convoluted cups, thin lamellae, evenly pigmented dark brown or olive-brown] ..... *C. concentrica* (Lendenfeld).

Axial skeleton compressed, predominantly plumose or longitudinal, less obviously reticulate, extra-axial skeleton predominantly plumose, ectosomal skeleton plumose [irregular cups, thin lamellae, no basal stalk, smooth surface on both interior and exterior faces, evenly pigmented olive-green/maroon] ..... *C. marshae* sp.nov.

Substrate and Depth Range

Restricted to shallow coastal waters, ranging from intertidal to 19m depth. Substrate predominantly rock or coral rubble, and the sponge is most abundant in areas where there are relatively light loads of sediment.

Geographical Distribution

Northwestern Australian waters (Fig. 5D). Lévi (1983) suggested that *C. stipitata* also occurs in the lagoon off Noumea, New Caledonia, but it is possible that he was referring to the new species described below from the Great Barrier Reef, *Cymbastela coralliophila* sp.nov.

Description

Shape: Stalked, cup-shaped growth form, usually with thick, uneven, crenellated margins, smooth interior surface, mostly smooth exterior surface of vase, but often with lateral growths and projections on exterior surface. Growth variants common, sometimes with 2-4 concentric, successively smaller cups growing inside each other, with or without buttressed exterior projections near base. Margins and stalk typically relatively thick, up to 14mm and 32mm maximum widths, respectively. Although growth variants may occur within metres of each other, specimens tend to be thinner, more elongate (more vasiform), and less convoluted with increasing depth (Figs 3A,B).

Surface features: Oscules not visible optically, although small, evenly distributed pores (0.8-1.8mm diameter) seen under higher magnification, usually situated on points of surface conules. In some cases distribution of pores coincides with distribution of parasitic barnacles (*Acasta* sp.), whereas other openings appear to be true inhalant or exhalant pores.

Colour: Live colouration clearly dependent on well-being of resident algal symbionts - variations in pigmentation related to degree of shading, water depth and water clarity. Typical live colouration of intertidal specimens olive-green on margins (Munsell 2.5GY 5/4), olive-green with maroon-brown tinge on inside of vase (5GY 4/4-2.5R 4/2), maroon-brown on exterior of vase and stalk (2.5R 4/4). Subtidal specimens typically evenly pigmented olive-brown or olive-maroon (2.5-10R 3/2). Heavily shaded, damaged specimens or material from waters with exceptionally high turbidity may be completely beige (i.e. without pigments).

Texture: Consistency always stiff, firm, but flexible, with roughened, sand-paper texture produced by spicules protruding slightly from dermal skeleton. Surface always optically smooth, microscopically hispid and microconulose, frequently raised into regular or irregular ridges or rounded digitate projections.

Ectosome: No specialized skeleton on surface, but with prominent, relatively closely meshed, diverging plumose brushes of choanosomal oxeas protruding through ectosome for short distances (up to 150μm maximum), producing microscopic surface conules. Subdermal skeleton more-or-less plumose, with more closely meshed multispicular skeletal tracts than on ectosome. Tracts may or may not be interconnected by paucispicular transverse fibres, but usually hidden by diverging spicules (Figs 4, 5B-C).

Choanosome: Axial skeleton compressed, composed of very close-meshed plumose or vaguely plumo-reticulate multispicular fibres, mostly running longitudinally along core of lamellae, occupying majority of lamella diameter. Only few interconnecting uni- or paucispicular tracts observed at core, but these mostly obscured by close-meshed reticulation. Disjunction between longitudinally orientated axial skeleton and vertically disposed extra-axial skeleton only noticeable very close to periphery. Choanosomal fibres

lightly invested with spongin, with few extra-fibre megascleres. Mesohyl matrix lightly reinforced with collagen, with abundant microalgae scattered throughout.

Spicules (refer to Table 1 for dimensions): Megascleres unmodified oxeas, symmetrical, thick, curved centrally, with mostly fusiform sharply pointed ends, sometimes with very slightly telescoped points but this feature never as well developed as in other species. Structural megascleres coring fibres slightly larger than those scattered between fibres (Fig. 5A).

ASSOCIATIONS

With the exception of a few specimens from very turbid waters, which may have shed their algal symbionts, most specimens of *C. stipitata* contained cyanobacteria (blue-green algae), dispersed evenly throughout the sponge mesohyl. Only rarely were these symbionts seen inside spongin fibres. The olive-green, olive-brown sponge pigmentation, characteristic of this species, may be a photosynthetic by-product of these symbionts: the several shallow water specimens tested were chlorophyll positive (as demonstrated by acetone extracts of tissues). Parasitic barnacles of the genus *Acasta* are also common within this sponge.

REMARKS

This species is immediately differentiated from other tropical Australasian *Cymbastela* species by the emphasis of its plumose skeletal architecture over other skeletal components. In other species the reticulate connections within the skeleton are more obvious, and overall skeletal architecture is predominantly plumo-reticulate, but in *C. stipitata* the reticulate component of the skeleton is masked slightly by the dense plumose tracts. In this regard the species is most similar to *C. marshae* sp.nov. from the Houtman-Abrolhos Is, WA, which has much smaller spicules (Table 1). In some respects it also resembles the northwestern Australian *C. vespertina*, which is found in deeper, less turbid waters. The latter species, however, has much thinner lamellae and is usually evenly pigmented maroon-brown to purple-grey alive. *Cymbastela stipitata* is contrasted further with other species below.

Cymbastela vespertina sp.nov.

SUBSTRATE AND DEPTH RANGE

Patch rock reef, fringing coral reef, or rock heads, sandy bottom over hard corals, gorgonians, sponges and algae, in areas of strong current; 6-32m depth range.

GEOGRAPHICAL DISTRIBUTION

Northwest coast of Australia, from Exmouth Gulf to Wessel Islands (Fig. 8C).

ETYMOLOGY

Latin, *vespertinus*, western, or of the evening; for the west Australian coastal distribution of this species.

DESCRIPTION

Shape: Thin-walled, lamellate, cup shaped sponges, 95-190mm high, 70-170mm maximum diameter, lamellae 2-4.5mm thick. Lamellae typically do not rejoin completely, usually producing asymmetrical cups. Apical margins of lamellae usually even, but larger specimens may consist of 2-4 concentric cups, with lamellae forming spiral walls. Sponges attached to substrate by large, flat basal plates, up to 55mm maximum diameter, with

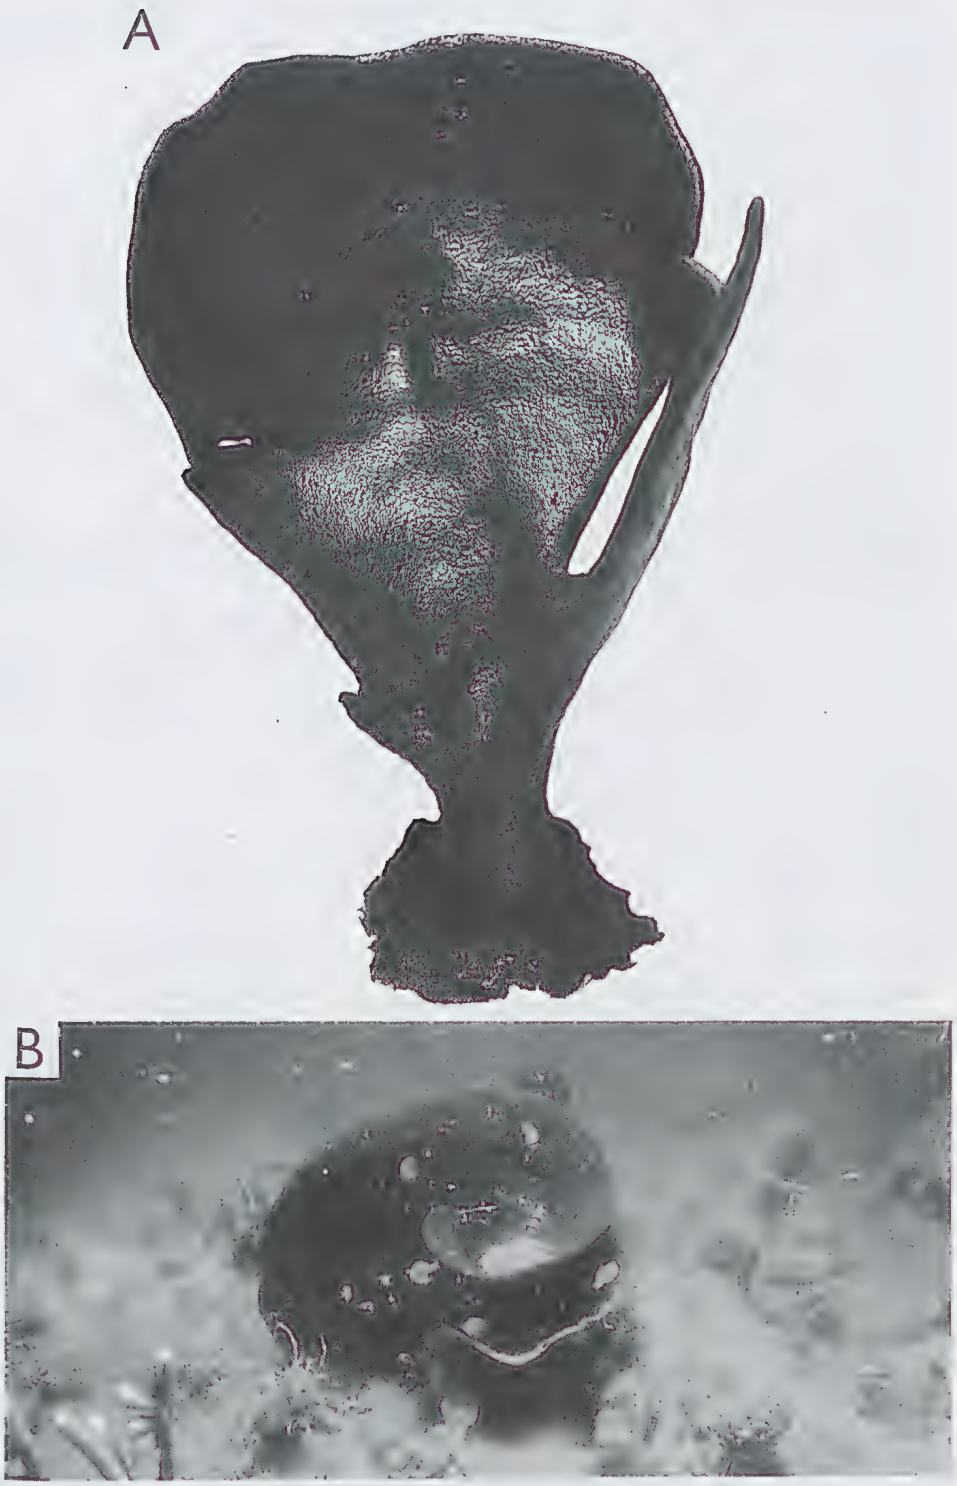

FIG. 6. *Cymbastela vespertina* sp.nov. A, holotype (NTM Z3939). B, paratype (NTM Z2615), in situ.

FIG. 7. *Cymbastela vespertina* sp.nov. (paratype QM G300002). SEMs of skeleton showing: A, section through lamella (scale=1mm); B, slightly compressed plumo-reticulate axial arrangement (scale=500µm); C, oxeas and terminations (scale=100µm).

short, thick stalk, 14-36mm long, 14-28mm diameter (Fig. 6A,B).

Surface features: Smooth, even, uninterrupted by any surface processes. Microscopically surface with minute conules. Oscules not seen, but small evenly distributed pores, up to 0.8mm diameter, scattered over surface of lamellae.

Colour: Live colouration dark maroon brown (Munsell 2.5R 4/4) to greyish purple (5R 5/2), always evenly pigmented, whereas in ethanol colour usually dark brown or dark grey.

Texture: Firm, slightly compressible texture, sandpaper-like to touch.

Ectosome: Membraneous, without specialised spiculation, but with regularly spaced plumose brushes, composed of 3-8 oxeas, from ascending extra-axial tracts, protruding through surface for short distances, up to 100μm from ectosome. Position of plumose spicule brushes on surface coincides with minute surface conules. Subectosomal region predominantly plumose, slightly plumo-reticulate, with ascending plumose portion of skeletal tracts greatly emphasised over uni- or paucispicular reticulate, transverse, connecting tracts. Spongin fibre mesh size in peripheral skeleton up to 140μm diameter, more open than in axial region (Figs 6,7).

Choanosome: Skeleton slightly axially compressed, plumo-reticulate, with plumose component emphasized only slightly over reticulate component of skeleton: former consisting of multispicular ascending tracts, latter with paucispicular, connecting tracts, both enclosed within spongin fibres (Fig. 8B). Spongin fibres light but well developed, with small mesh sizes, up to 90μm maximum diameter. Mesohyl with moderate quantities of brown-pigmented collagenous spongin, and only few spicules dispersed outside fibres. Choanocyte chambers oval, 28-90μm diameter.

Spicules (refer to Table 1 for dimensions): Megascleres oxeas without any modifications, relatively long, slender, slightly curved centrally, tapering to sharp fusiform points, with very few examples bearing telescoped points (Fig. 8A).

Associations

This species is usually associated with symbiotic microalgae (cyanobacteria) in shallow water (i.e. is chlorophyll positive), and the symbionts are probably responsible for producing the characteristic dark purple-mauve live pigmentation, although one specimen (Z3939) was pale beige in situ and may have shed its algae. Parasitic barnacles are rare.

Remarks

This species was originally thought to be merely a modified, deeper-water form of *C. stipitata*, as there are similarities in skeletal architecture and spicule dimensions. However, morphological differences described above, particularly the asymmetrical cup shape, the very thin lamellae and darker pigmentation, and differences in free amino acid profiles between *C. vespertina* and *C. stipitata* (Hooper et al., 1992), indicate that these two sympatric populations are heterogenous and sibling species.

Cymbastela concentrica (Lendenfeld) comb.nov. (Figs 9-11, Table 1)

Antherochalina concentrica Lendenfeld, 1887:788, pl.22, fig.42.

Material Examined

Lectotype (here designated): AM Z1993: Port Molle (now Airlee Beach), Qld, 20°13'S, 148°49'E, no other collection details known. (cf. published locality of St Vincent Gulf, South Australia). Paralectotypes: BMNH 1886.8.27.451, 460: same locality.

Other Material. Queensland - NTM Z3169 (fragment QM G300009): Outer slope of reef front, Blue Lagoon, Lizard I., Great Barrier Reef, 14°40'S, 145°48'E, 10-20m depth, 1987, coll. A.W.D. Larkum (ref.no. PC 348T, PC 346). QM G300003: Inner Gneerings, Moreton Island, 26°38.5'S, 153°09.5'E, 14m depth, 01.v.1991, coll. Thorogood, JA, SCUBA (ref.JT-8).

Substrate and Depth Range

Inshore fringing reefs and coral reef slope, up to 20m depth.

Geographical Distribution

Northern, central and southern Queensland (Fig. 11C).

Description

Shape: Cup- or vase-shaped growth forms, up to 150mm high, 125mm maximum width, consisting of relatively thin (approximately 2mm wide), convoluted, conical lamellae or symmetrical cups on short basal stalk. Stalk length up to 45mm long, 25mm diameter. Lamellae may produce concentric whorls inside cup, or merely contain a few irregular bumps; margins of lamellae slightly convoluted (Fig. 9A-C).

Surface features: Lamellae smooth, slightly irregular, with low conules and ridges on exterior surface, more even interior surface; no buttresses or external processes.

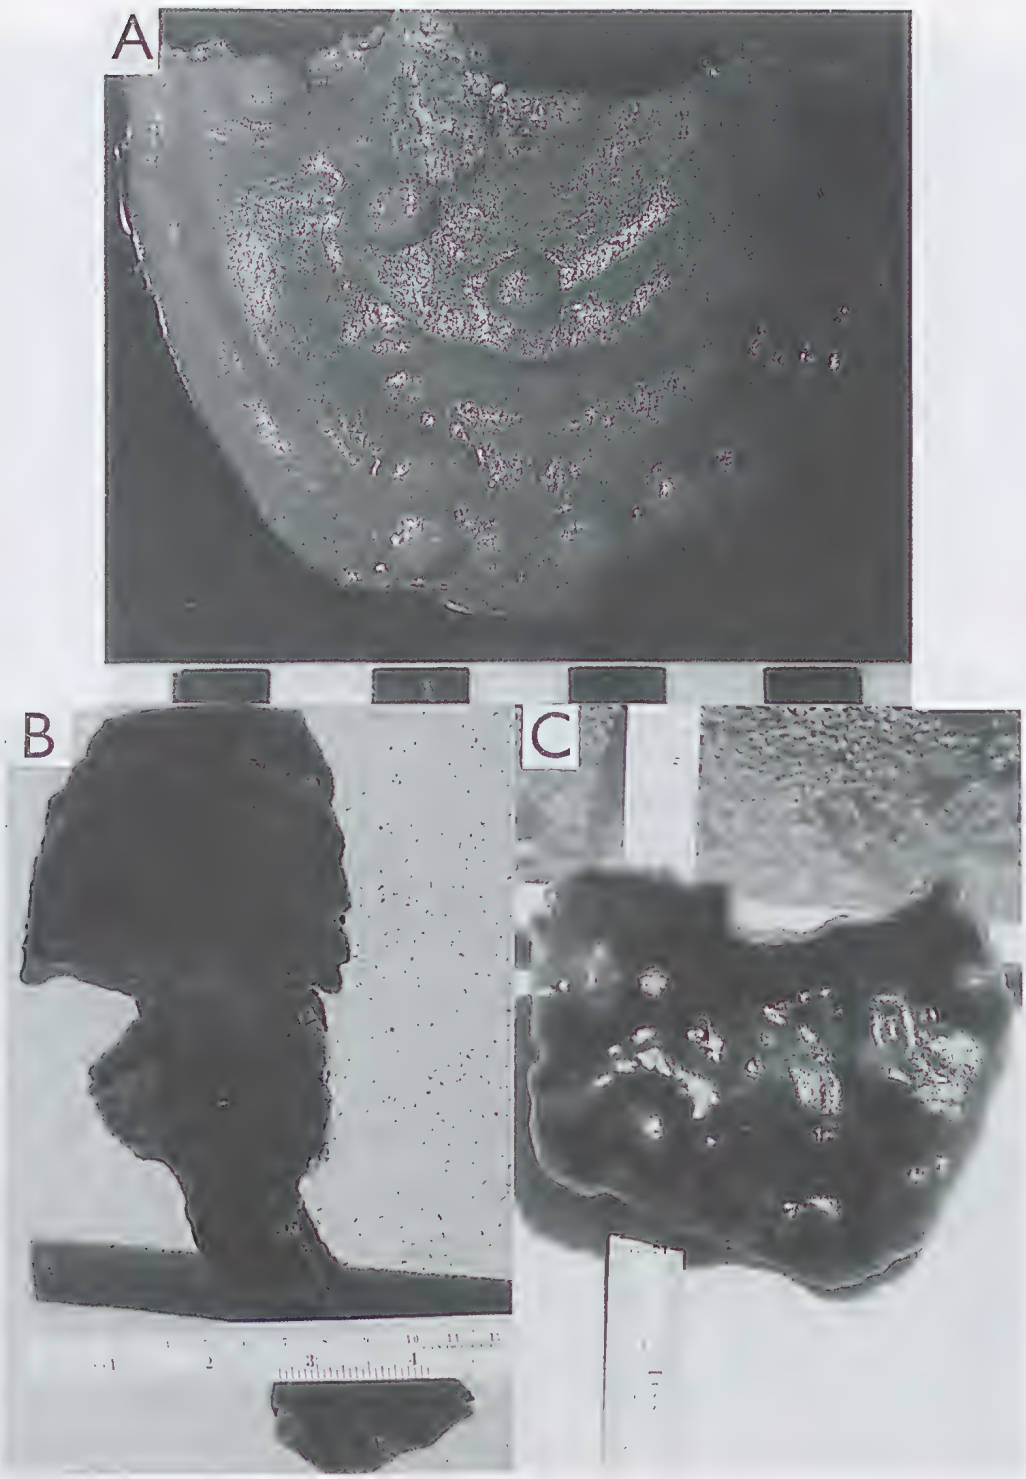

FIG. 9. *Cymbastela concentrica*. A, Paralectotype (BMNH 1886.8.27.451). B, specimen (NTM Z3169; photo A. Larkum). C, field number PC 346, unaccompanied by voucher specimen (photo A. Larkum).

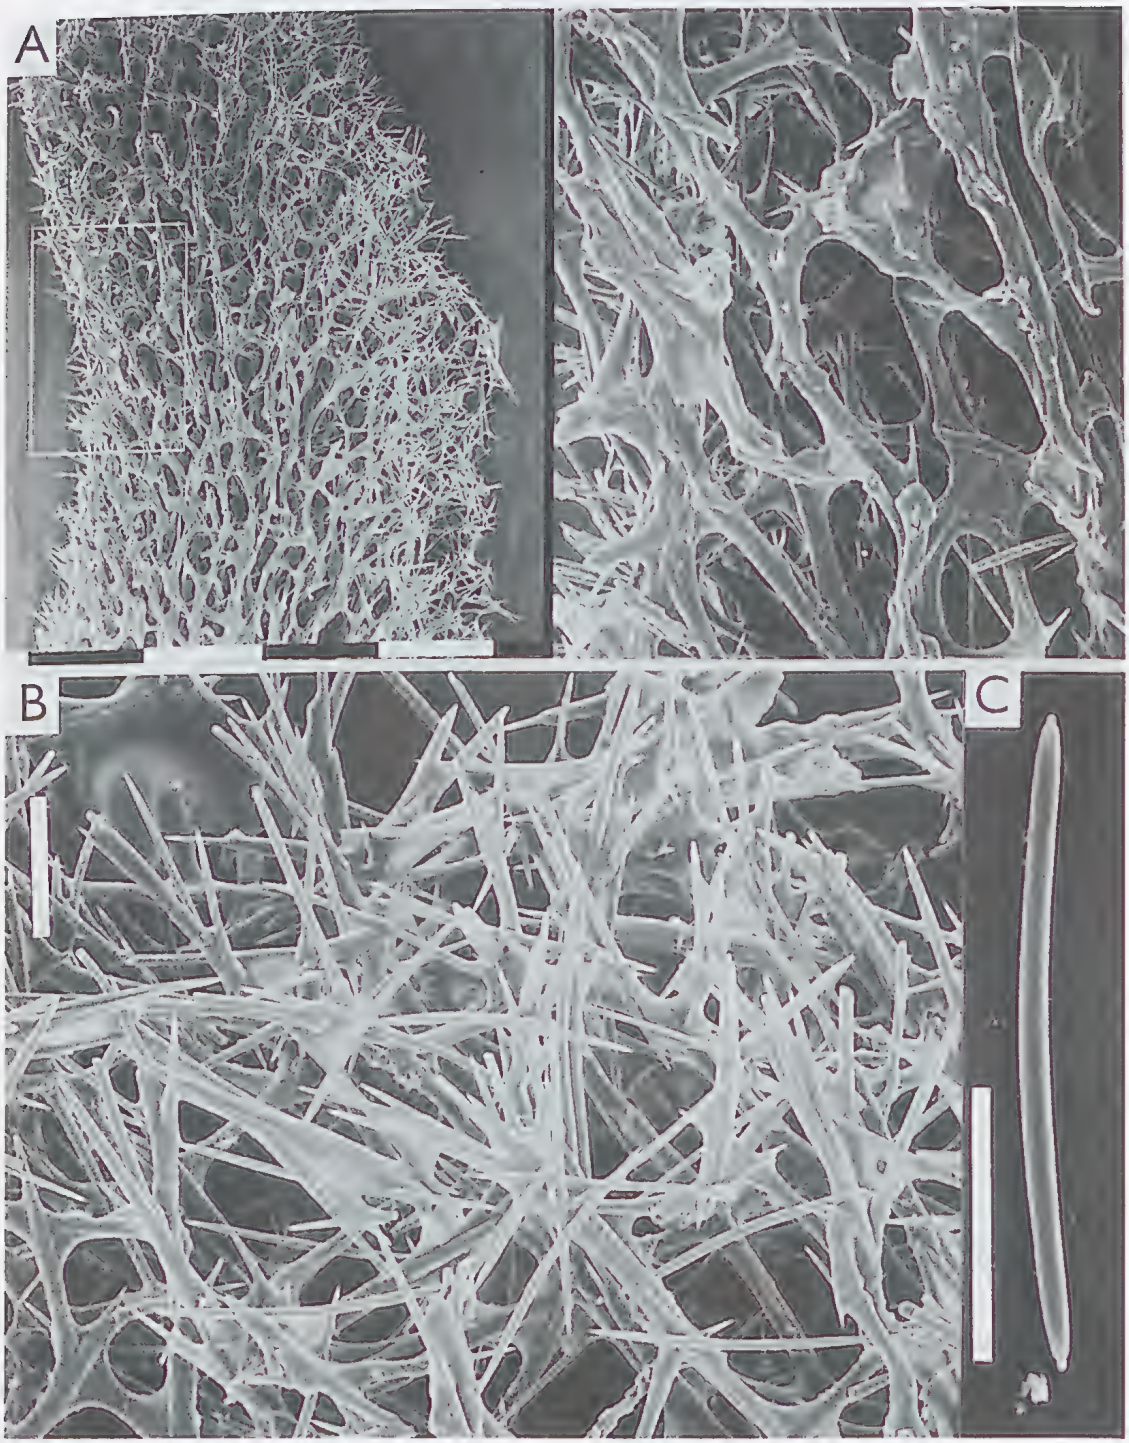

FIG. 10. *Cymbastela concentrica*. A, SEM of skeleton (specimen NTM Z3169) (scale=500μm; left magnified 21.2 times, right magnified 186 times). B, peripheral skeletal architecture (scale=100μm). C, spicule with telescoped ends (lectotype AM Z1993) (scale=50μm).

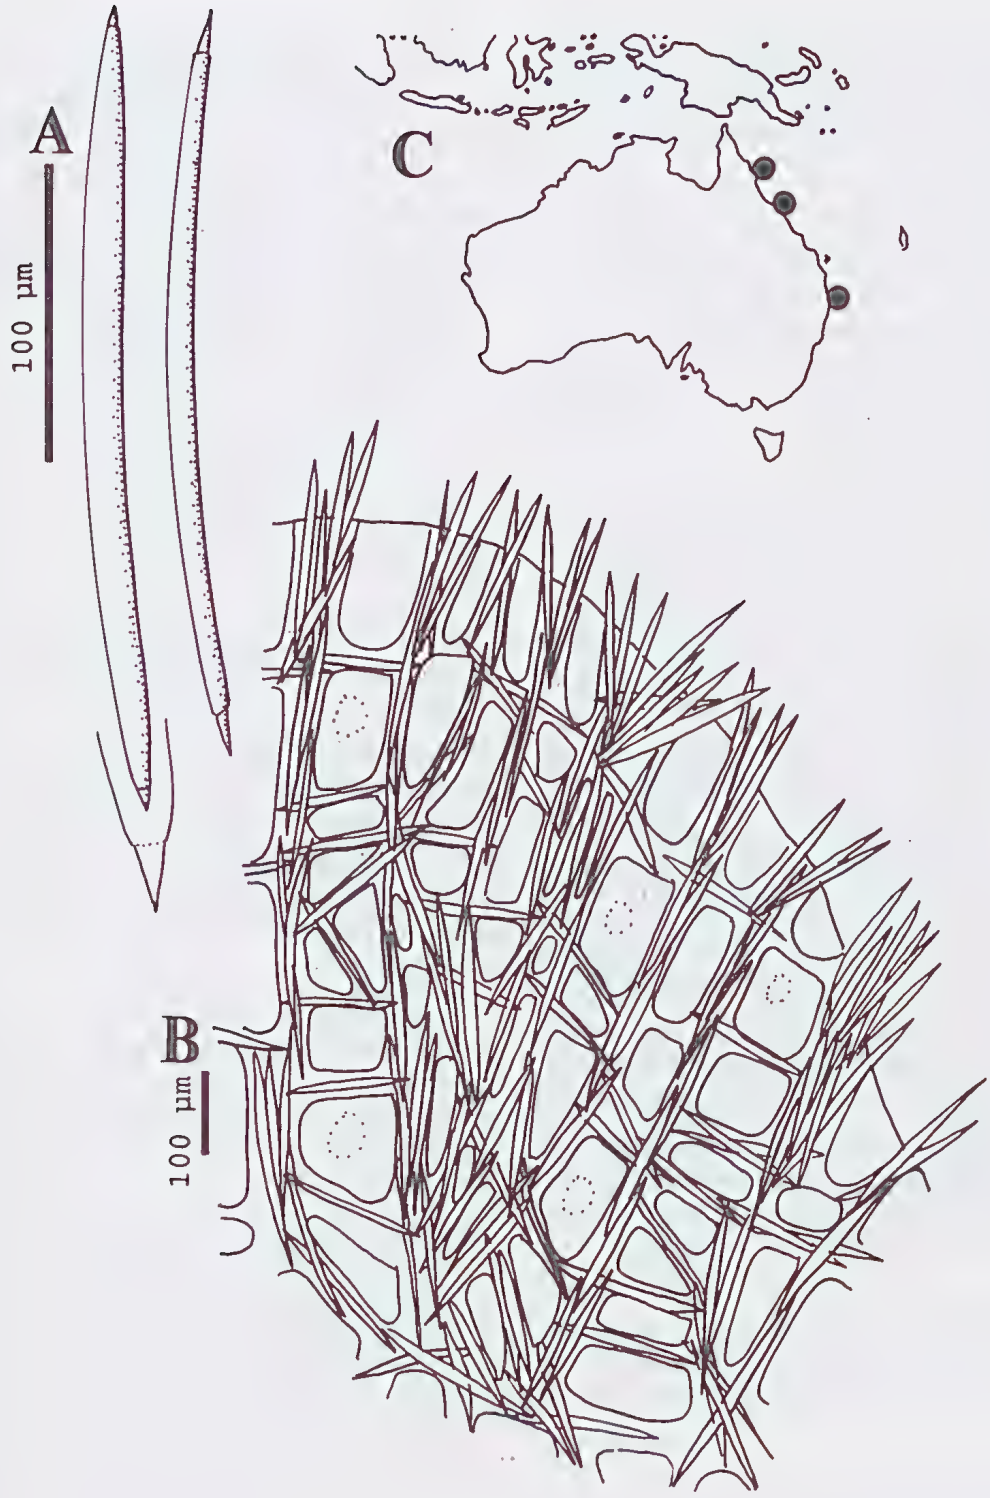

FIG. 11. *Cymbastela concentrica*, lectotype (AM Z1993). A, spicules. B, section through peripheral skeleton. C, known distribution.

Colour: In life, dark brown (interior) (Munsell 5YR 3/2) or olive brown (exterior) (2.5YR 4/4). Chlorophyll pigments abundant (seen in acetone extracts of freshly preserved material), due to presence of large population of cyanobacteria (microalgal) symbionts.

Texture: Smooth, stiff and flexible consistency, with a slightly velvet surface texture.

Ectosome: Optically smooth, lacking specialized skeleton, but microscopically villose, with substantial portions of spicule from peripheral skeleton protruding through surface and forming plumose brushes. Spicules protrude up to 230μm from surface, and brushes may contain up to 8 spicules (Figs 10, 11B). Microalgae, seen in fresh material, appear to be concentrated near periphery of skeleton.

Choanosome: Skeletal architecture plumo-reticulate, with poorly differentiated axial and extra-axial skeletal regions - reticulate skeleton emphasised over plumose portion (Figs 10, 11B). Central region of choanosomal skeleton only slightly axially condensed, predominantly reticulate, with plumose paucispicular ascending tracts curving gradually towards surface, interconnected by uni- or paucispicular transverse tracts, whereas peripheral skeleton more clearly diverges into plumose ascending multi- or paucispicular tracts, interconnected by uni- or paucispicular transverse tracts. Spongin fibres and spicule tracts, 40-60μm wide in axis, become less heavily cored and more widely spaced towards periphery, 20-40μm wide, ultimately forming distinctive plumose dermal brushes. Spongin fibres (22-60μm wide) lightly developed, nearly fully cored by megascleres, producing ovoid to eliptical meshes (42-77μm, 60-185μm wide in axial and extra-axial regions respectively). Collagen abundant in mesohyl but very lightly pigmented. Choanocyte chambers oval to elliptical, 45-150μm diameter.

Spicules (refer to Table 1 for dimensions): Variable length, relatively, slender, fusiform oxeas, moderately curved at centre, usually with very faintly telescoped points (Fig. 11A).

Associations

Cyanobacteria were only seen in freshly preserved material, not in the type material, and appears to be concentrated mainly in the peripheral skeleton.

Remarks

Lendenfeld (1887) states that *C. concentrica* was originally collected from St Vincent Gulf, South Australia, whereas both the AM and BMNH registers, and the specimen labels with the type material, indicate that the collection locality was Port Molle, Queensland. Although the exact type locality of this species will always be doubtful, the new record of the Queensland material described here from Lizard and Moreton Is suggests that the Museum register notations may be correct. According to Burton (1934:558), and notes in the BMNH register (in M. Burton's handwriting), this species has some similarities with *Phakellia flabellata* (Carter) from southern Australia. However, the skeletal architecture and spiculation of *C. concentrica* is quite different from that of *Phakellia*, and the two species are regarded as convergent in these two superficially prominent features.

The redescription presented above differs slightly from the description given by Lendenfeld (1887), who recorded oxea dimensions of 130x5μm. In this regard his description conforms more closely to the new specimens described above than to the type material (Table 1). Apart from their smaller spicule dimensions these two specimens are identical to the type material in growth form, including lamellae thickness and surface features, skeletal architecture, spicule-spongin fibre structure and spicule geometry, and it is suggested here that all five specimens of *C. concentrica* described above are conspecific. However, the existence of these two anomalous specimens casts some doubt over the accuracy of absolute spicule dimensions as a useful diagnostic character within this genus (see Fig. 24), suggesting that spicule size may vary with latitudinal distribution.

Cymbastela concentrica is similar to most of the other lamellate Australasian *Cymbastela* species in a number of features. Many species contain symbiotic algae (i.e. are chlorophyll positive), they all have a thin, lamellar, plate-like, cup- or vase-shaped growth form, with well developed spongin fibres, and a more-or-less slightly condensed plumo-reticulate axial skeleton, plumose or plumo-reticulate extra-axial skeleton, and if present, a plumose ectosomal skeleton. Species appear to differ substantially only in spicule dimensions, spicule geometry (presence or absence of telescoped points, and possession of hastate or fusiform points), and the degree to which the skeleton is organized into axial and extra-axial sections. For example, *C. stipitata* (from inshore waters of northern Australia) has larger megascleres, spicules are only rarely terminated by telescoped points, and there is a more obvious differentiation between the axial and extra-axial regions of the skeleton, including a more con-

densed axial core, and an emphasis on the plumose portion of the skeleton. *Cymbastela cantharella* from the outer reefs of New Caledonia also has a stalked lamellar growth form, slightly differentiated axial and extra-axial skeletons, but it has distinctive orange, yellow-orange live colouration, and relatively slender oxeas. In contrast, *Cymbastela concentrica* has a relatively poorly differentiated axial and extra-axial skeleton, only slightly condensed choanosomal axis with emphasis on the reticulate extra-axial portion of the skeleton. This takes the form of a plumo-reticulate extra-axial skeleton, a plumose ectosome, and oxeas which are similar in size to those of *C. cantharella.*

Cymbastela cantharella (Lévi)
(Figs 12-14, Table 1)

Pseudaxinyssa cantharella Lévi, 1983:719-722, fig.1, pl.1.

MATERIAL EXAMINED

HOLOTYPE: MNHN LBIM DCL3141: Outer reef, SW coast New Caledonia, 40m depth, no other details known.

OTHER MATERIAL: NTM Z3869: Precise locality unknown, Noumea lagoon, SW coast, New Caledonia, 22°20'S, 166°13'E, 25m depth, coll. ORSTOM, SCUBA (ref. R1261). NTM Z3872 (fragment QM G300004): Exterior of Grand Recif Mbere, off Noumea, New Caledonia, 22°20'S, 166°13'E, 30m depth, 21.ix.1990, coll. J.N.A. Hooper, SCUBA (stn JH-90-018).

SUBSTRATE AND DEPTH RANGE

Slope and ledges near base of barrier reef, dead coral and silt substrates, 15- 75m depth.

GEOGRAPHICAL DISTRIBUTION

Known only from the New Caledonia region (Fig. 14C).

DESCRIPTION

Shape: Short, erect cup-shaped or semi-vasiform lamellae, 80-150mm high, up to 170mm maximum diameter, on short stalk, 30-40mm long, 10-17mm diameter, with thin lamellate walls, 3-6mm diameter, usually with convoluted margins, occasionally with secondary cups or lamellae growing inside primary cup, often with buttresses and secondary projections (Fig. 12A).

Surface features: Surface of lamellae predominantly smooth, although distinct differences between interior (inhalant) and exterior faces of cups exist. Exterior of lamellae microscopically smooth, optically uneven, interior of cup with numerous small oscules, 0.5-2mm diameter, each surrounded by slightly raised membraneous lip (Fig. 12B). Oscules approximately 2mm apart, throughout interior surface of lamellae producing concentric striations within interior of cup.

Colour: Pale orange alive (Munsell 2.5-7.5 YR 8/10), beige in ethanol.

Texture: Firm, flexible, slightly compressible; exterior of lamellae with sandpaper like texture, interior more compressible.

Ectosome: Membraneous, without specialised skeleton, with heavy layer of slightly darker collagen, up to 80μm wide, through which choanosomal oxeas protrude for about half their length. Projecting oxeas occur individually or in paucispicular plumose bundles, regularly dispersed across surface, arising from ascending radial tracts in peripheral skeleton (Figs 13, 14B).

Choanosome: Choanosomal skeleton plumo-reticulate, without axial compression or any noticeable differentiation between axial and extra-axial regions, apart from plumose ectosomal spicules (Fig. 14B). Two components of skeleton predominant: first, radial spongin fibres, cored by multispicular tracts of oxeas, run longitudinally through lamellae, and gradually ascend to surface, becoming plumose and diverging near periphery; second, radial fibres interconnected by uni- or paucispicular tracts of oxeas, only weakly organised as a reticulum. The skeleton in places is almost halichondroid (Fig. 13). Spongin fibres only lightly invested in spongin, up to 75μm diameter, forming elongate or rectangular meshes, up to 125μm diameter, with small oval choanocyte chambers, 25-40μm diameter. Mesohyl heavily reinforced with collagen and containing scattered small (possibly juvenile) spicules.

Spicules (refer to Table 1 for dimensions): Oxeas relatively short, slender, slightly curved at centre, occasionally asymmetrical, tapering, fusiform, sharply pointed but usually with very slightly telescoped points at absolute apex of spicule (Fig. 14A).

ASSOCIATIONS

No symbiotic cyanobacteria were seen in any of the three specimens examined.

REMARKS

Cymbastela cantharella is apparently unlike all other species of the genus in that it contains a number of biologically active metabolites (Lévi, 1983, and pers.comm.), although the nature of this

chemical activity is not yet published. It also differs from other tropical species in lacking any evidence of symbiotic microalgae, and in this respect it is similar to the two temperate species described here. *Cymbastela cantharella* has other features typical of the genus, especially growth form - being thinly flabellate with irregular, buttressed surface processes similar to those seen on *C. stipitata*, and the geometry of the oxeas is also similar in these two species. However, the New Caledonian species differs from other *Cymbastela* in external colouration (orange alive, possibly due to the lack of photosynthetic pigments found in other tropical species), prominent surface sculpturing on the oscular face of cups, skeletal architecture (having a dense radial-plumose skeleton, with a secondary paucispicular secondary reticulate skeleton, with an overall nearly-halichondroid appearance, and radial-plumose ectosomal skeleton), and specific dimensions of oxeas (Table 1).

SUBSTRATE AND DEPTH RANGE

Coral reef substrates, including lagoon, sloping fringing reef, irregular coral boulders with muddy sand between, gorgonian beds, and also areas of high sedimentation. Depth range extends from subtidal to 20m.

GEOGRAPHICAL DISTRIBUTION

Northern, central and southern sections of the Great Barrier Reef, Queensland (Fig. 17C).

ETYMOLOGY

The species name refers to the restricted distibution of all material so far described, the sponge being found exclusively on coral reefs.

DESCRIPTION

Shape: Large vase-shaped, cup-shaped or simply lamellate growth forms, usually with large marginal opening, or sometimes nearly flattened completely against substrate, 80-170mm high, up to 350mm maximum marginal diameter. Usually attached to substrate by short stalk, up to 30mm high, 25mm diameter, sometimes lamellae are direct outgrowths of the basal attachment. Lamellae relatively thick, lobate, 8-15mm thick excluding lateral projections (Fig. 15).

Surface features: External, exhalant, surface optically smooth, relatively even, with or without bumps, ridges and lateral growths. Internal, inhalant, surface relatively uneven, often with concentric striations and ridges, or with irregular bumps, lobate growths and depressions on lamella walls, typically with small digitate or lobate projections at centre of cup. Occurrence and development of surface outgrowths, on both interior and exterior surfaces of lamellae is highly variable. Oscules small, 0.5-2mm diameter, dispersed on tips of microconules or ridges on interior surface of cups, subdermal canals visible below slightly translucent ectosome (Fig. 15C-D).

Colour: Live colouration typically mottled olive-brown (Munsell 7.5YR 5/4), olive-green (5Y 6/6) with maroon-brown tinge externally (5R 4/2), green (7.5GY 3/4) or olive-green internally (2.5GY 5/4). Colour in ethanol white or greenish-white.

Texture: Compressible, difficult to tear, rough exterior texture.

Ectosome: Ectosome microscopically hispid, with specialised skeleton. Subectosomal skeleton ascending, plumose, produced by pauci- or multispicular tracts of larger, choanosomal oxeas running at right angles to surface, overlain by specialised ectosomal skeleton of tangential, multispicular brushes made up of smaller ectosomal oxeas. Specialised dermal skeleton markedly plumose, mostly orientated tangentially or paratangentially to surface (Figs 16, 17B).

Choanosome: Choanosomal skeleton with only slight axial condensation, with axial and extra-axial components only slightly differentiated (Fig. 17B). Axial region predominantly radial-plumose, less markedly plumo-reticulate, with skeletal lines mostly directed longitudinally through lamellae, but gradually ascending towards peripheral skeleton; extra-axial skeleton more-or-less radial-plumose, with multispicular ascending spongin fibres interconnected by paucispicular transverse fibres (Fig. 16). Spongin fibres well formed but only very lightly invested with spongin, 75-110μm diameter. Fibre reticulation forms elongate oval to elliptical meshes, 85-350μm diameter, relatively similar in diameter between axial and extra-axial regions; choanocyte chambers relatively large, oval, 90-210μm diameter. Ascending fibres cored by multispicular tracts of larger choanosomal oxeas, whereas transverse fibres uncored or with uni- or paucispicular skeletal lines. Mesohyl matrix reinforced with moderate quantities of collagen. Very thin, smaller oxeas, similar in length to those on surface skeleton are dispersed throughout the mesohyl, possibly juvenile forms of larger choanosomal oxeas.

Spicules (refer to Table 1 for dimensions): Choanosomal oxeas thick, slightly curved at centre, typically symmetrical, occasionally anisoxeote, with hastate-rounded or slightly pointed, usually very faintly telescoped ends. Ectosomal oxeas thin, mostly straight, fusiform, with sharply pointed, rarely telescoped ends (Fig. 17A).

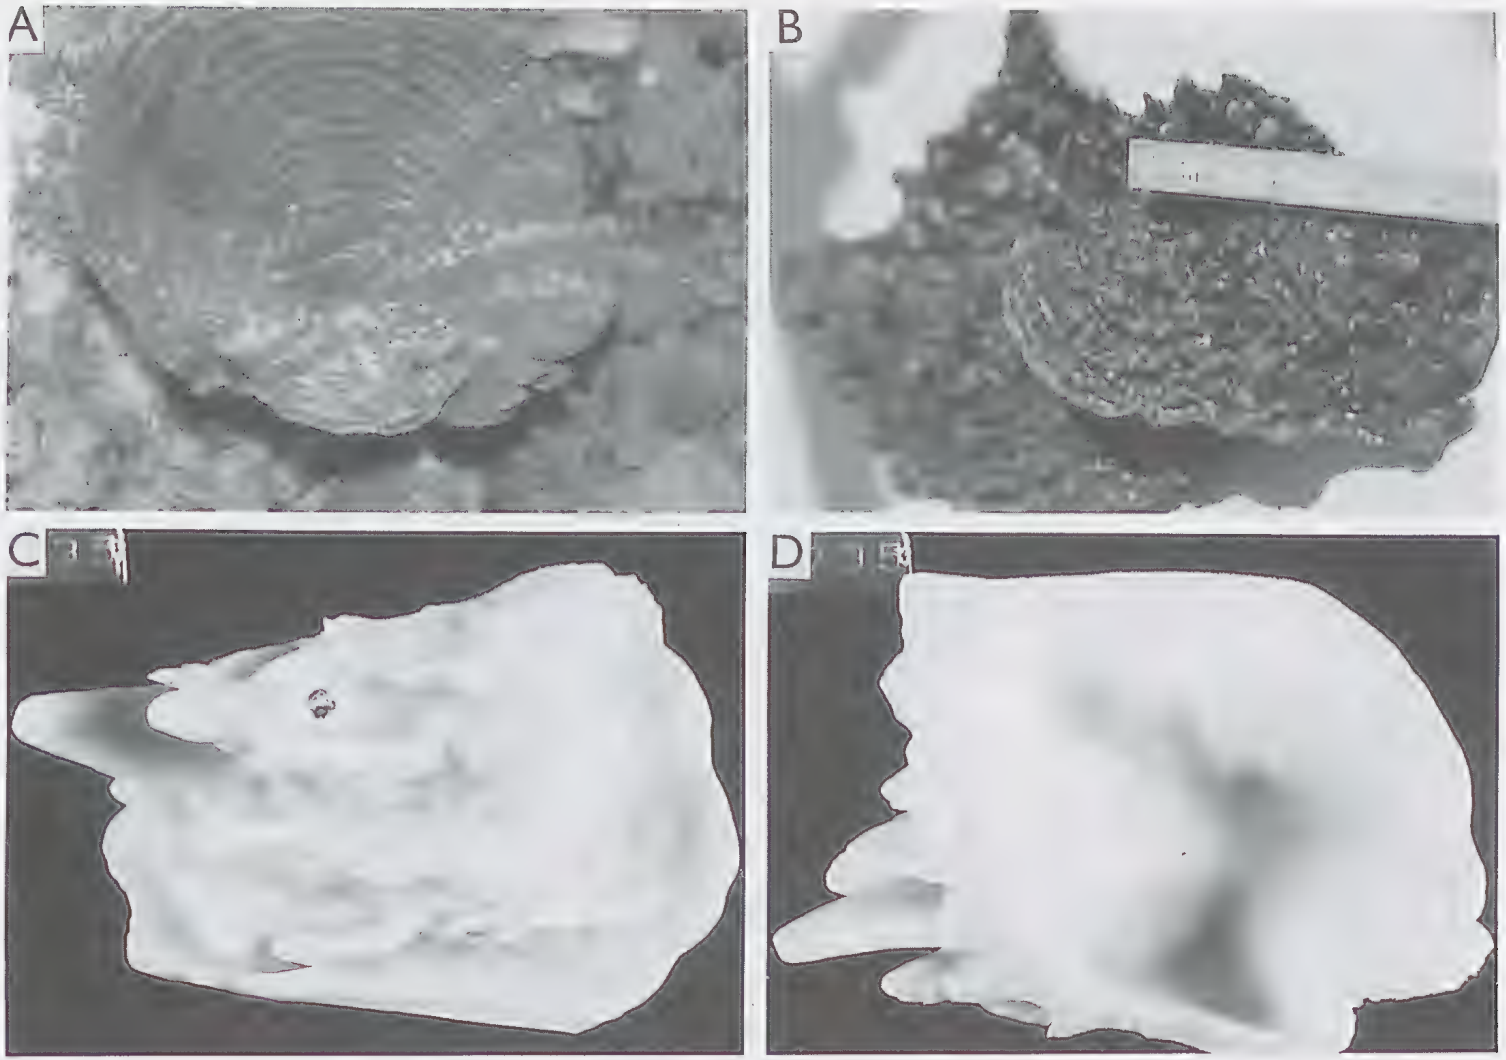

FIG. 15. *Cymbastela coralliophila* sp.nov. A, specimen in situ (NTM Z2735; photo C. Wilkinson). B, specimen (NTM Z3166), showing interior surface of lamellae in live state. C-D, specimen (NTM Z2735), showing close up view of exterior (C) and interior (D) surfaces of lamellae, in preserved state.

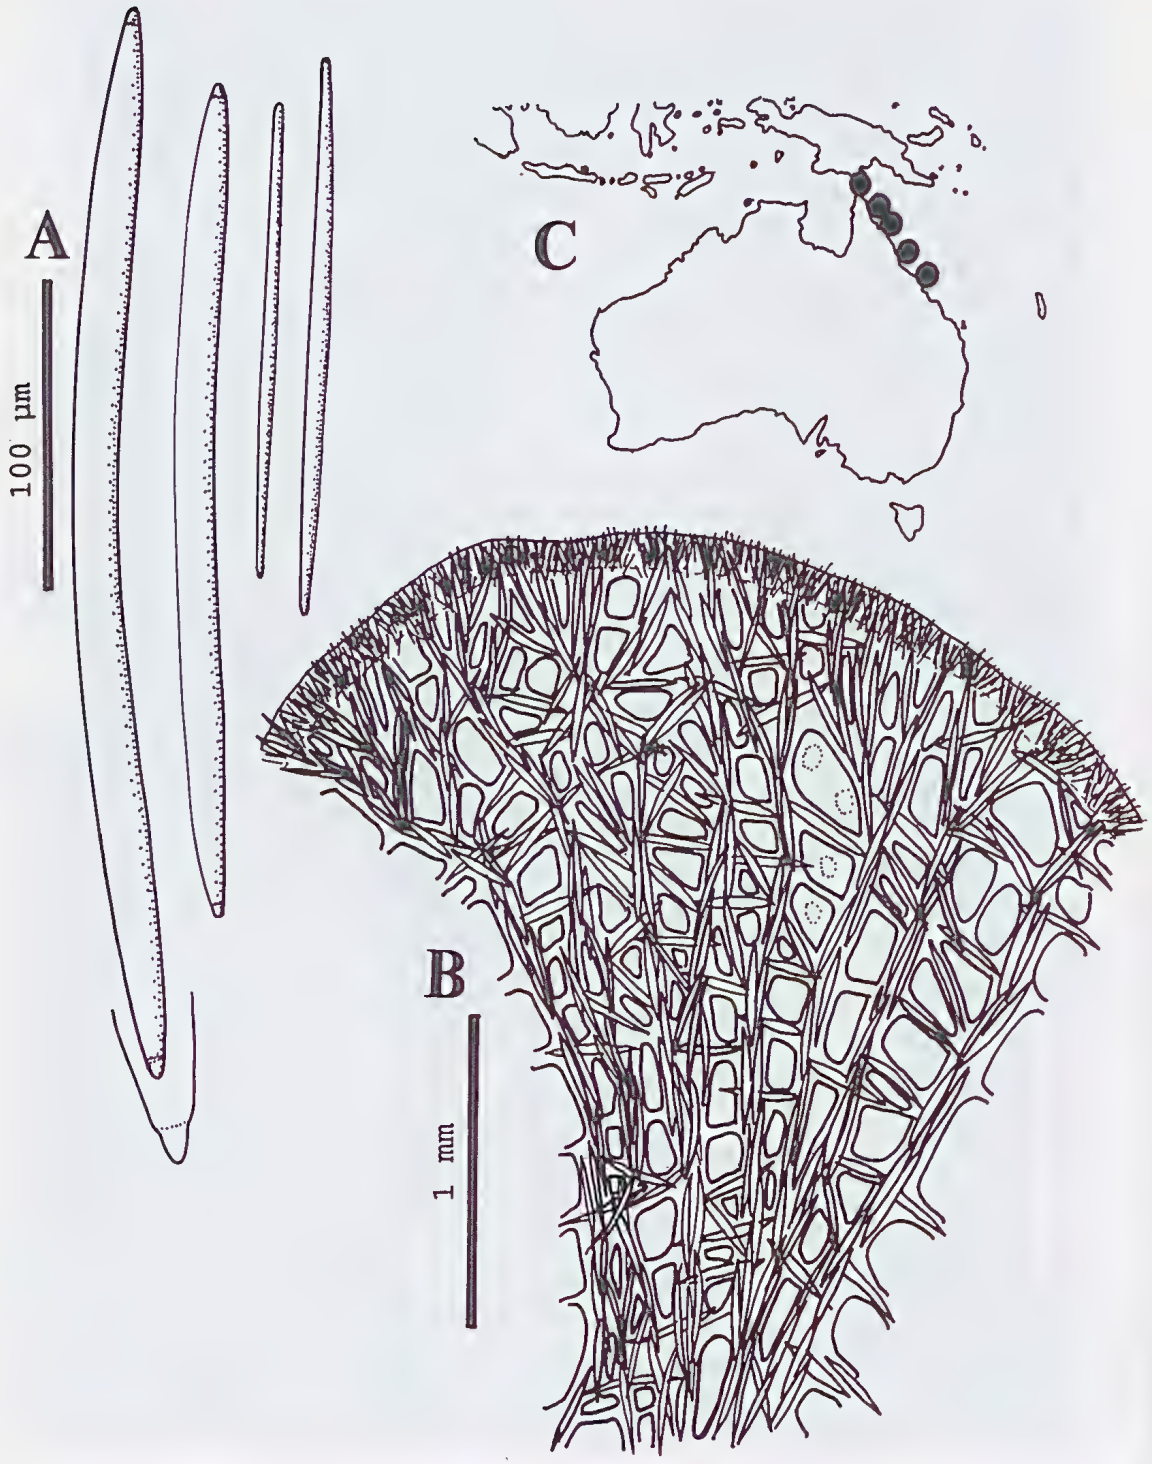

FIG. 17. *Cymbastela coralliophila* sp.nov. (specimen NTM Z2735). A, choanosomal and ectosomal spicules. B, section through peripheral skeleton. C, known distribution.

Reproduction

Oviparous, with synchronous release of eggs and sperm (A. Ayling, pers. comm.).

Associations

Sponges tested chlorophyll positive, and it is likely that the species' live pigmentation is partially or entirely produced by cyanobacterial symbionts. Several specimens also had numerous zoanthids on upper and lower surfaces, and barnacles (*Acasta* sp.) embedded within the mesohyl.

Remarks

Cymbastela coralliophila has been recorded frequently from the Great Barrier Reef, but until now it has remained undescribed.

The species conforms with Burton's (1931) interpretation of the genus *Axinyssa*, as distinct from his nominal genus *Pseudaxinyssa*, in that it contains two distinct size classes of oxeas, the smaller found predominantly on the surface, the larger forming the structural skeleton. On the other hand, the very close similarities in growth form, skeletal architecture and spiculation that exist between this species and the other Australasian lamellate *Cymbastela* suggests that this feature is not important above the species level of classification. *Cymbastela coralliophila* also differs from other members of the genus, as construed here, in having an almost flattened, usually relatively large cup-shaped growth form, with flabellate lamellae. The skeletal structure is most similar to *C. cantharella*, with the radial-plumose skeletal tracts predominant over the reticulate component of the skeleton, and with only minor differences between the axial and extra-axial regions. The species are contrasted further in Table 1.

Cymbastela marshae sp.nov.

(Figs 18-20, Table 1)

Material Examined

Holotype: NTM Z2876: Northern edge of Pelsar Islets, Houtman-Abrolhos Is, WA, 28° 47.6'S, 114° 00.7'E, 25m depth, 09.vii.1987, coll. J.N.A. Hooper, USSR RV 'Akademik Oparin', SCUBA (stn JH-87-001).

Other Material: Houtman-Abrolhos Is, WA - NTM Z2901 (fragment QM G300005): Pelsar Islets, 28°47.2'S, 113°58.5'E, 22m depth, 10.vii.1987, coll. J.N.A. Hooper, USSR RV 'Akademic Oparin', SCUBA (stn JH-87-002). NCI Q66C-4198-F: 1.5 km N of northern point, West Wallabi I., Wallabi Group, 28°25.7'S, 113°42.0'E, 8m depth, 12.ix.1990, coll. NCI, SCUBA.

Substrate and Depth Range

Growing at base and on reef slope of *Acropora* and *Seriatopora* coral reef, in sand, silt or rock substrates, in *Turbinaria* zone, 8-25m depth.

Geographical Distribution

Known only from the Houtman-Abrolhos Islands, WA (Fig. 20C).

Etymology

Named after Mrs Loisette Marsh, Curator of Marine Invertebrates, Western Australian Museum, Perth, in respect of her dedication to the study of the marine fauna of Western Australia.

Description

Shape: Thin, irregularly lamellate lobes forming asymmetrical vases, or symmetrical cup-shaped sponges, 125-255mm high, 120-235mm wide at apex of lamellae, with thin lamellae, 2-6mm maximum width, attached directly to substrate by a basal attachment, without a basal stalk (Fig. 18).

Surface features: Smooth, relatively even surface. Exterior surface with few low, irregular bumps, shallow depressions and concentric ridges, with or without horizontal lamellate projections growing on side of exterior surface. Interior, oscular surface of lamellae smooth, with concentric ridges, few low, irregular conules or depressions, sometimes with secondary lamellae or whole cups growing within interior surface. Very small oscules scattered over interior of cups, up to 1.5mm diameter.

Colour: Olive-green and maroon alive (Munsell 5Y 5/4 and 2.5R 4/8), evenly pigmented on exterior and interior surfaces, beige in ethanol.

Texture: Firm, flexible, slightly compressible texture, smooth to touch, difficult to tear.

Ectosome: Membraneous, without specialised skeleton, with plumose brushes of choanosomal oxeas protruding through surface for up to 170μm, consisting of 2-8 spicules per bundle. Ectosome with thin layer of darker pigmented granular collagen, 40-70μm wide, with heavy concentrations of microalgae, and also with a thin, disorganised paratangential layer of choanosomal oxeas scattered between erect, protruding ectosomal brushes. Subectosomal skeleton cavernous, predominantly plumose, slightly reticulate, with reticulate component decreasing closer to periphery (Figs 19, 20B).

Choanosome: Choanosomal skeleton plumoreticulate, with axial skeleton dominated by longitudinal tracts running through lamellae, gradually ascending towards surface, becoming

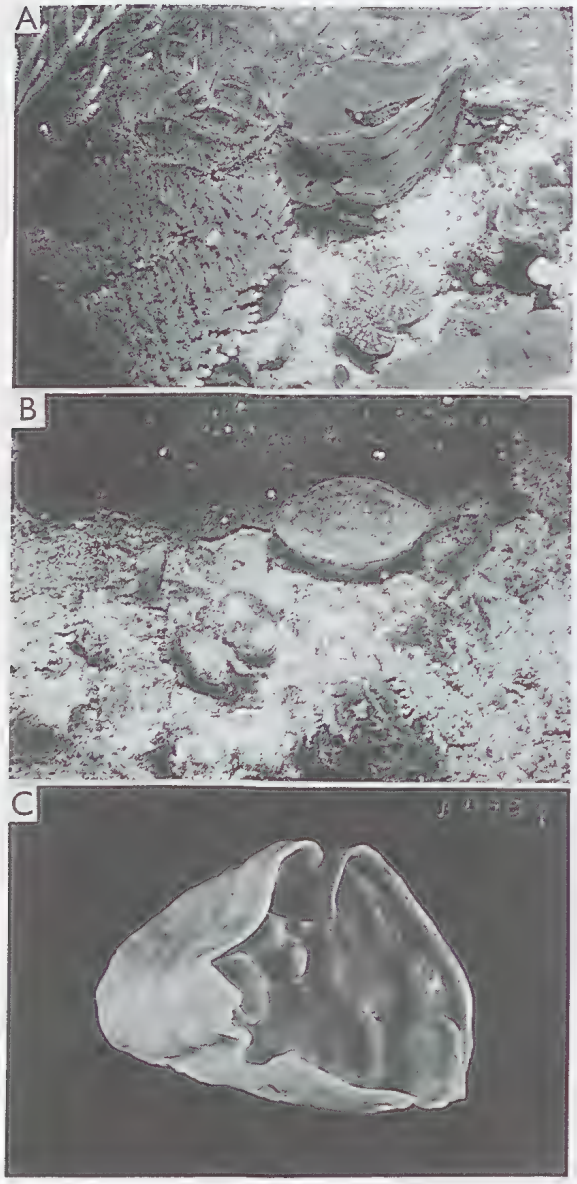

FIG. 18. *Cymbastela marshae* sp.nov. A, holotype (NTM Z2876), in situ. B-C, specimen (NTM Z2901) in situ (B) and preserved (C).

nearly plumose near peripheral skeleton (Fig. 20B). Axial skeleton slightly condensed at centre of lamella with reasonably well differentiated axial and extra-axial regions. Spongin fibres well developed, with obvious differentiation between multispicular primary (longitudinal and ascending) and uni- or paucispicular secondary (transverse, connecting) elements (Fig. 19). Primary fibres 30-80μm diameter, rarely fully cored with megascleres, secondary fibres much smaller, 15-25μm diameter, usually with greater silica to spongin ratio. Fibre meshes elongate oval or diamond-shaped in axis, 70-105μm maximum diameter, generally more cavernous in periphery, up to 150μm maximum diameter. Choanocyte chambers small, up to 45μm diameter. Mesohyl matrix only lightly invested with collagenous spongin, with abundant microalgae scattered throughout.

Spicules (refer to Table 1 for dimensions): Oxeas relatively short, slender, slightly curved at centre, with tapering, fusiform, usually telescoped points (Fig. 20A).

ASSOCIATIONS

Although not analysed chemically (acetone extracted), the olive-green and maroon pigments of this species are probably due to the presence of cyanobacteria scattered within the mesohyl. Each of the specimens examined was also found to have several barnacles boring within the lamella wall, near the base of the sponge.

REMARKS

This species is most closely related to *C. stipitata* in skeletal structure, as the plumose longitudinal and ascending primary tracts dominate the skeletal architecture. Both species have condensed axial regions and differentiated axial and extra-axial skeletons, with well developed plumose ectosomal skeletons. *Cymbastela marshae* also has a cavernous subdermal region, and spicules are about half the dimensions of those in *C. stipitata* (Table 1). The present species is close to *C. coralliophila* in growth form, lamella thickness and surface pigmentation.

Cymbastela notiaina sp.nov.
(Figs 21-23, Table 1)

MATERIAL EXAMINED

HOLOTYPE: SAM TS4025 (fragments NTM Z1623a, QM G300007): Precise locality unknown, Gulf of St Vincent, SA, 34°33-45'S, 137°57'-138°10'E, depth and date of collection unknown.

SUBSTRATE AND DEPTH RANGE

Unknown.

GEOGRAPHICAL DISTRIBUTION

South Australia (Fig. 23C).

ETYMOLOGY

Greek, *notos*, south; *notiaina* refers to the southern distribution of this species.

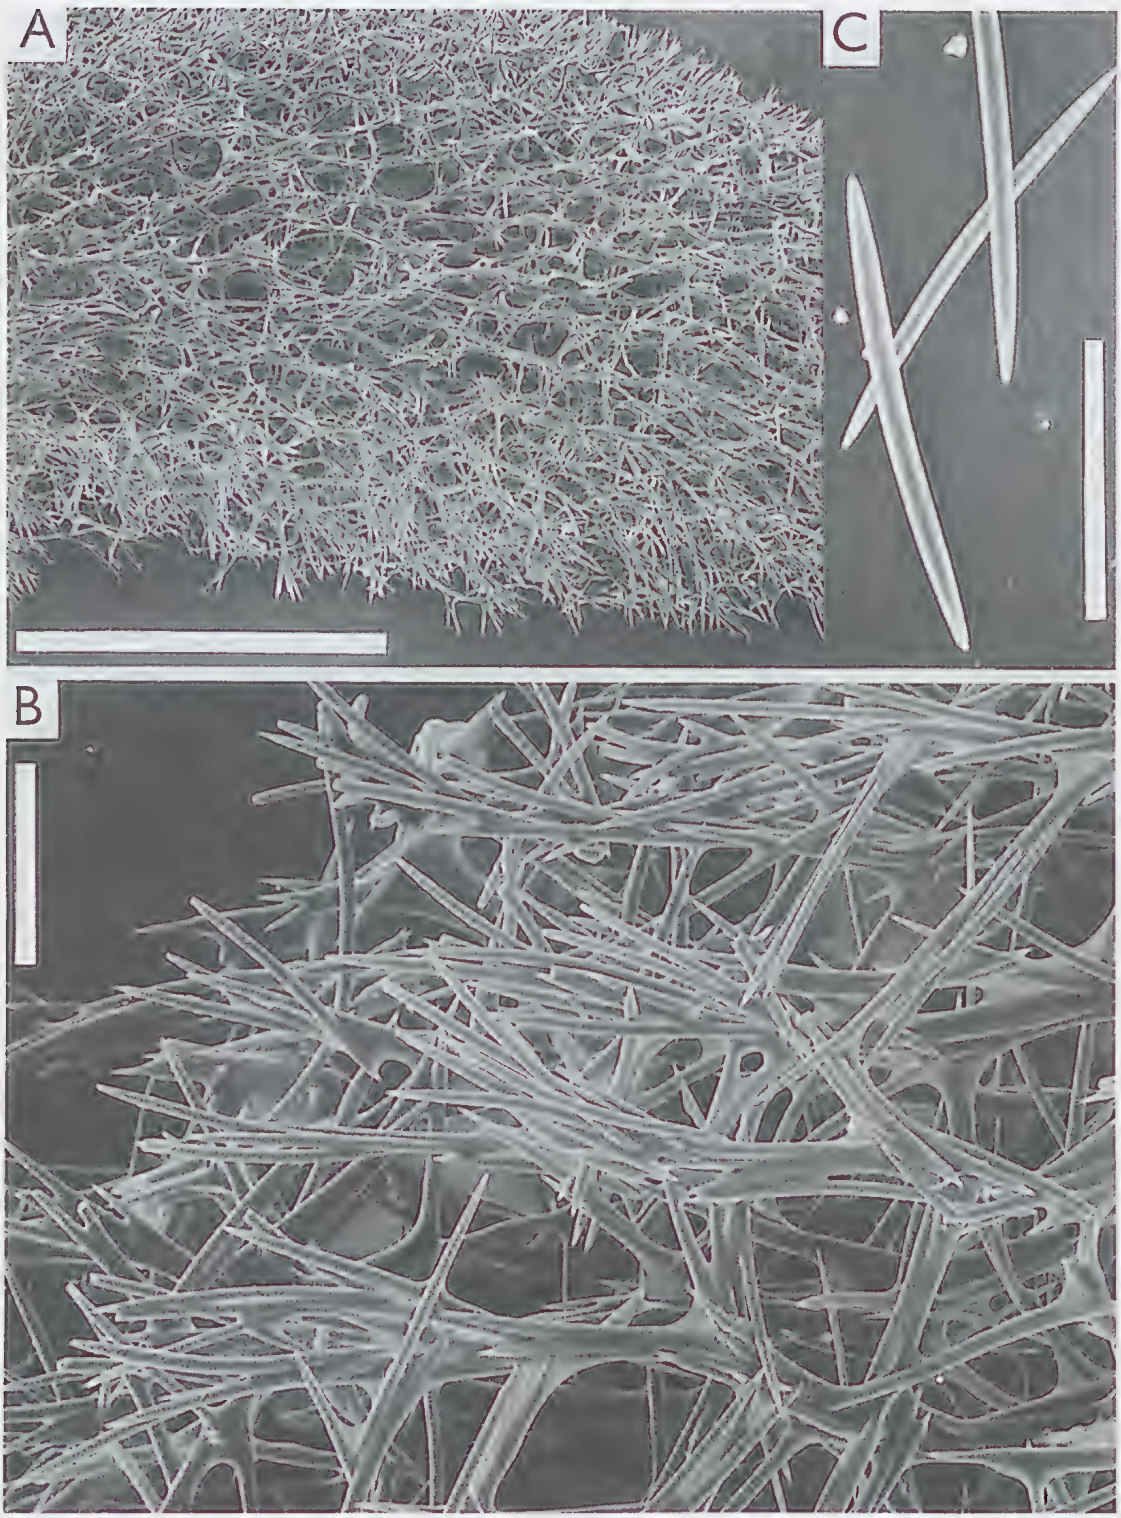

FIG. 19. *Cymbastela marshae* sp.nov. A, SEM of skeleton (specimen (NTM Z2901) (scale=1mm). B, peripheral skeletal architecture (scale=100μm). C, oxeas (scale=100μm).

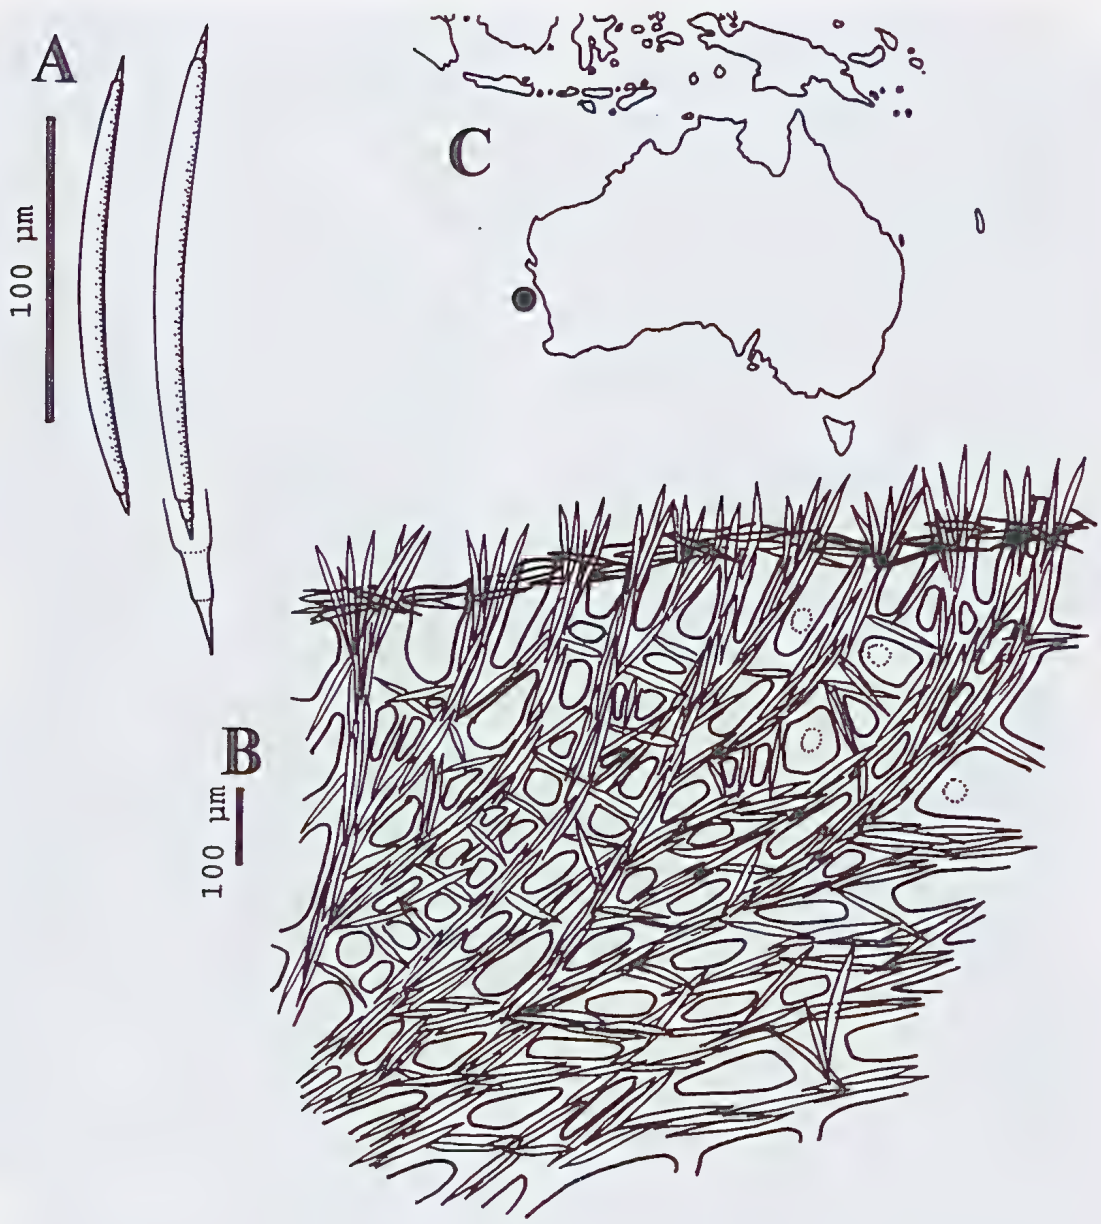

FIG. 20. *Cymbastela marshae* sp.nov. A, spicules. B, section through peripheral skeleton. C, known distribution.

DESCRIPTION

Shape: Small, symmetrical vasiform sponge, 96mm high, 125mm maximum diameter at apex of cup, on short thick stalk with expanded basal attachment, 12mm long, 35mm diameter, and thin lamellae, 3-5mm thick (Fig. 21).

Surface features: Interior and exterior surfaces optically even, without conules, buttresses or other lateral growth projections. Exterior surface has longitudinal, concentrically striated ridges. Oscules minute, less than 1mm diameter, dispersed over interior surface of cup.

Colour: Live colouration unknown, olive-brown in ethanol.

Texture: Firm, flexible, compressible in preserved state, smooth to touch.

Ectosome: Ectosome optically smooth, membraneous, slightly hispid due to protruding

spicule brushes, slightly microconulose, with microconules corresponding to surface brushes. Ectosomal skeleton distinctly plumose, with bundles of 2-15 choanosomal spicules protruding up to 90μm from surface, perched on ends of ascending extra-axial skeletal tracts (Figs 22, 23B).

Choanosome: Choanosomal skeleton with no axial condensation, and only slightly differentiated axial and extra-axial regions (Fig. 23B). Skeleton almost regularly reticulate at the core, with oval meshes, 70-120μm diameter, formed by multispicular spongin fibres, both longitudinal and connecting. Skeleton plumo-reticulate towards periphery, with ascending multispicular fibres predominant over uni- or paucispicular transverse connecting fibres. Spicules form plumose brushes close to, and protruding from, surface. Fibre meshes in peripheral skeleton elongate-rectangular, slightly larger than in axis, 100-140μm diameter (Fig. 22). Spongin fibres relatively large, 40-85μm diameter, partially but never fully occupied by spicules. Mesohyl matrix lightly reinforced with collagen, choanocyte chambers oval, 40-90μm diameter.

Spicules (refer to Table 1 for dimensions): Oxeas almost vestigial by comparison with other species, poorly silicified, very thin, small, only slightly curved at centre, with prominently telescoped ends and rounded tips (Fig. 23A).

Associations

No symbiotic cyanobacteria were seen in the holotype.

Remarks

This species is presently known only from the holotype described above, although a small fragment from a second specimen exists in the SAM collection (SAM TS4058 [section/fragments NTM Z1665, QM G300011], from Port Noarlunga, SA), may also belong to the species. *Cymbastela notiaina* is easily differentiated from other taxa by its regular, nearly completely reticulate choanosomal skeleton, the small size of megascleres (Table 1), and the telescoped, rounded (strongylote) points of oxeas, unlike any other species.

DISCUSSION

Taxonomy

Small differences in field characteristics, such as live colouration, growth form, surface features, including outgrowths on the surface and lamellae thickness, as described above for each species, can serve as field identifiers for the seven known species of *Cymbastela.* However, morphological differences seen in preserved material, which correlate with these species boundaries are less obvious. Certainly, in terms of general skeletal structure and spicule geometry the genus is relatively homogenous, and it is only through small but significant differences in a small number of skeletal characters that species can be reliably differentiated. These characters, which are shown to be most important, include spicule length, spicule geometry, including the presence or absence of telescoped ends on spicules, and degree of silicification, and the relative, proportional development of the axial and extra-axial skeletons. On this basis it was possible to construct a key to species of *Cymbastela* (see above), with emphasis given to the morphology of preserved specimens. Thus, whereas the characters used to differentiate species in this key may seem trivial, these differences correspond with more obvious field characteristics, many of which are no longer visible in the preserved material.

It was also noted that, in general, species could be separated by their mean spicule dimensions. Generally, the relative size of oxea megascleres decreases with increasing latitude (Fig. 24A-B), such that species from low (tropical) latitudes (*C. stipitata, C. coralliophila, C. vespertina*) have larger oxeas than those species from higher latitudes (*C. cantharella, C. marshae, C. notiana*). *Cymbastela concentrica*, which has a wide latitudinal distribution (14-26°S; Fig. 24B), also has a relatively wide range of spicule dimensions (Fig. 24A, symbol 5).

Biogeography

Although it is possible that more extensive sampling along the cool temperate Australasian coastline will reveal additional species, *Cymbastela* is presently known to be predominantly a shallow water, tropical or subtropical genus, usually associated with coral substrates. The genus appears to be endemic to the Indo-west Pacific, extending only as far as New Caledonia (longitude 166°E) to the east, and to the Houtman-Abrolhos Islands (113.5°E) to the west, and so far there are no confirmed records of the genus from either Indonesia (unpublished *Siboga* and *Snellius II* collections, R.W.M. Van Soest, pers.comm.) or New Zealand (personal observations). However, it is possible that misidentified specimens of *Cymbastela* exist in other museum collections. The genus is certainly not present in the published

collections of Hentschel (1912), from the Aru and Kai Islands, southeast Indonesia (ZMB collections), in which close similarities with the northwest Australian sponge fauna can be seen (e.g. Hooper, 1991).

Three species of *Cymbastela* have restricted, allopatric distributions (*C. cantharella, C. marshae, C. notiaina*; Fig.25), whereas on the northwest and northeast coasts of Australia there are two groups of more-widely distributed, sympatric species. Within the northwestern area of sympatry (Fig. 25), there is some evidence of niche separation between the two populations, *C. stipitata* and *C. vespertina*. The former species has a predominantly shallow water distribution, found mostly in the intertidal region and only exceptionally down to 19m depth, whereas *C. vespertina* is found mostly in deeper water, only rarely above 8m depth. Population characteristics of the northeast Australian sympatric species, *C. coralliophila* and *C. concentrica*, have not yet been determined, and the latter species, in particular, is still poorly known.

PHYLOGENY

Under Van Soest et al.'s (1990) interpretation of the existing family Axinellidae *Cymbastela* would be placed with a group of genera having axially condensed and extra-axially plumo-reticulate skeletons, for example *Auletta, Axinella, Axinosia, Homaxinella, Phakellia, Pseudaxinella, Reniochalina* and *Teichaxinella*, which Van Soest et al. (1990) retained in a newly defined concept of family Axinellidae. Of these genera *Cymbastela* is most closely related to *Axinella*. Conversely, they placed the genus *Axinyssa*, previously considered to be a close relative of '*Pseudaxinyssa*' s.l. (= *Cymbastela*), in a redefined family Halichondriidae since it has poorly developed spicule tracts. This group would contain 'axinellid' genera such as *Axinyssa* and *Amorphinopsis*, several genera previously in-

FIG. 21. *Cymbastela notiaina* sp.nov. A, holotype (SAM TS4025).

cluded in Desmoxyidae (e.g. *Myrmekioderma*), and other genera traditionally associated with the halichondrids and hymeniacidonids (e.g. *Ciocalypta*, *Hymeniacidon*). A third group of 'axinellids' with dendritic skeletons (e.g. *Acanthella*, *Dictyonella*, *Scopalina*), were removed to the new family Dictyonellidae. The fourth family, Desmoxyidae, wäs also previously aligned with the Axinellida, differing from other 'axinellids' in having a reticulate-fasciculate choanosomal skeleton and a fleshy corrugated surface (Van Soest et al., 1990:18). It contained several desmoxyid genera (e.g. *Higginsia*), but excluding *Myrmekioderma*, as well as some Axinellidae (e.g. *Ptilocaulis*). We consider that these new family divisions proposed by Van Soest et al.

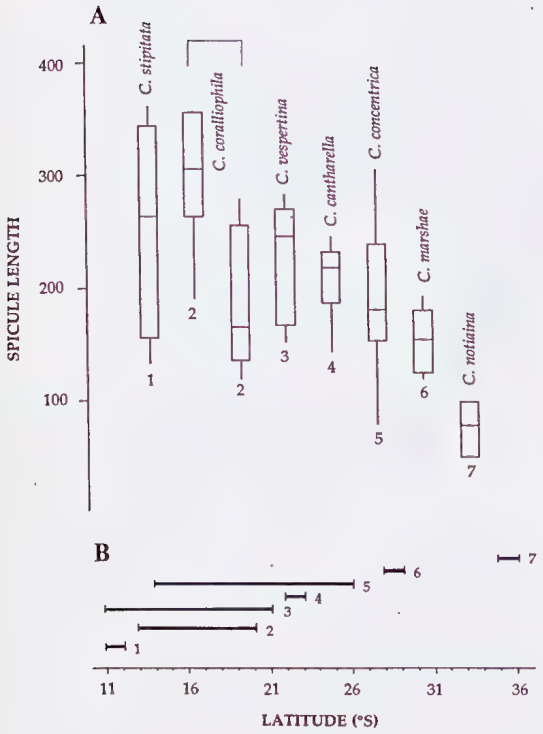

FIG. 24. A, Comparison in spicule lengths (μm) between seven species of *Cymbastela*, and B, latitudinal differences in distribution for each species. Box-and-whisker plots show the range of spicule dimensions (i.e. 'whiskers'), the median values (i.e. 50% of data values, between lower and upper quartiles - open boxes), and the average length of oxeas for each species (i.e. mid-range bars). Key to species codes: 1, *C. stipitata*; 2, *C. coralliophila* (large and small oxeas); 3, *C. vespertina*; 4, *C. cantharella*; 5, *C. concentrica*; 6, *C. marshae*; 7, *C. notiaina*.

(1990) have some merit over the existing, confused system for Axinellidae - Halichondriidae - Hymeniacidonidae, but we are uncertain whether all these 'axinellids' and 'halichondrids' have a monophyletic origin, and we leave open the question of their ordinal classification for the time being. Further evidence from molecular and genetic nature may be useful in evaluating these relationships in an objective context.

ACKNOWLEDGEMENTS

We thank Peter Murphy and associates (NCI, Townsville), Clive Wilkinson (AIMS, Townsville) and Cécile Debitus (ORSTOM, Noumea), for providing access to their diverse collections of marine sponges from Australia and New Caledonia; Prof. Georgy Elyakov, scientific staff and crew of the USSR RV 'Akademik Oparin' (PIBOC) for their collaborative field work at the Houtman-Abrolhos Islands (1987); Avril Ayling ('Sea Research', Daintree) for unpublished information on reproductive observations, Tony Larkum (Sydney University) for other information on several of the new species described here, and Rob Van Soest (ZMA, Amsterdam) for valuable unpublished information and comments on the manuscript. Penny Barents (AM, Sydney), Shane Parker (SAM, Adelaide), Shirley Stone (BMNH, London), Claude Lévi (MNHN, Paris), Dieter Kühlmann (ZMB, Berlin), Klaus Ruetzler (USNM, Washington) and Manfred Grasshoff (SMF, Frankfurt) are thanked for providing access to type material from their respective collections.

THE TADPOLE OF THE AUSTRALOPAPUAN FROG *RANA DAEMELI*. *Memoirs of the Queensland Museum 32(1): 138. 1992:-* The ranid frog *Rana daemeli* (Steindachner) is widespread in New Guinea and, in Australia, occurs in northern Queensland north of Townsville (Menzies, 1987; pers. obs.).

Little is known of the biology of this species. Zweifel (1980) and Menzies (1987) analysed calls of *R. daemeli* from Papua New Guinea, and Menzies (1987) described the form of the spawn. In this note I describe the tadpole of *R. daemeli* from northern Queensland.

Tadpoles were collected with a dip net and preserved immediately in 10% formalin, or returned to the laboratory where they were kept in glass aquaria and fed fresh algae. Measurements of preserved specimens were made using a dissecting microscope with an eyepiece micrometer. All measurements are in millimetres; those involving apertures were taken from the centre of the aperture. Terminology follows Altig (1970), and the staging system is that of Gosner (1960).

Tadpoles were collected in Melaleuca swamps and temporary and permanent streams between Ollera Creek, 63km north of Townsville, and Cape Tribulation. Specimens were found primarily among debris and algae in the deepest sections of these habitats. Tadpoles and metamorphs have been collected during March, May and September, indicating that this species has an extended breeding season, or that larval development is extended.

A stage 36 tadpole is illustrated in Figure 1. Details of the oral disc are illustrated in Figure 2. A stage 36 tadpole has the following measurements: 59.6 total length, 22.0 body length, 6.4 basal tail muscle height, 5.9 basal tail muscle width, 4.0 maximum dorsal fin height located 14.8 from body terminus, 3.0 maximum ventral fin height located 16.8 from body terminus, 12.3 maximum body width, 10.2 maximum body height, 2.6 eye diameter, 7.3 interorbital distance, 3.8 internarial distance, 2.7 snout-naris, 7.0 snout-eye, 11.2 snout-spiracle, 4.2 naris-eye, 4.5 transverse oral disc diameter. Other major characteristics include; oral disc emarginate, oriented anteroventrally; marginal papillae large, in a single row laterally, two rows posteriorly, a wide gap anteriorly; papillae on posterior margin extremely elongated, forming a fringe along the posterior margin of the disc; submarginal papillae only at the corner of the jaws; spiracle short, sinistral, located ventrolaterally and oriented posterodorsally; vent tube dextral, attached to ventral fin, opening 4.0 from tail-body junction.

The tooth row formula is 2(2)/3(1). The A2 gap is wide, and the P1 gap extremely narrow. The keratinised jaw sheaths are narrow and serrated. The upper sheath is broadly curved, and the lower sheath broadly V-shaped. The eyes are dorsal. The nares are extremely small, and are covered with skin in some specimens. The fins are low, tapering to a narrow but not sharp point.

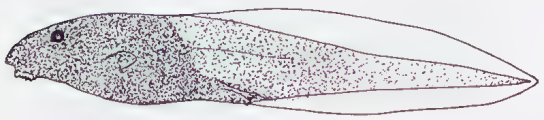

FIG. 1. Lateral view of a stage 36 *Rana daemeli* tadpole. Scale bar = 15mm.

FIG. 2. Oral disc of a stage 36 *Rana daemeli* tadpole. Scale bar = 1mm.

In life tadpoles are heavily pigmented dorsally with gold and black, with a green tinge along the midline. Black pigmentation is more prominent laterally. Tadpoles are dark grey on the anterior portion of the ventral surface, and light grey with a purple tinge on the posterior portion of the ventral surface. Small clumps of gold pigment occur on the fins. A tadpole reared to metamorphosis was olive green dorsally and grey ventrally, weighed 1.42g and was 24.3mm in length. These tadpoles belong to the Benthic (Type 2: Profundal) ecomorphological guild of Altig & Johnston (1989). The typical ranid features of an emarginate oral disc and a fringe of elongated papillae along the posterior margin of the disc (Webb & Korky, 1977) should serve to distinguish this species from other Australian tadpoles so far described.

R. Alford commented on the manuscript. Field work was funded by ARC grant A18931875 to R. Alford.

TRACE FOSSILS FROM THE PHE FORMATION (LOWER CAMBRIAN), ZANSKAR VALLEY, NORTHWESTERN INDIA

NIGEL C. HUGHES AND MARY L. DROSER

Hughes, N.C. & Droser, M.L. 1992 06 29: Trace fossils from the Phe Formation (Lower Cambrian), Zanskar Valley, northwestern India. *Memoirs Queensland Museum* **32**(1):139-144. Brisbane. ISSN 0079-8835.

Trace fossils from the upper part of the Tsarap Member of the Phe Formation, Zanskar Valley, northwest India, provide the first evidence for the age of these strata. *Taphrhelminthopsis* cf. *circularis* and *Helminthopsis* sp. suggest an Early Cambrian age. *T.* cf *circularis* in the absence of body fossils may indicate that these traces predate the trilobites and are correlative with the Tommotian. □ *trace fossil, Cambrian, Himalaya.*

Nigel C. Hughes, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; Mary L. Droser, Department of Earth Sciences, University of California, Riverside, CA. 92521, USA; *10 April, 1992.*

The lower Palaeozoic history of India is not well known, despite much recent work. The Zanskar region is particularly poorly understood, although a series of recent studies provide some understanding of the early Palaeozoic in this region (Nanda & Singh, 1976; Srikantia et al., 1980; Gaetani et al., 1986; Garzanti et al., 1986; Whittington, 1986). Trace fossils studies are currently of special significance because the Precambrian-Cambrian boundary is formally based on the appearance of key ichnogenera (Narbonne et al., 1987). This paper records trace fossils within the Phe Formation and constrains the position of the Precambrian-Cambrian boundary in this region.

TRACE FOSSILS AND THE PRECAMBRIAN-CAMBRIAN BOUNDARY IN INDIA

Following Seilacher's (1955) pioneering work on the trace fossils of the Salt Range in Pakistan recent work in India has concentrated on the use of trace fossils for recognising the Precambrian-Cambrian boundary (Tandon & Bhatia, 1978; Bhargava et al., 1982; Bhargava & Srikantia, 1982; Raina et al., 1983; Kumar et al., 1983; Shah & Sudan, 1983, 1984; Singh & Rai, 1983; Kumar et al., 1984; Kumar, 1984). The diversity of trace fossils increases at stratigraphically higher levels in pre-trilobite bearing strata of India (Tandon & Bhatia, 1978; Raina et al., 1983; Kumar, 1984), which is consistent with patterns described from many sections worldwide (e.g. Fedonkin, 1979; Crimes & Anderson, 1985; Fritz & Crimes, 1985; Crimes, 1987; Narbonne & Myrow, 1988; Narbonne et al., 1987). The Precambrian-Cambrian boundary is formally defined on the basis of trace fossils and, while initial progess has been made, much work is still needed before it can be accurately determined in the Indian Himalaya. Kumar et al. (1984, fig. 2) reported that *Phycodes* first occurs at the top of member A of the Lolab Formation in Kashmir, 750m above deposits containing Upper Riphean microflora. If complete, this section appears to be the best candidate for recognising the Precambrian-Cambrian boundary in India. A complete Precambrian-Cambrian boundary section may be present in the Krol-Tal belt, from which Ediacaran fossils (Mathur & Shanker, 1989; 1990), small shelly fossils (Bhatt et al., 1983) and archaeocyathids (Singh & Rai, 1983) have been reported. However, the Ediacaran faunas apparently occur above the small shelly fossils (Kumar, 1990), and the accuracy of some of these identifications is uncertain. M. Wade (pers. comm.) suspects that many, but not all, are algal or cyanobacterial mat structures.

STRATIGRAPHY AND TRACE FOSSILS OF THE PHE FORMATION

STRATIGRAPHY

Lowermost Palaeozoic rocks in the Zanskar Valley are assigned to three formations; the basal, silt/sandstone-dominated Phe Formation, the dolomitic Karsha formation and the silt-dominated Kargiakh Formation (Garzanti et al., 1986). Although Garzanti et al. (1986) noted bioturbation in the Phe Formation they did not recognise any fossils. Trilobite fragments have been reported (Garzanti et al., 1986) within the Karsha Formation, and late Middle Cambrian trilobites occur in the Kargiakh Formation (Garzanti et al., 1986) (some 400 m above the top of

the Phe Formation). These relationships suggest that the Phe Formation is older than late Middle Cambrian; some of the Phe Formation might be Precambrian (Garzanti et al., 1986), raising the possibility of a Precambrian-Cambrian boundary section in Zanskar.

The Phe Formation comprises at least 800 m of siltstones and fine-grained sandstone (Garzanti et al., 1986). It is divided into a silt-rich lower Tsarap Member, and an upper sandier Doda Member (Nanda & Singh, 1976). Nanda & Singh (1976) recognised an uppermost Thonde Member, from which trilobites have been collected at Kargiakh nulla (Dungrakoti et al., 1974). The trilobites were assigned to *Ptychoparia* sp and *Asaphus* sp and, on this basis, it was suggested that the Phe Formation is Upper Cambrian to Lower Ordovician (Gupta, 1978). However, further work has shown that fossiliferous strata in Kargiakh nulla are not part of the Phe Formation. Instead they overlie the Karsha Formation. These deposits are now assigned to the Surichun Member of the Kargiakh Formation (Garzanti et al., 1986). Although subsequent collection of the Kargiakh nulla site yielded neither *Ptychoparia* nor *Asaphus* (these assignments are likely incorrect), the agnostid *Lejopyge laevigata* confirms a latest Middle Cambrian age (Whittington, 1986). A variety of mid Middle Cambrian trilobites have recently been collected from the Kargiakh Formation, some from limestones, by Mr. A. Dogra and Dr. Sat Paul of Jammu University and are currently being described. As there are no major unconformities or structural discontinuities between the Kargiakh, Karsha and Phe Formations the age of the Karsha/Phe Formations is pre-mid Middle Cambrian.

Gupta & Shaw (1981) reported and figured *Ellipsocephalus hoffi* and *Agraulos* sp. which they claimed were collected from the Phe Formation in the Kargiakh and Doda valleys. Reasons to doubt the validity of this report include: 1, the grid co-ordinates given do not coincide with the positions of these localities; 2, the three dimensional, slightly distorted nature of their specimens contrasts with the condition of other Cambrian trilobites collected from the Himalaya, which are flattened and are strongly deformed; and 3, recollection of this area by M. Gaetani and N. Hughes has not revealed any fossils similar to those described by Gupta & Shaw (1981). Similar doubts about the reliability of Gupta & Shaw's (1981) paper has been recorded by Whittington (1986) and their paper should be disregarded, in line with the suggestion of Talent et al. (1990).

Trace Fossils

The Phe Formation was examined at several localities but trace fossils were observed only in the section due north of the village of Purni (33°8'24"N, 77°6'6"E) which corresponds to Section 1 on the map of Garzanti et al. (1986). These traces were described and photographed in situ and were not collected.

Within this section, traces occur in the upper part of the Tsarap Member of the Phe Formation, which is predominately composed of heterolithic dark grey siltstones and very fine grained light grey/buff sandstones. Sandstones are thinly bedded (1-5cm) and may be parallel, hummocky or cross stratified. Siltstones range from thin laminae to very thin beds (0.2-3.0cm). Where ripple structures are well preserved, wavy bedding is recognised (Fig. 1A). Wave, current, and interference ripples are all common on bedding surfaces (Fig. 1H). Short, narrow tool marks indicate palaeoflows towards the WSW. Slump features are common. The Phe Formation was deposited in an intertidal to shallow subtidal setting (Garzanti et al., 1986; pers. obs. N.C.H.).

Trace fossils are common on several bedding surfaces at the base of the section 100m north of Purni village. *Taphrhelminthopsis* cf. *circularis* (Fig. 1B-D) is most common occurring as a bilobate structure with a well defined, broad central furrow. Burrow width is 1.5-2.0cm. The furrow is about 0.2-0.3 of the width of the trace fossil. The trace fossils are sinuous to arcuate and up to 50cm long. Striations are not present. No complete circles were observed so specific assignment is questionable.

Helminthopsis (Fig. 1G) occurs as a groove, 0.2-0.4cm wide consisting of a central furrow with raised levees or as a full burrow. Traces are up to 15cm long, forming irregular meanders that were not observed to cross and commonly occur on rippled surfaces.

The tops of vertical burrows, 0.5-0.7cm in

H

diameter, some apparently paired, are present on bedding surfaces, but no cross sections of these burrows were observed. Horizontal *Planolites* burrows, up to 0.8cm wide and 7.0cm long, are also present. One possible example of a back-filled burrow (Fig. 1F) occurs in siltstones. The burrow is infilled with very fine sand.

A slab of Phe Formation in scree on the track between Purni and Testa villages (Fig. 1E) shows abundant horizontal traces and vertical *Skolithos* burrows, which are 0.5cm wide and unpaired. In cross section this slab shows an ichnofabric index of 3 (Droser & Bottjer, 1986).

DISCUSSION

The trace fossils indicate that these deposits are no older than Vendian. *Taphrhelminthopsis* is characteristic of Cambrian and younger strata (Crimes, 1987, in press). Fritz & Crimes (1985) reported *Taphrhelminthopsis* from Precambrian strata from the Cassiar Mountains, British Columbia but Crimes (1987) suggested that *Taphrhelminthopsis* in these strata indicates that perhaps the boundary in this section should be lower. In the current Precambrian-Cambrian boundary stratotype in Newfoundland Taphrhelminthopsis first occurs in the second trace fossil zone, (*Rusophycus avalonensis*) above the Precambrian-Cambrian boundary (Narbonne & Myrow, 1988).

Helminthopsis similarly first appears in Cambrian strata in well documented sections (Crimes, 1987) and is also thought to be characteristic of Phanerozoic strata. Both genera occur throughout the Phanerozoic and therefore do not further constrain the age. However, *Taphrhelminthopsis circularis*, appears to range from just above the first Phanerozoic-type traces to just below the first trilobites (Crimes, 1987, in press).

Skolithos, Planolites and simple back filled burrows, all appear in the Vendian and range through the Phanerozoic and therefore do not aid in age resolution.

Crimes (1992) recognised an evolutionary development of simple sediment filled burrows from the Precambrian to the Cambrian. The straight to slightly curved *Planolites* first occurs in Vendian deposits. Slightly more complex irregularly meandering burrows which cross, such as *Gordia*, occur later in the Vendian. Burrows which spiral and have first-order meanders appear subsequently. *Helminthopsis*, which consists of irregular, but non-crossing first and second order meanders normally first occur in Cambrian strata, and are characteristic of the Early Cambrian. Crimes (1992) reported increasing complexity of 'stuffed' burrows, with the meandering bilobate stuffed burrow *Taphrhelminthopsis* characterising Early Cambrian deposits.

We suggest that at least the upper part of the Tsarap Member is of Early Cambrian age based on *Helminthopsis* and *Taphrhelminthopsis,* and particularly the close similarity to *T. circularis*. If *T. circularis* is restricted to the pre-trilobite Cambrian (Crimes, 1987), it could explain the absence of body fossils in the Phe Formation. The Precambrian-Cambrian boundary may lie within the lower, unfossiliferous 200m of the Tsarap Member of the Phe Formation.

Like most other Early Cambrian trace fossil assemblages (Crimes & Anderson, 1985; Crimes, 1987) the fossils from the Phe Formation are found in shallow, nearshore deposits. *Taphrhelminthopsis* is common in the Lower Cambrian of India, occurring in the Himalaya in southeastern Kashmir (Bhargava & Srikantia, 1982) and in the Lesser Himalaya in the Tal Formation near Kauriyala, Uttar Pradesh (Kumar et al., 1983), and possibly near Mussoorie (Singh & Rai, 1983).

ACKNOWLEDGEMENTS

Peter Jell read the manuscript and offered helpful criticisms. Mary Wade kindly discussed aspects of the paper. N.C.H. gratefully acknowledges receipt of a Natural Environmental Research Council Fellowship which enabled him to visit the Himalaya. Rae and John Sheridan provided skillful assistance in the field and excellent companionship. Rigsen Jora facilitated our travel within the region. Dawa Jora and Punzok acted as guides and we are grateful to them and to our horsemen for assisting our safe passage. Isabel Montañez and Sue Turner kindly provided essential literature.

SCALPELLID BARNACLES (CIRRIPEDIA: THORACICA) FROM THE NORTHEASTERN AND CENTRAL EASTERN AUSTRALIAN CONTINENTAL SHELF AND SLOPE

DIANA S. JONES

Jones, D.S. 1992 06 29: Scalpellid barnacles (Cirripedia: Thoracica) from the northeastern and central eastern Australian continental shelf and slope. *Memoirs of the Queensland Museum* **32**(1): 145-178. Brisbane. ISSN 0079-8835.

Eleven species of scalpellid barnacles are described from continental shelf and slope waters off northeastern and central eastern Australia. Nine of these species were collected by the Cidaris I expedition which sampled barnacles mainly from the continental slope of north-eastern Queensland and the adjacent Coral Sea. The additional two scalpellid species were contained in the deep-water cirripede collections of the Queensland Museum, Brisbane, and the Australian Museum, Sydney. The species are fully described and illustrated since previous descriptions often have described conchology only and detailed descriptions, especially of arthropodal structures and of dwarf or complemental males, are either absent or are brief and inadequate. All the scalpellids collected by Cidaris I were first records from Queensland waters and, with the exceptions of *Verum australicum* Hoek and *Anguloscalpellum pedunculatum* (Hoek), first records from Australian waters. They were listed, but not described, in the recent catalogue of the Australian cirripede fauna (Jones et al., 1990). In the present contribution *Trianguloscalpellum hirsutum* sensu Jones et al. (1990) is regarded as a synonym of *T. hamulus* (Hoek), *T. hamulus* and *A. persona* are new records for Australian seas, and *S. stearnsii* is recorded from Queensland for the first time. ☐ *Crustacea, Thoracica, Lepadomorpha, Scalpellidae, Australia, new records, taxonomy.*

Diana S. Jones, Western Australian Museum, Francis St, Perth, Western Australia 6000, Australia; 14 November, 1991.

Documentation of the littoral and shallow water cirripede fauna of Australia began during the French expeditions of discovery at the beginning of the nineteenth century (Jones, 1991). The first contributions towards knowledge of the deeper water Australian cirripede faunas were not made until the late nineteenth and early twentieth centuries and are contained in Hoek's reports on the Cirripedia collected during the voyages of 'Challenger', between 1873 and 1876, and 'Siboga', from 1899 to 1900 (Hoek, 1883, 1907, 1913). Subsequently significant contributions have been made through the works of Calman (1918, 1919), Nilsson-Cantell (1927, 1928), Newman (1960), Utinomi (1968), Foster (1981) and Zevina (1981a). More recently, documentation of Australian shelf and slope (as well as littoral) cirripede faunas has been completed (Jones et al., 1990).

The Cidaris I expedition, which sampled the deep-sea fauna of the Coral Sea, was organised by the James Cook University of North Queensland, Townsville, in 1986. Some samples were obtained from the continental shelf and the majority from the continental slope and adjacent Coral Sea off the northeastern Queensland coast, out from Townsville (19°16'S, 146°49'E), at depths of 287 to 1612m. The present report covers the nine species of scalpellid barnacles collected by this expedition and further reports will cover the remaining lepadomorphs and the Verrucomorpha and Balanomorpha collected during the expedition. On examination of the deep-water barnacle collections housed in the Queensland Museum, Brisbane, and the Australian Museum, Sydney, two further scalpellid species were discovered that had been collected from the waters of the north-eastern and central eastern Australian continental slope. For comparative purposes, slope material from northwestern Australia housed in the Western Australian Museum, Perth, was utilized to validate identifications. Where relevant this material has also been included in the present contribution.

Eleven continental shelf and slope scalpellids are described and illustrated. Supplementary descriptions of each species, especially of arthropodal structures and dwarf and complemental males, are given since these have either not been described previously, or existing descriptions are brief or inadequate. The classification and sequence used for the Scalpellidae is that of Zevina (1981a, 1982). All measurements are in centimetres.

TYPE LOCALITY
East coast of Japan, between the bay of Tokyo and the Inland Sea.

DISTRIBUTION
Indian Ocean, Malay Arch., Indonesia, northwestern Australia, South China Sea, Japan. Depth range 182-2117m. Now known from central eastern Australia (465-562m).

MATERIAL EXAMINED
W15533, S of Swain Reefs (23°28'S, 153°19'E), 562m, 1 spec.; W10196, 130km E of Capricorn Gp (23°28'S, 153°19'E), 562m, 15 specs; W1097, 100km E of Capricorn Gp (23°30'S, 153°04'E), 540m, 6 specs; W11303 (part), E of Bunker Gp (23°54'S, 153°01'E), 465m, 1 spec.; W14339 (27°20'S, 153°53'E), 600m, 1 spec.; P35288, E of Gold Coast (28°02'-27°59'S, 153°59'E), 540m, 1 spec.

DESCRIPTION
Large individuals female. Capitulum laterally compressed, fourteen capitular plates, calcareous, partially reduced. Carina angularly flexed, umbo at angle. Carinolatus with horn-like projection which is very variable, almost wanting to strongly developed, when free projecting portion can be one-third to one- half length of plate. Peduncle with prominent external rings of overlapping calcareous scales. Measurements of the 25 specimens: CH 1.75-4.93 (mean 3.28), CW 1.05-3.90 (mean 2.17), PL 1.43-12.85 (mean 4.23), PW 0.55-1.98 (mean 23).

Cirrus I with rami very unequal in length and shape, anterior ramus much shorter than posterior ramus, proximal and intermediate segments of anterior ramus very protuberant especially towards posterior, segments transversely oblong and only united with one another over part of breadth, segments of posterior ramus square. Cirri II and III elongated, rami subequal, bearing three to six pairs of long setae on anterior margins, anterior ramus of cirrus II more setose than

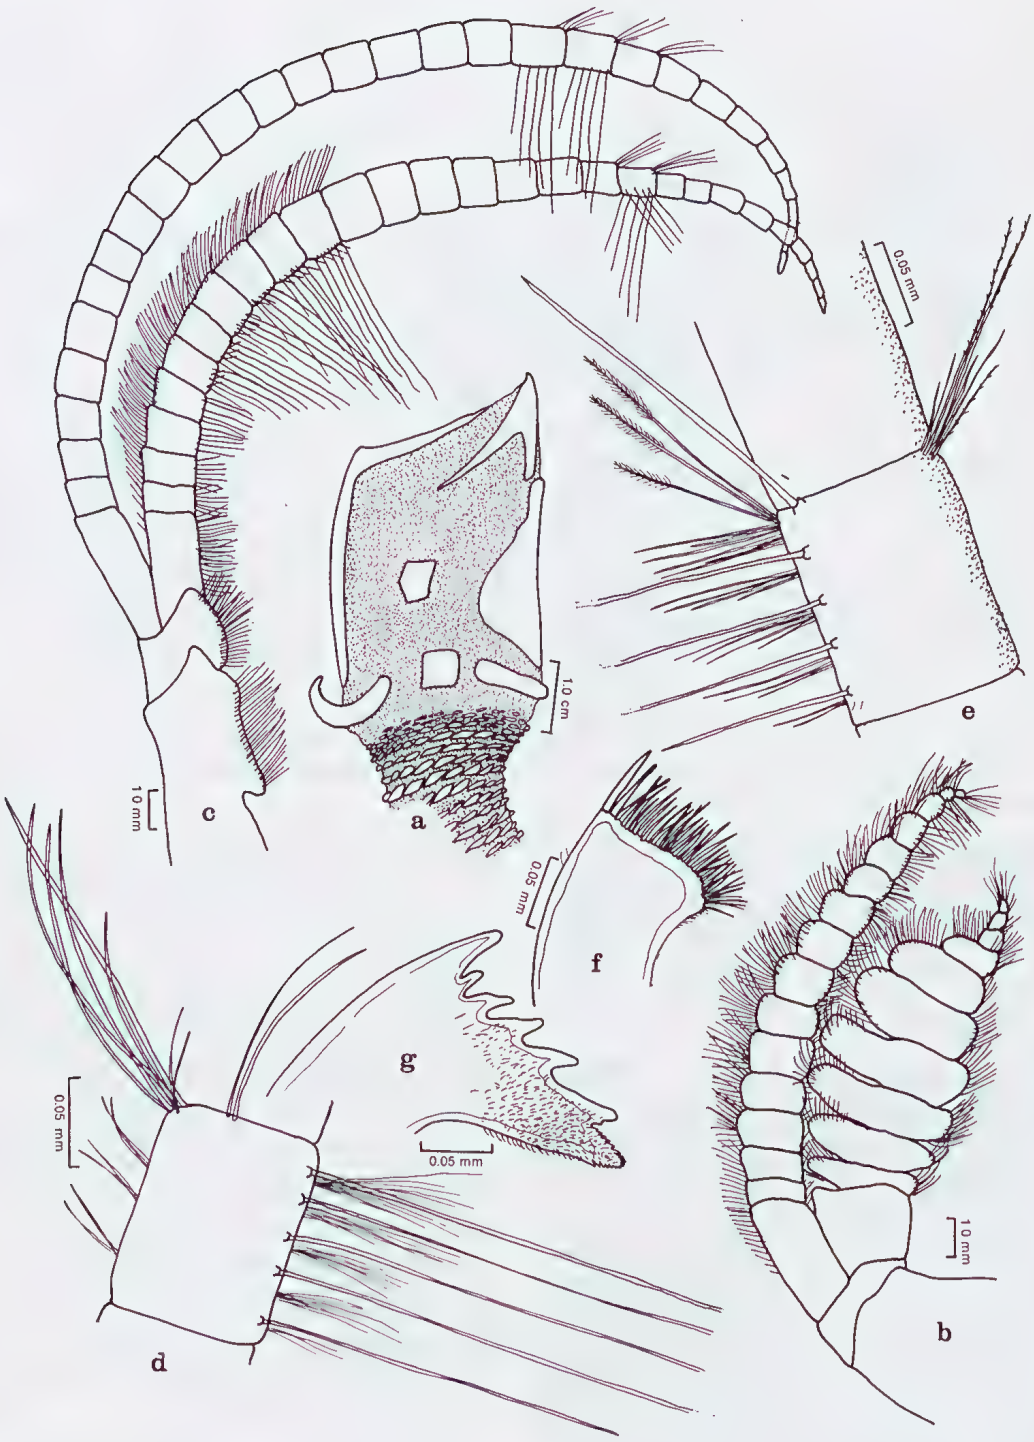

FIG. 1. *Scalpellum stearnsii* Pilsbry, 1890. a, lateral view. b, cirrus I. c, cirrus II. d, intermediate segments, anterior ramus, cirrus III. e, intermediate segments, anterior ramus, cirrus V. f, maxillule. g, mandible.

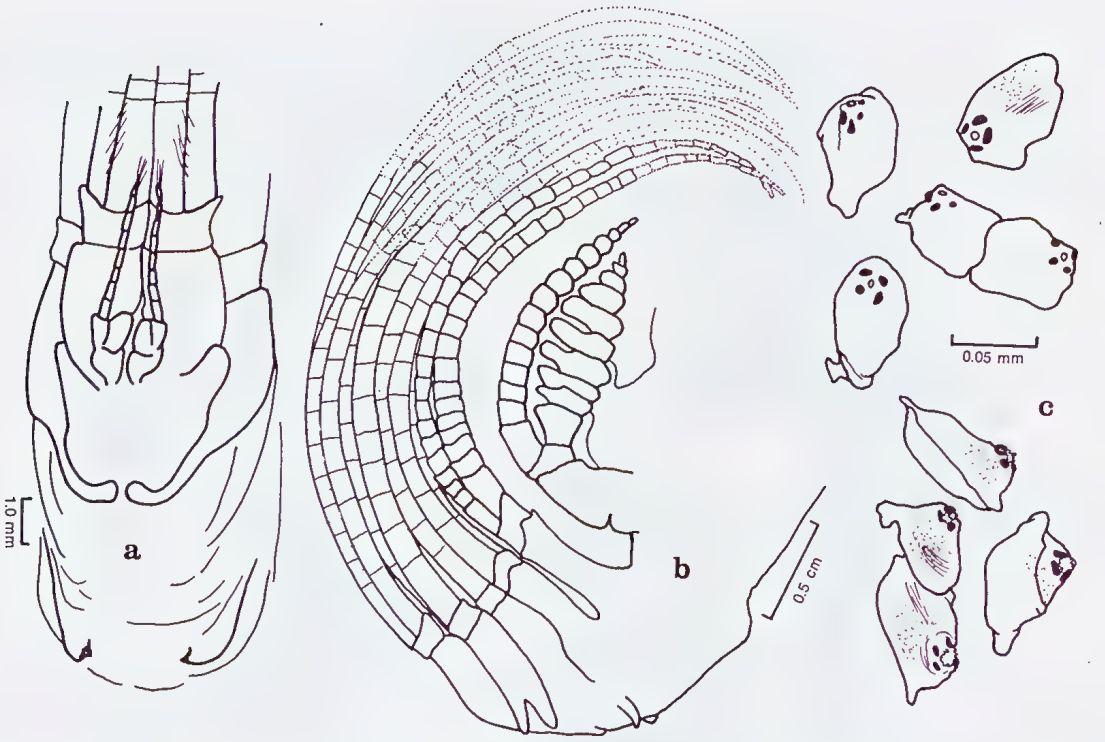

FIG. 2. *Scalpellum stearnsii* Pilsbry, 1890. a, posterior view, caudal appendages and pedicels of posterior cirri. b, lateral view of prosoma. c, dwarf males.

posterior ramus of cirrus II and both rami of cirrus III. Cirri IV, V and VI very long, rami subequal, segments elongated, bearing five to seven pairs long setae on anterior margins, posterior margins of proximal segments of cirri V and VI bearing dense scales, scales more numerous on anterior rami. Chaetotaxy ctenopod. Cirral formulae, see Table 1.

Maxillule with sinuous cutting edge bearing many setae (28-34 pairs), seta at upper angle stout and slightly larger than remainder. Mandible with five main teeth, simple, second smallest, subsidiary teeth may be present between main teeth, lower angle pectinate with short, chitinous hairs. Labrum strongly bullate, not cleft, teeth absent. Caudal appendages small, multi-articulate (6-10 segments), slightly longer than height of pedicel of cirrus VI, with tuft of long setae apically.

Dwarf males (8-10) at occludent margins of both scuta of female, located just above adductor muscle in deep pits in scutal membrane; sac-like, boat-shaped when viewed laterally, peduncle and capitulum not differentiated, four rudimentary, calcareous plates around subterminal orifice, short rudimentary tentacles between plates, body externally covered with minute erect spicules, two small, prehensile antennae on ventral surface.

REMARKS

The species has been reported from northwestern Australian waters (Jones et al., 1990) but not previously from eastern Australia. S. *stearnsii* is similar to *S. scalpellum* (Linnaeus) (= *S. vulgare* Leach) but the form of the carinolatera distinguishes *S. stearnsii*.

The species was first described from shallow water (11-18m), from the east coast of Japan (Pilsbry, 1890a,b). One year later Fischer (1891) described *S. calcariferum* from Sagami Bay, Japan, which later authors considered to be synonymous with *S. stearnsii* Pilsbry (Weltner, 1897; Gruvel, 1902). Fischer (1891) and Annandale (1909) also both pointed out the close resemblance between *S. stearnsii* Pilsbry and the fossil species *S. magnum* Darwin of the Coralline Crag, Sudbourne.

S. inerme, a species with highly degenerate capitular plates, was described from a depth of 293m from the Bali Straits (Annandale, 1905). Pilsbry (1907) considered *S. inerme* a distinct

species. Hoek (1907) established *S. stearnsii* var. *gemina*, which also had degenerate plates, and var. *robusta* which had a broader and longer capitulum than the typical form, from specimens collected by 'Siboga' in the Malay Archipelago at depths of 204-450 m. Pilsbry (1911) synonymized *S. stearnsii* var. *gemina* with *S. inerme*, but considered var. *robusta* identical with the typical form. However, Annandale (1916b), after examining a good series of specimens from Japan and the Malay Archipelago, considered *S. inerme* to be an extreme form of Hoek's var. *gemina* and proposed the degenerate plate form as *S. stearnsii* var. *inerme*, a view with which Nilsson- Cantell (1928, 1934) agreed. Annandale (1916b) found two Japanese specimens referable to var. *robusta*, and a number of indeterminate forms between var. *robusta* and var. *gemina*, and suggested that, as there was no evidence for Japanese and Malayan races, the two varieties should be united under *S. stearnsii*.

The specimens listed here represent the first records of *S. stearnsii* from eastern Australian waters. The specimens showed conchological characters which have been ascribed to the degenerate plate forms *S. stearnsii* var. *gemina* and *S. inerme* (tergum incompletly calcified in the form of an inverted V, scutum and upper latus reduced in size, peduncular scales smaller, arranged in more numerous rows). Soft-parts morphology and the structure of the dwarf males, however, agreed with descriptions of the more perfectly calcified form *S. stearnsii*, thus supporting the inclusion of *S. inerme* and *S. stearnsii* var. *gemina* in synonymy with the typical form.

SUPPLEMENTARY DESCRIPTION

Large individuals hermaphrodite. Capitulum oval, inflated in upper half, especially between tergum and neighbouring valves. Fourteen capitular plates, concealed by and embedded in thick, opaque membrane, externally velvety; some capitular plates imperfectly calcified, widely separated, paired plates relatively small. Peduncle variable in length, depending on degree of contraction, calcareous scales transversely elongated, arranged in alternating rows. Measurements of the 10 specimens: CH 3.15- 6.60 (mean 5.28), CW 2.47-5.81 (mean 4.31), PL 2.41-8.65 (mean 4.82), PW 1.14-2.90 (mean 2.36).

Cirrus I setose, well separated from cirrus II, anterior ramus shorter than posterior ramus, proximal segments of anterior ramus protuberant posteriorly, inner surfaces of segments of both

rami extremely setose. Cirrus II long, rami subequal, anterior ramus more densely setose than posterior ramus, setae setulate, inner surfaces of segments of both rami densely setose. Cirri III to VI very long, cirri increasing in length towards posterior, rami subequal, segments elongate bearing three to five pairs long, setulate setae on anterior faces, bunch of long finely setulate setae at postero-distal corner of proximal segments of cirri III to V. Chaetotaxy ctenopod. Cirral formulae, see Table 2.

Maxillule with sinuous cutting edge bearing numerous paired setae (30-38 pairs), stout spine at upper angle. Mandible with three main teeth, first large, acute, widely separated from rest, lower angle pectinate. Labrum prominent, bullate. Caudal appendages multi-articulate (22-30 segments), one-third to one-half length of cirrus VI, distal borders of segments with circlets of setae bearing fine setules, terminal segment with dense tuft of long setae with fine setules. Penis one-quarter length of cirrus VI, slender, minutely annulated, tapering distally, sparsely setose, setae long, plumose. Complemental males (3-4) at occludent margins of both scuta of hermaphrodite, located just above adductor muscle, in shallow pocket formed by fold in scutal membrane; sac-like, ovoid, calcareous plates and cirri absent, orifice slit-like, lateral; externally with elongated spicules arranged in transverse rows.

Remarks

Material collected by Cidaris I is the first record of *A. alcockianum* within Australian waters (Jones et al., 1990). Additional material examined in the course of this study has extended the range of the species from northeastern to central eastern Australia. The specimens agreed in general with published descriptions for this species. Some variation in the form of the tergum has been described - for example, the scutal margin of the tergum may be less hollowed out (Annandale, 1906a; Nilsson-Cantell, 1928) or more hollowed out (Annandale, 1916a; Lakshmana Rao & Newman, 1972). The Australian series (n = 10) demonstrated ontogenetic changes of this plate, which is less hollowed out in smaller specimens (e.g. CH 3.55) but more hollowed out as capitular size increases (e.g. CH 6.60).

Nilsson-Cantell (1928) described a female specimen of *A. alcockianum* from Mozambique Channel at a depth of 1647m. All other descriptions of this species are based on hermaphrodites, including the Australian series.

Type Locality

Timor Sea (10°22'30"S, 120°7'30"E); 109-366m; bottom temp 13.1°C.

Distribution

Indonesian seas, also New Zealand. Depth range 109-915m. Now also recorded from eastern Australia (550m).

Material Examined

W11327, E Bunker Gp (23°15'S, 153°07'E), 550 m, 7 specs.

Supplementary Description

Large individuals hermaphrodite. Capitulum ovoid, inflated. Fourteen capitular plates embedded and mostly concealed by opaque, thick membrane, externally finely hirsute; umbos apical, apices projecting through membrance (especially carinolatera); some capitular plates imperfectly calcified (e.g. terga), all plates except scuta relatively small, especially inframedian latus. Peduncle as long as or longer than capitulum, narrowing towards capitular junction, large calcareous scales transversely elongated, arranged in alternating rows. Measurements of the 7 specimens: CH 1.55-4.05 (mean 3.20), CW 1.02-2.79 (mean 2.07), PL 1.62-5.33 (mean 3.40), PW 0.63-1.86 (mean 2.31).

TABLE 3. Measurements and cirral formula of *Alcockianum persona* (Annandale, 1916).

CH	CW	PL	PW		CI	CII	CIII	CIV	CV	CVI	Ca
4.05	2.79	4.40	1.86	(R)	14/18	26/28	36/38	17+/17+	15+/14+	15+/17+	13

rami subequal, anterior ramus more setose than posterior ramus, setae setulate. Cirri III to VI very long, cirri increasing in length towards posterior, rami subequal, segments square to elongate, bearing three to six pairs long setulate setae on anterior faces, bunch of long, finely setulate setae at postero-distal corner of proximal segments of cirri III to VI. Chaetotaxy ctenopod. Cirral formula, see Table 3.

Maxilla with characteristic development of olfactory organ in the form of a blunt process. Maxillule with slightly sinuous cutting edge bearing numerous paired setae (25-30 pairs), two stout spines at upper angle. Mandible with 5 teeth, first acute, large, widely separated from remainder, lower angle molariform. Labrum extremely bullate, prominent. Caudal appendages multiarticulate (13-16 segments), twice length of pedicel of cirrus VI, segments with circlets of setulate setae, distal segment with dense tuft of setae, proximal segment expanded. Penis relatively long, one-third to one-half length of cirrus VI, annulated, tapering distally, setose towards apex, apex blunt with circlet of fine short setae. Complemental males at occludent margin of both scuta of hermaphrodite, located just above adductor muscle in deep pit in scutal membrane; ovoid, sac-like, four reduced calcareous plates around subterminal orifice, externally with small spicules, two prehensile antennae on ventral margin.

REMARKS

A. persona is similar to *A. alcockianum* but the two species are easily distinguished by characters of the tergum, carinolatera, caudal appendages and mandible.

The specimens of *A. persona* described above are the first collected from Australian seas. These specimens agree in general with published descriptions of conchology for *A. persona* (Annandale, 1916). However, the form of the mandible of Australian specimens differs from that previously described in that they exhibit five definite teeth, rather than four as figured by Annandale (1916b) for Indonesian material and Foster (1980) for New Zealand specimens. Australian specimens also do not exhibit a notch on the maxillule, whereas New Zealand specimens show a slight notch (Foster, 1980) and Indonesian material a broad shallow notch (Annandale, 1916b). The characteristic blunt conical olfactory lobe of the maxilla is, however, exhibited by Indonesian, Australian and New Zealand specimens.

TYPE LOCALITY

Eastern Indian Ocean (13°54'15"N, 94°02'15"E); 'Investigator' station 372; 1176m.

DISTRIBUTION

Indian Ocean. Depth range 237-1960m. Now also recorded from northeastern Australia (956-969m).

MATERIAL EXAMINED

W*13238 (18°08'S, 147°36'E), 956-969m, 1 spec.

SUPPLEMENTARY DESCRIPTION

Large individuals female. Capitulum irregularly ovate, laterally compressed. Fourteen capitular plates, smooth, thin, imperfectly calcified, separate, eight in shape of Greek lambda (λ). Inframedian latus large, vase-shaped. Peduncle shorter than capitulum, numerous calcareous scales present, narrow, transversely elongated, arranged in alternating rows. Cirrus I long, placed at a distance from cirrus II, rami very unequal, anterior ramus shorter and broader than posterior ramus; inner surfaces of both rami densely setose. Cirri II to VI very long, cirri increasing in length to posterior, rami subequal, segments elongate, bearing four to six pairs of long setae on anterior faces. Chaetotaxy ctenopod. Cirral formula, see Table 4.

Maxillule with definite notch, cutting edge below notch bearing two to three pairs setae, lower angle spinose, three stout subequal spines at upper angle. Mandible with three main teeth, lower angle pectinate. Labrum bullate. Caudal append-

ages moderately long, one-fifth length of cirrus VI, multi-articulate (6-8 segments), long setae with setules at distal tip. Penis absent. Dwarf males unknown. Ova large, ovoid, yolky, lemon yellow in preserved material.

Remarks

This species was first described by Annandale (1910) from material collected in the Andaman Sea. Annandale (1913) also described *S. longius* from the Andamans and commented that the species may possibly be '... merely a complete form of *S. lambda*...', differences being the degree of reduction of the capitular plates, the structure of the carinolatera and the relative lengths of the rami of cirrus I and the number of segments in the caudal appendages. Stubbings (1936) examined *S. longius* from Zanzibar and found the specimens agreed with the type description and '...showed no tendency to vary towards *S. lambda*'.

The sole Australian specimen described here shows characters attributable to both *S. lambda* and *S. longius*. The form of the carinolatera and the degree of reduction of the capitular plates agree in general with conchology described for *S. lambda* but differ in the following details: the apex of the carina almost touches the carinal margins of the terga; the tergal branch of the scutum is much shorter than that illustrated by Annandale (1910) but not as short as shown by Zevina (1981a); scutum, rostrolatera and carinolatera are more similar to the form illustrated by Annandale (1910) than that of Zevina (1981a); scutal arm of upper latus exhibits a bifid tip. Mandibles and maxillules of the Australian material resemble the forms figured by Stubbings (1936) for *S. longius*. In addition, both mandibles of the Australian specimen have three small, well- spaced spines on the upper margin of the third tooth and on the upper margin of the lower angle, which have not been figured previously for either *S. lambda* or *S. longius*. Rami of cirrus I in the Australian specimen are very unequal in length. These structures have been described as equal (Annandale, 1913) or subequal (Stubbings, 1936) in *S. longius* and unequal in *S. lambda* (Annandale, 1910). Caudal appendages of the Australian specimen are eight segmented. This structure appears to be similar in *S. lambda* (8 segments; Annandale, 1910) and *S. longius* (6 segments; Annandale, 1913; 8 segments; Stubbings, 1936).

The similarity of conchological and arthropodal characters support the conclusion that *S. longius* is a junior subjective synonym of *S. lambda*, as originally suggested by Annandale (1913) and later formalized - although not discussed - by Newman & Ross (1971) and Zevina (1981a). The Australian specimen collected by Cidaris I extends the geographical range of this species from the Indian Ocean to the waters of northeastern Queensland (Jones et al., 1990).

Distribution

Zanzibar; between Australia and New Guinea. Depth range 463- 2561m. Now also recorded from northeastern Australia (1187- 1590m).

Material Examined

W*13239 (16°54'S, 137°14'E), 1473-1590m, 1 spec.; W*13240 (17°19'S, 147°11'E), 1402-1406m, 10 specs; W*13241 (17°20'S, 147°48'E), 1187-1200m, 1 spec.

Supplementary Description

Large individuals female. Capitulum oval, elongate, laterally compressed. Thirteen capitular plates, distinctly furrowed, closely approximate. Inframedian latus elongate, vase- shaped. Peduncle short, one-third to one-sixth capitular height, calcareous scales distinct, larger towards capitulum, arranged in five to six alternating rows. Measurements of the 12 specimens: CH 1.24-2.40 (mean 2.00), CW 0.58-1.35 (mean 1.06), PL 0.20-0.87 (mean 0.56), PW 0.09-0.68 (mean 0.52).

Cirrus I set apart from cirrus II, rami unequal,

anterior ramus shorter and much broader than posterior ramus, both rami densely setose. Cirri II to VI very long, cirri increasing in length to posterior, rami subequal, segments elongate, bearing four to five pairs of long setulate setae on anterior faces. Chaetotaxy ctenopod. Cirral formulae, see Table 5.

Maxillule with slight notch, four to five spines on cutting edge below notch, three stout subequal spines at upper angle, lower angle spinose. Mandible with three main teeth, lower angle pectinate, upper margin of third tooth with several small spines. Labrum extremely bullate, teeth absent. Caudal appendages short, marginally longer than pedicel of cirrus VI, multiarticulate (nine segments), long setae bearing fine setules distally. Penis absent. Dwarf males in pocket at occludent margin, on inner surface of and towards apex of right and left scuta of female, three to six males per pocket; males sac-like, ovoid, externally with chitinous spines, calcareous plates absent.

REMARKS

The material collected by Cidaris I extends the range of *V. australicum* into the waters of north-eastern Australia (Jones et al., 1990). The conchology of the specimens agrees in general with the original description of Hoek (1883). However, Hoek stated (p.118) that the 13 plates were 'closely locked together' and that there were 'no distinct interspaces between the different valves'. In the ontogenetic series of the Australian material an interspace develops between the carinal margin of the tergum and the upper portion of the carina in larger specimens (CH 2.20+). Hoek's type description was based on a smaller specimen (CH 1.25).

Hoek (1883) did not describe the internal structure of *V. australicum* and did not observe dwarf

SUPPLEMENTARY DESCRIPTION

Large individuals hermaphrodite. Capitulum subtriangular, inflated towards peduncle. Fourteen capitular plates, concealed by chitinous, hirsute membrane, apices projecting through membrane, plates of lower whorl short, small. Carinolatus elongated, subtriangular, extending outwards from capitulum laterally in larger specimens. Peduncle longer than capitulum, calcareous scales present, transversely elongated, arranged in alternating rows, covered by chitinous, hirsute membrane. Measurements of the 49 specimens: CH 2.68-4.68 (mean 4.05), CW 1.91-3.39 (mean 2.91), PL 4.60-12.97 (mean 8.19), PW 1.28-2.98 (mean 1.96).

Cirrus I slightly separated from cirrus II, rami unequal, proximal segments of anterior ramus wider than those of posterior ramus, strongly protuberant posteriorly, distal segments antenniform, segments of posterior ramus not protuberant. Cirri II to VI long, cirri increasing in length towards posterior, rami subequal, segments square, bearing four to seven pairs of long setae on anterior margins. Chaetotaxy ctenopod. Cirral formulae, see Table 6.

Maxillule with large spine at upper angle, cutting edge slightly sinuous, bearing numerous pairs of stout setae. Mandible with three large teeth, lower angle molariform, pectinated. Labrum extremely bullate, cutting edge straight with minute teeth. Caudal appendages multiarticulate, long (6-37 segments), half to two-thirds length of cirrus VI. Penis long, slender, tapering distally, sparsely setose, circlet of short dense setae at distal tip. Complemental males globulo-ovoid, orifice terminal, surrounded by four minute rudimentary plates, externally with chitinous spines in regular pattern, two prehensile antennae on ventral margin, extensile penis present; in shallow scutal pocket of hermaphrodite, three to four males per pocket, membrane of pocket with chitinous spines in regular pattern, membrane closely apposed to males.

REMARKS

Foster (1978, 1980) described material from New Zealand waters, Norfolk Island and the Kermadecs and mentioned that the species was also known to occur in the waters of eastern Australia (29°S), at a depth of 500-600m. Cidaris I speciemens of *A. pedunculatum* extended the known geographic range of the species northwards into the waters of north-eastern Queensland (17°S) (Jones et al., 1990) and material examined in the present study further extends the total range of the species from 32°S to Torres Strait (9°S).

Australian hermaphrodites agree well with published descriptions. The presence of a penis in the complemental male is confirmed and the orifice is terminal, rather than lateral as illustrated by Foster (1978) for New Zealand material. The close proximity of the scutal pocket membrane to the complemental males suggests the possibility of an interlocking function between the chitinous spines of the inner surface of the pocket and the external surface of the males, thus maintaining the males securely in the pouch.

MATERIAL EXAMINED
W*13244 (16°59'S, 147°11'E), 1545-1564m, 1 spec; W*13243 (17°06'S, 147°12'E), 1517-1539m, 2 specs.

SUPPLEMENTARY DESCRIPTION
Large individuals female. Capitulum irregularly ovate, carinal margin more strongly curved than occludent margin. Thirteen capitular plates partially covered by thin, finely setose membrane, fine growth lines visible externally on all plates. Peduncle short, cylindrical, calcareous scales well developed, overlapping, arranged in alternate rows, covered with thin, finely setose membrane. Cirrus I much shorter than and set apart from cirri II to VI, anterior ramus shorter than and slightly wider than posterior ramus, both rami setose, especially inner surfaces. Cirri II to VI long, cirri increasing in length towards posterior, rami subequal, segments elongate, bearing four to five pairs long setae on anterior faces. Chaetotaxy ctenopod. Cirral formulae, see Table 7.

Maxillule with shallow median notch, two stout subequal setae at upper angle, one long seta and three pairs shorter setae below notch. Mandible with three main teeth, lower angle molariform with one or two small teeth on lower margin. Labrum bullate, cutting edge straight, teeth absent. Caudal appendages multiarticulate (5-6 segments), short, extending just beyond pedicel of cirrus VI, one twelfth length of cirrus VI, long setae bearing setules apically. Penis absent. Dwarf males in single row in shallow pocket at occludent margin, on inner surface of both scuta, towards apices; sac-like, four small rudimentary plates around terminal orifice, externally with small cuticular spines.

REMARKS
Material collected by Cidaris I extended the distribution of *A. daschae* into the waters of northeastern Australia (Jones et al., 1990). The form of the mandible of Australian specimens differs from that figured by Zevina (1981b). The pectination of the molariform lower angle, especially of the lower margin, is absent with only one or two small teeth or residual teeth present on the lower mandibular margin in Australian material.

TYPE LOCALITY
Sulawesi (5°39'S, 122°12'E), 'Siboga' Station 208, 1886m, substrate solid green mud.

DISTRIBUTION
Indo-west Pacific - South Arabian coast, Sulawesi. Depth range 687-1886m. Now also known from northeastern Australia (687- 1228m).

MATERIAL EXAMINED
W*13245 (17°20'S, 147°48'E), 1187-1200m, 3 specs; W*13246 (18°04'S, 147°19'E), 687-704m, 1 spec.; W*13247 (17°45'S, 147°48'E), 1223-1228m, 2 specs; W*13248 (18°11'S, 148°22'E), 1109-1110m, 1 spec.

SUPPLEMENTARY DESCRIPTION
Large individuals female. Capitulum elongate, irregularly ovate, laterally compressed, carinal margin arched, occludent margin almost straight. Thirteen capitular plates, closely approximate, partially covered by thin, finely setose membrane, all plates except carina externally finely striated. Peduncle short, cylindrical, well-developed calcareous scales present, overlapping, arranged in rows, covered with thin, finely setose membrane. Measurements of the seven specimens: CH 0.89-

margin of third tooth with two small spines. Labrum bullate. Caudal appendages minute, less than one-quarter length of basal segment of pedicel of cirrus VI, with tuft of long setae apically. Penis absent. Dwarf male small, sac-like, four small rudimentary plates around terminal orifice; one specimen in shallow pocket at occludent margin towards apex of right scutum.

REMARKS

Material collected by Cidaris I extended the distribution of *A. elegans* into the waters of north-eastern Australia (Jones et al., 1990). This species appears to be rare, being known previously from only two specimens (Hoek, 1907; Stubbings, 1936). Conchological characters of the seven Australian specimens agree fairly closely with the original species description of Hoek (1907). The appendages of the female, and the dwarf males of *A. elegans* were undescribed prior to the present report.

TYPE LOCALITY
Banda Sea (5°26.6'S, 132°32.5'E); 'Siboga' station 256, 397m, bottom greyish green mud.

DISTRIBUTION
Banda Sea, Johul Bank (198 km S of Timor), Phillipines. Depth range 128-397m. Now also recorded from northeastern Australia (490-1119m).

MATERIAL EXAMINED
W*13249 (18°08'S, 148°15'E), 1115-1119m, 1 spec.; W*13250 (18°04'S, 147°17'E), 490-512m, 1 spec.; W10195, 130 km E of Capricorn Gp (23°28'S, 153°19'E), 562m, 1 spec.

SUPPLEMENTARY DESCRIPTION
Large individuals hermaphrodite. Capitulum elongate, ovate, apex slightly produced, occludent margin almost straight. Fourteen capitular plates, closely approximate, covered by thin, finely setose membrane. Peduncle short, cylindrical, well developed calcareous scales present, arranged in rows, covered with thin, finely setose membrane. Measurements as follows: CH 1.63, 0.83; CW 0.87, 0.35; PL 0.88, 0.25; PW 0.61, 0.30.

Cirrus I much shorter than cirri II to VI and set above and apart from remaining cirri, rami unequal, anterior ramus shorter and slightly wider than posterior ramus, rami setose, setae long, bearing setules. Cirri II to VI very long, cirri increasing in length towards posterior. Cirrus II with rami subequal, segments becoming elongate distally, anterior ramus more setose than posterior ramus, anterior faces of both rami bearing three to five pairs of long, setulate setae on anterior margins. Cirri III to VI with rami subequal, segments elongate, bearing three to four pairs of long setulate setae on anterior margins. Chaetotaxy ctenopod. Cirral formula, see Table 9.

Maxillule with slightly sinuous cutting edge bearing numerous small spines (10 to 12 pairs), upper angle with one stout spine, lower angle with short spines. Mandible with three main teeth, lower angle pectinate. Labrum extremely bullate. Caudal appendages very thin, long, one-quarter to one-third length of cirrus VI, multiarticulate (21 segments), circlet of fine setae apically. Penis long, thin, tapering distally, sparsely setose but setae more dense distally, circlet of fine setae apically.

REMARKS
This species appears to be comparatively rare. It was known previously from three specimens from the Philippines (Rosell, 1981), one from Indonesia (Hoek, 1907) and two from south of Timor (Annandale, 1916b). The three specimens collected by the Cidaris I expedition extended the known geographical range of *T. hamulus* to the waters of northern Queensland (Jones et al., 1990). The material agrees fairly closely with published conchological illustrations of the species (Hoek, 1907; Rosell, 1981). Only the larger of the two Cidaris I specimens was dissected. Details of arthropodal structures and mouthparts are described here for the first time as only the mandible has been figured previously (Rosell, 1981). Annandale (1916b) made brief mention of characters of the cirri and caudal appendages. The smaller (and presumably juvenile) specimen collected by the Cidaris I expedition is presently attributed to *T. hamulus*, based on conchology. However, the much deeper collection locality of this specimen has to be reckoned with. Until more specimens are collected and more information on the ontological development of this species is obtained, the identification cannot be confirmed. As has been the case with previous specimens, no complemental males were located in Australian material and these are yet to be described.

* segements not distinct

WAM 935-86 NW of Port Hedland (18°37'S, 116°40'E), 732- 736m, 1 spec.

SUPPLEMENTARY DESCRIPTION

Large individuals female. Capitulum subtriangular, 14 capitular plates, approximate, fully calcified, covered by thin, pale brown, chitinous membrane, sparsely hairy, apices of plates projecting freely through membrane, growth lines faint. Peduncle one-quarter to one-third capitular height, well-developed calcareous scales present, arranged in alternating rows. Measurements of the three specimens: CH 0.96, 1.68, 3.05; CW 0.56, 1.05, 2.43; PL 0.44, 0.88, broken; PW 0.31, 0.61, broken.

Cirrus I with rami unequal, posterior ramus longer than anterior ramus, anterior ramus with intermediate segments protuberant posteriorly, both rami with many long, finely setulate setae, especially on inner surfaces. Cirrus II longer than cirrus I, rami subequal, anterior ramus more densely setose than posterior ramus, long setae finely setulate. Cirri III to VI elongate, cirri increasing in length towards posterior, rami subequal, segments elongate bearing three to four pairs of long, setulate setae on anterior margins. Chaetotaxy ctenopod. Cirral formulae, see Table 10.

Maxillule without definite notch but slight indentation apparent below upper angle, one stout spine at upper angle, cutting edge below indentation almost straight with many paired setae. Mandible with three teeth, molariform lower angle pectinate. Labrum extremely bullate. Caudal appendages stout, approximately one- half to two-thirds length of basal segment of pedicel of cirrus VI, two- or three-segmented but segments indistinct, setulate setae terminally. Penis absent. Dwarf males globulo-ovoid, orifice terminal, calcareous plates absent, a pair of antennae at opposite pole to orifice, outer surface with muscle striations, not covered with spicules arranged in transverse rows but by minute spiniferous excrescences; in pocket at occludent margin, on inner surfaces of right and left scuta of female just above adductor muscle pit of scuta, one male per pocket.

REMARKS

The considerable range of variation exhibited by this wide-ranging species has been noted by various authors (e.g. Gruvel, 1902; Calman, 1918; Newman & Ross, 1971). The two specimens collected by Cidaris I were the first records of *A. michelottianum* from the waters of eastern Australia (Jones et al., 1990).

However the identification is provisional. Of the three specimens examined, only the middle-sized specimen (CH 1.68) was dissected. Differences and similarities of this material to published descriptions of *A. michelottianum* are discussed below.

Australian material shows the maxillule without a notch, but with a slight indentation below the upper angle. Newman & Ross (1971), examining slightly smaller specimens, interpreted a similar but slightly more pronounced indentation as evidence for a distinct notch in the maxillule. However, for a larger specimen (CH 3.0) Nilsson-Cantell (1927) described the cutting edge of the maxillule as nearly straight, although Newman & Ross (1971) suggested an indication of a slight notch in Nilsson-Cantell's illustration of this appendage. Zevina (1972) showed no distinct notch but illustrated a more sinuous configuration to the cutting edge than described previously. Lakshmana Rao & Newman (1972) found no supramedian notch on the cutting edge of the maxillule in mid- Pacific material.

Segmentation of the caudal appendages of young specimens of *A. michelottianum* is indistinct but larger specimens show distinct segmentation (e.g. Gruvel, 1902: 7-8 segments; Calman, 1918: 4-6 segments; Nilsson-Cantell, 1927: 7 segments; Zevina, 1972: 1-6 segments; Lakshmana Rao & Newman, 1972: 2-4 segments). Australian material exhibits indistinctly two- segmented (CH 1.68) or three-segmented (CA 3.05) caudal appendages. This character appears to vary with age.

The posterior cirri of the medium-sized Australian specimen bear four pairs of long, setulate setae along the anterior margins of the intermediate segments. Newman & Ross (1971) figured three pairs per segment for slightly smaller animals and Nilsson-Cantell (1927) and Lakshmana Rao & Newman (1972) described four pairs per segment for larger specimens; this difference may, therefore, be attributable to age.

All three Australian specimens show carinolatera projecting beyond the carinal edge of the capitulum, the projection being strongest in the larger specimen. This condition is not illustrated by Newman & Ross (1971), whose material (CH 1.18-0.32) covers the size range of the smallest Australian specimen. The original illustration of *S. velutinum* (Hoek, 1883) showed the carinolatera projecting beyond the capitulum and this condition is also illustrated by Gruvel (1902, 1905) and Zevina (1972). These plates, however, may only slightly project from the capitulum (Hoek, 1883 as *S. eximium*; Nilsson- Cantell, 1927). The degree of projection appears to be variable, reflecting different stages in ontogenetic development.

Conchology of the two larger Australian specimens is very similar to that figured for Chilean specimens (CH 3.1-1.6) of *S. velutinum* (Zevina, 1972), although the peduncular scales appear more developed (i.e. larger in size and closely approximate) in the Australian examples. It must be noted that the conchology of the smallest Australian specimen, presently assigned to *A. michelottianum*, is also very similar to that illustrated by Ultinomi (1968) for *S. hirsutum* (CH 1.3, CW 0.9). This author commented that externally the female capitulum of *S. hirsutum* closely resembled *S. velutinum* but that characters of the maxillule (a distinct small notch below the upper angle), mandible (pectination of the upper margin of the third mandibular tooth) and the dwarf male (minute spiniferous excrescences on surface) warranted specific separation. However, the dwarf males of the Australian material herein ascribed to *A. michelottianum* exhibit similar surface spiniferous excrescences rather than cuticular hairs. *S. hirsutum* is only known from two specimens - the Arafura Sea, 390m (Utinomi, 1968) and the Moluccan Sea, 1485m (Hoek, 1883). Ren (1983) described *A. ciliatum* from the East China Sea. It shows conchological characters very similar to *A. michelottianum*. He also synonymized *S. hirsutum* (Utinomi, 1968) but not *S. hirsutum* sensu Hoek, 1883 with *A.* ciliatum. Differences in the caudal appendages (uniarticulate, expanded oval-shaped) and the maxillule (notched) distinguish *A. cilitum* from *A. michelottianum*. Dwarf males of *A. ciliatum* remain to be described.

Arcoscalpellum moluccanum (Hoek, 1883)
(Figs 18,19)

Scalpellum moluccanum Hoek, 1883: 104, pl. 5, Figs 3-4; 1907: 56, 85, pl. 7, fig. 13; Gruvel, 1905: 76, fig. 85; Nilsson-Cantell, 1927: 747 fig. 3.

TYPE LOCALITY

Banda Sea (4°21'S, 129°7'E), 'Challenger' station 195, 2606m, bottom temp. 3.0°C, substrate grey ooze.

DISTRIBUTION

Indonesia, Tasman Sea. Depth range 788-2745m. Now also known from northeastern Australia (904-1491m).

MATERIAL EXAMINED

W*13253 (17°20'S, 147°48'E), 1187-1200m, 7 specs; W*13254 (17°51'S, 147°09'E), 904-916m, 1 spec.; W*13255 (17°12'S, 147°11'E), 1489-1491m, 1 spec.

SUPPLEMENTARY DESCRIPTION

Large individuals female. Capitulum subtriangular, inflated. Fourteen capitular plates, covered by relatively thin chitinous membrane, sparsely hirsute, apices of plates projecting freely through membrane, growth lines fairly distinct. Peduncle stout, narrowing towards base, shorter than capitulum, well- developed calcareous scales present, arranged in alternating rows. Measurements of the seven specimens: CH 1.78-2.09 (mean 1.91); CW 1.10-1.33 (mean 1.22); PL 0.99 - 1.46 (mean 1.23); PW 0.87 - 1.17 (mean 1.02).

Cirrus I set apart from cirrus II, stouter and much shorter than cirri II to VI, anterior ramus shorter than posterior ramus, intermediate segments of anterior ramus strongly protuberant posteriorly, segments of posterior ramus not protuberant, both rami setose, especially posterior faces and medial faces of anterior ramus. Cirri II-VI elongate, rami subequal, cirri increasing in length towards posterior. Cirrus II with three to four pairs of setae along anterior border of segments, anterior ramus more setose than posterior ramus, posterior surfaces of both rami setose. Cirri III and IV with anterior and posterior rami with two to four pairs of setae along anterior margins of segments, posterior surfaces of segments sparsely setose.

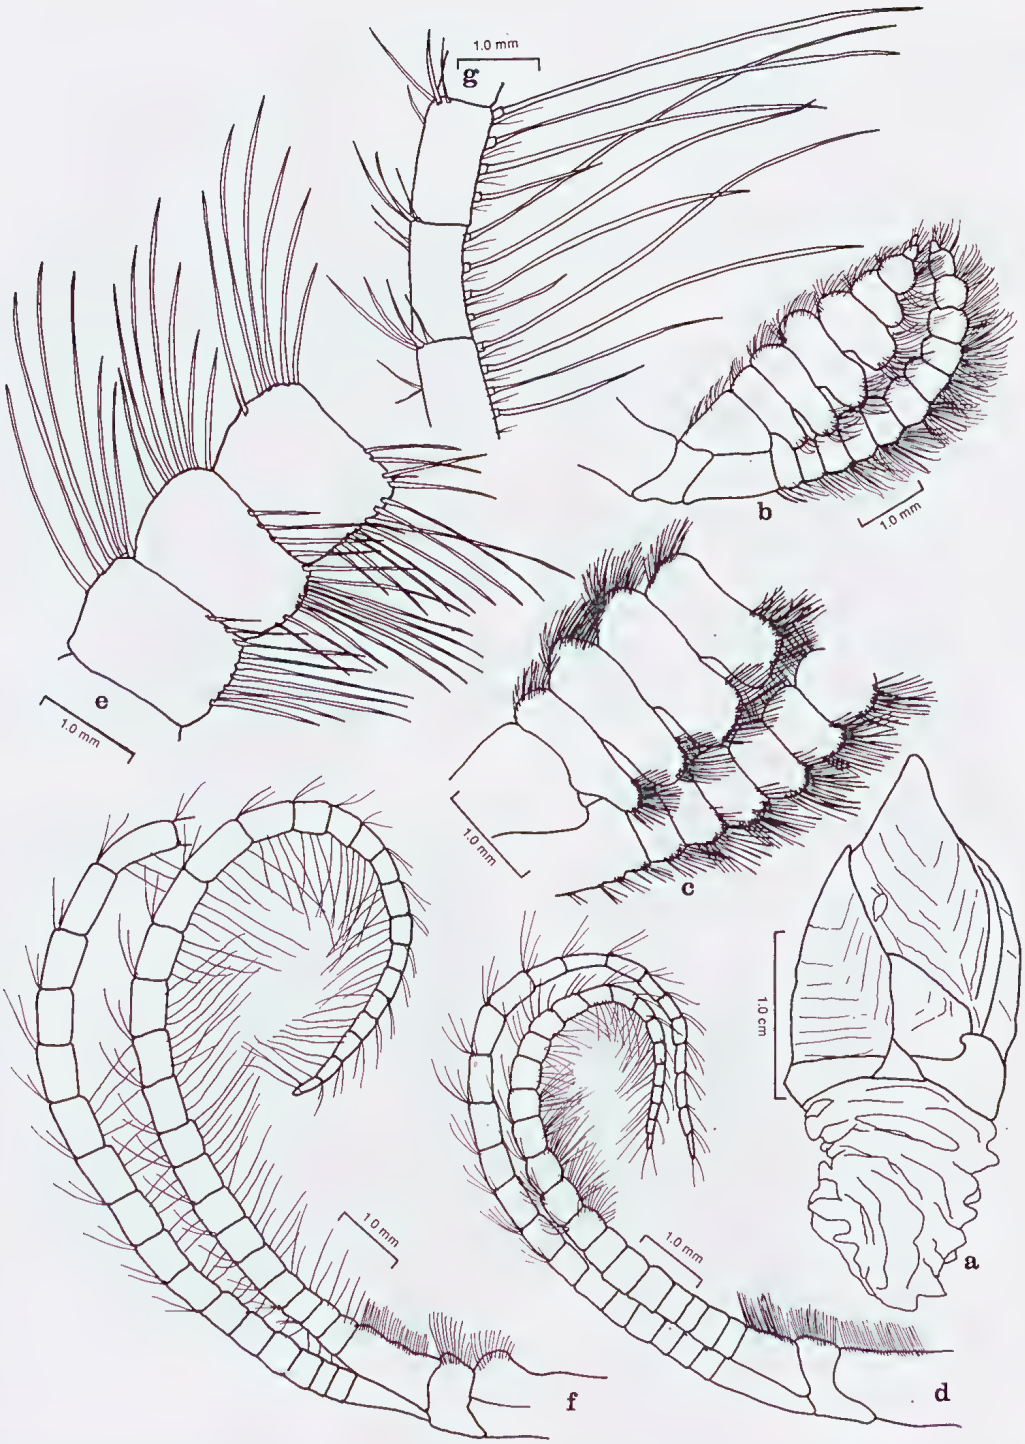

FIG. 18. *Arcoscalpellum moluccanum* (Hoek, 1883). a, lateral view. b, cirrus I. c, proximal segments, cirrus I. d, cirrus II. e, intermediate segments, anterior ramus, cirrus II. f, cirrus III. g, intermediate segments, posterior ramus, cirrus III.

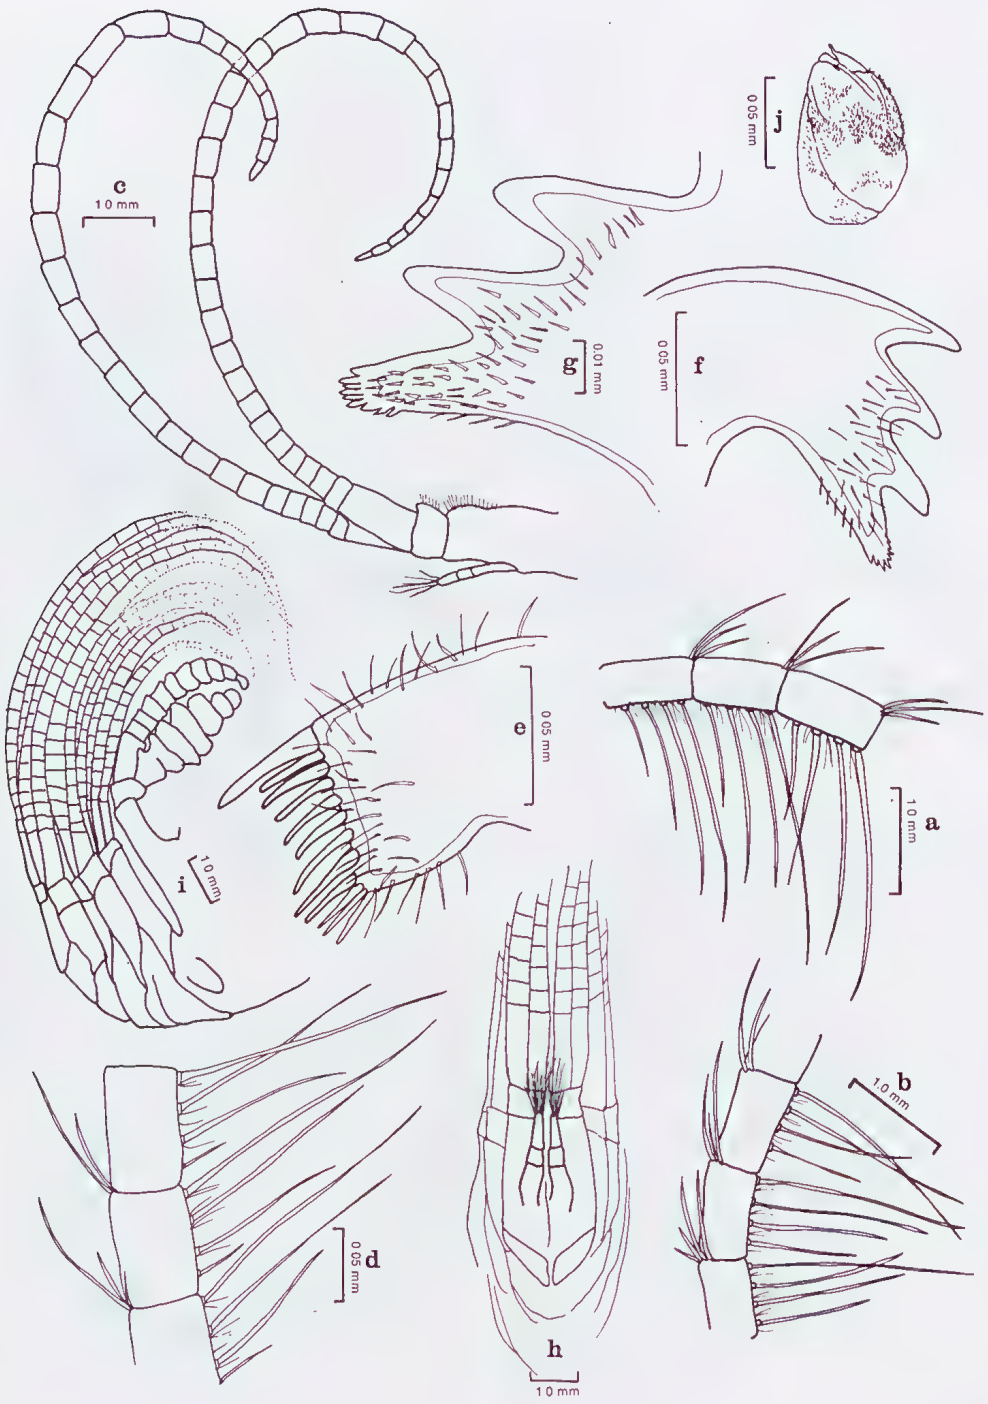

FIG. 19. *Arcoscalpellum moluccanum* (Hoek, 1883). a, intermediate segments, anterior ramus, cirrus IV. b, intermediate segments, posterior ramus, cirrus V. c, cirrus VI. d, intermediate segments, posterior ramus, cirrus VI. e, maxillule. f, mandible. g, lower angle of mandible. h, posterior view, caudal appendages and pedicels of posterior cirri. i, lateral view of prosoma. j, dwarf male.

TABLE 11. Measurements and cirral formulae of *Arcoscalpellum moluccanum* Hoek (1883).

CH	CW	PL	PW		CI	CII	CIII	CIV	CV	CVI	Ca
2.05	1.33	1.33	1.10	(R)	9/13	24/25	29/30	29/30	31/28	33/29	3
				(L)	10/13	24/26	29/25+	26+/30	31/30	31/32	3

Cirri V and VI with four pairs of setae along anterior margins of segments, posterior surfaces of both rami sparsely setose. Chaetotaxy ctenopod. Cirral formulae, see Table 11.

Maxillule without notch, large stout spine at upper angle, cutting edge almost straight, bearing seven to eight pairs of setae, lower angle slightly protuberant, bearing five pairs of setae. Mandible with three large teeth, lower angle pectinated. Labrum extremely bullate, cutting edge straight, teeth absent. Caudal appendages slightly longer than basal segment of pedicel of cirrus VI, three-segmented, several long, stiff setae distally. Penis absent. Dwarf males small, elongate, ovoid, externally covered with chitinous, short, stout setae, antennae present, rudimentary plates around orifice lacking; in pouch inside occludent margin of right scutum of female, at base of occludent orifice, just above adductor muscle.

REMARKS

The species was previously known from four specimens (Hoek, 1883, 1907; Nilsson-Cantell, 1927) and only their conchology has been described. The nine Australian specimens collected by Cidaris I constitute the first records of *A. moluccanum* in Australian waters (Jones et al., 1990). They agree closely with the original description of *A. moluccanum* (Hoek, 1883). The conchology of both the Atlantic species *T. regium* (Thomson) and the Antarctic and eastern Pacific *A. darwinii* (Hoek) is very similar to that of *A. moluccanum*.

The form of the carinolatera, especially where they meet at the base of the carina, and the position of the rostrum relative to the rostrolatera, separate *A. moluccanum*, *A. darwinii* and *T. regium*. The internal anatomy of *A. moluccanum* described above is similar to previous brief descriptions of these parts for *T. regium* (Hoek, 1883; Pilsbry, 1907). Descriptions of the dwarf males of *T. regium* (Hoek, 1884) are more similar to those *A. moluccanum* than to *A. darwinii*. The mouthparts and the caudal appendages (three segmented in *A. moluccanum*, 4 to 6 segmented in *T. regium*, four to five segmented in *A. darwinii*) are similar in all three species. It is possible that *A. moluccanum* may be a geographical 'race' as suggested by Hoek (1883). Until comparison of the type material of *A. regium* and *A. moluccanum* can be made, the identity of the Australian specimens is tentative.

ACKNOWLEDGEMENTS

I am indebted to Dr M. Pichon, Dr P. Arnold and Mr F. Hoedt, James Cook University, for the opportunity to examine the cirripede material collected by the Cidaris I expedition. Mr P. Davie, QM, and Dr P. Berents and Mr R. Springthorpe, AM, kindly loaned specimens from their respective collections. I thank Mr D. Neville for translating Russian papers. In addition, I thank Dr F. Wells and Prof. B. Foster for critically reading the manuscript and Mrs A. Nevin for typing the manuscript.

DISTRIBUTION OF THE LONG-NECKED FRESHWATER TURTLE *CHELODINA NOVAEGUINEAE* AND NEW INFORMATION ON ITS ECOLOGY

RODNEY M. KENNETT, ARTHUR GEORGES, KEN THOMAS AND T.C. GEORGES

Kennett, R.M., Georges, A., Thomas, K. & Georges, T.C. 1992 06 29. Distribution of the long-necked freshwater turtle *Chelodina novaeguineae* and new information on its ecology. *Memoirs of the Queensland Museum* **32**(1): 179-182. Brisbane. ISSN 0079-8835.

Recent collections have extended the westerly distribution of *Chelodina novaeguineae*. The species occupies semi-permanent and seasonally ephemeral waterholes from coastal northeast Queensland to the Daly Waters region of the Northern Territory. *C. novaeguineae*, along with *C. longicollis* and *C. steindachneri*, may have speciated from a common ancestor whose widespread distribution around the periphery of the continent covered the present distribution of these species. *C. novaeguineae* aestivates or migrates overland to permanent water when the waterhole it occupies dries. Its reproductive pattern of dry season nesting, small egg size and long incubation period conflicts with a current interpretation of the phylogeny of Australian chelid turtles. □*Chelidae, Chelodina novaeguineae, ecology, distribution.*

Rodney M. Kennett, Wildlife Research, Conservation Commission of the Northern Territory, PO Box 496, Palmerston, Northern Territory 0831, Australia, and Faculty of Science, Northern Territory University, PO Box 40146, Casuarina, Northern Territory 0811, Australia; Arthur Georges, Ken Thomas and T.C. Georges, Applied Ecology Research Group, University of Canberra, PO Box 1, Belconnen, Australian Capital Territory 2616, Australia;
7 November, 1991.

Chelodina novaeguineae was first described from the Binaturi River in New Guinea (Boulenger, 1888) and later found to occur also in north-eastern Queensland, Australia (Goode, 1967). Its distribution in Australia is poorly known. Covacevich and Couper (1991) provide a map showing its Queensland distribution based on specimens held in the Queensland Museum and these data together with anecdotal reports (Goode, 1967; Cann, 1978) suggest it is distributed not only on Cape York Penninsula but throughout the Gulf of Carpentaria, in Arnhem Land, and as far south as Newcastle Waters in the Northern Territory. More recent collections (King & Horner, 1987; Covacevich et al., 1990) confirm that the species' distribution extends into the Gulf country of western Queensland and the Northern Territory.

In this note, we provide a range extension for *C. novaeguineae*, review museum specimens to provide an updated map of the distribution of the species, and provide new information on its ecology.

RESULTS

On 29 April, 1990, we collected two live specimens and three shells of *C. novaeguineae* from Malogie Waterhole, a small permanent waterhole in the Roper River catchment near Scarlet Hill on Kalala Station (16°8'S 133°36'E) in the Northern Territory. Another three shells were collected from Stuart Swamp near the township of Daly Waters (16°14'S 133°27'E) (Table 1). The specimens were determined to be *C. novaeguineae* on the basis of the following characters:

- The plastron is greatly expanded anteriorly, less than 1.9 times longer than broad (unlike *Chelodina rugosa*, *C. expansa* and *C. oblonga*), but extends barely as far as the inner edges of the overlying marginal plates of the carapace (unlike *C. longicollis*).
- The intergular shield is markedly more than twice as long as the suture between the pectoral shields (unlike *C. rugosa*, *C. expansa* and *C. oblonga*).
- The common boundary of the 12th marginals is not raised to form a distinct inverted 'V' when viewed from the rear (unlike *C. longicollis*).
- The carapace is broadly oval (unlike *C. steindachneri*).

Stuart Swamp drains into Daly Waters Creek in the upper catchment of the Roper River. When full, the swamp covers several square kilometres but poor wet season rainfall over the previous three years had reduced the waterhole to a relatively small muddy hole about 75m in diameter at the time of our visit. The waterhole dried completely a few months later for the first time in many

TABLE 1. Details of *Chelodina novaeguineae* collected from Kalala Station, Northern Territory, April 1990.

Location where specimen is held	Specimen number	Carapace length	Carapace width	Plastron length	Plastron width	Shell depth	Sex
NT Museum	NTMR 16324	210	169	169	110	79	—
	NTMR 16325	230	188	190	118	88	—

years (Bill Cook, Kalala Station, pers. comm.). Malogie Waterhole was the only waterhole in the area to retain water in 1990, while many others dried for the first time in living memory (Bill Cook, pers. comm.).

The turtles were transported to Canberra where abdominal palpation on 26 May, 1990 revealed the female to be gravid. Nine hard-shelled (calcareous) eggs were obtained on 28 May, 1990 by inducing oviposition with an injection of synthetic oxytocin (Ewert & Legler, 1978). A tenth egg was found in the holding tank weeks later but was not measured. Mean egg length was 31.4±0.2mm, egg width was 21.8±0.1mm and egg weight was 8.6±0.1g (mean, standard error, n=9). The eggs were incubated at 30°C in a plastic container on a bed of vermiculite moistened to a constant ratio of 4g vermiculite to 3g water. An opaque white patch appeared on each of the nine eggs within 36 hours indicating development had commenced (Thompson, 1985) and the eggs hatched on 25 September, 1990, 120 days later. Mean hatchling carapace length was 31.3±1.0mm, mean carapace width was 26.6±0.4mm and mean weight was 5.4±0.3g (mean, standard error, n=3).

DISCUSSION

Recent collections of *C. novaeguineae* (King & Horner, 1987; Covacevich et al., 1990; this paper) have substantially increased the known Australian range of the species. Formerly only known from northeast Queensland (Cogger, 1988), *C. novaeguineae* has now been recorded from the Gulf country near the Queensland and Northern Territory border (Covacevich et al., 1990) and from Maria Island in the Gulf of Carpentaria (King & Horner, 1987). King & Horner (1987) suggest that the population on Maria Island in the Gulf of Carpentaria may have been established by turtles swept out of rivers during flooding in either the Roper, Towns or Limmen-Bight Rivers. Our finding of *C. novaeguineae* in the upper reaches of the Roper River, is consistent with this suggestion and confirms Cann's (1978) reports of *C. novaeguineae* in the Daly Waters area and his reference to their presence in the lower reaches of the Roper River (Cann, 1972). A list of current holdings in Australian Museums (AM, Australian Museum; QM, Queensland Museum; SAM, South Australian Museum; NTM, Northern Territory Museum), excluding those of Table 1, is as follows:

AM R40700, 08°55'S 143°03'E, Kuru [Village], Western District, PNG; AM R129346, Greta Creek, near Bowen; QM J5269, 18°04'S 146°33'E, Palm Is., NEQ; QM J10265, 20°24'S 148°35'E, Proserpine, NEQ; QM J13326, 19°16'S 146°49'E, Townsville, Thornley Pk, NEQ; QM J15560, J15900, 19°13'S 146°38'E, Townsville, Black R., NEQ; QM J20627/28/30/31/33/35, 14°35'S 144°03'E, Wakooka Outstation, lagoon 6.4km W, NEQ, 29 Nov, 1970; QM J36751, 15°25'S 141°58'E, Mitchell R., NWQ, late 1978; QM J37566, 14°07'S 143°16'E, Stewart R. 23km NNW Mt Croll NEQ, 6 Aug, 1979; QM J37819, 17°53'S 142°34'E, Cape York Peninsula, Gilbert R., NEQ, 10 Aug, 1979; QM J45005, 19°14'S 144°02'E, Lynd Hwy, NEQ, 1 Dec 1981; QM J47923, 180°39'S 146°01'E, Ingham Q, 19 Mar, 1988; QM J50730, 19°16'S 146°49'E, Townsville Town Common , NEQ, 2 Jul, 1990; QM J50731, J50732, J50997, J50998, 16°58'S 138°05'E, 5km SW of Old Doomadgee, NWQ, 24 Jun 1990; SAM R14361, 17°56'S 138°49'E, Doomadgee Mission, NWQ, Jun, 1963; NTM R5753 , 14°53'S 135°43'E, Maria Is., NT, 11 Jul, 1972; NTM R5898, 14°53'S 135°43'E, Maria Is., NT, 26 Jul, 1972.

Chelodina longicollis, *C. novaeguineae* and *C. steindachneri* are closely related. Their distributions (Fig. 1) suggest that their common ancestor may have had a distribution extending around much of the periphery of the Australian continent. This widespread species may have exhibited clinal variation in morphology and reproductive parameters consistent with differences we observe

FIG. 1. A map of Australia showing the locations of collection of specimens held in Australian museums (●) and the likely distribution of *Chelodina novaeguineae* in stipple. Shown also are the distributions of *C. longicollis* and *C. steindachneri* (after Cogger, 1988). The exact boundary between *C. longicollis* and *C. novaeguineae*, while in the Burdekin drainage (John Cann, pers. comm.), is uncertain.

in these characters among the three species today. Progressive aridity in the Pleistocene, around 25,000 years ago, or earlier during similar periods of expanding aridity in the past 15 million years may have led to the separation of three isolated populations, the one in the west speciating to *Chelodina steindachneri*, the one in the north and New Guinea speciating into *C. novaeguineae* and related forms and the one in the southeast speciating into *C. longicollis*. Studies of populations of *C. longicollis* and *C. novaeguineae* in the Burdekin drainage where they are in sympatry or parapatry with possible hybridization (John Cann, pers. comm.) are worthy of further investigation.

Chelodina novaeguineae occupies semi-permanent and seasonally ephemeral waterholes throughout its range and occurs sympatrically with *C. rugosa* in the Gulf country (Covacevich et al., 1990). Unlike *C. rugosa* in these waterholes, *C. novaeguineae* will migrate many kilometres overland to permanent water rather than aestivate (Covacevich et al., 1990; later expanded in pers. comm.). This seems to be a hazardous strategy in waterholes that dry annually. *C. novaeguineae* in the Daly Waters area, on the other hand, appear to aestivate and can be dug out of the mud when the waterhole dries up (Bill Cook, pers. comm.)

The presence of *C. novaeguineae* in the Roper River was known to Aboriginal people at Jinduckin near Mataranka, who hunt for 'Nganymalin', the 'smelly armpit turtle', in small creeks well upstream (Jesse Roberts, Mangarrayi language group, pers. comm.). A pungent secretion exuded from glands in the auxillary and inguinal pockets is a distinctive feature of *C. novaeguineae* and its southern relative, *C. longicollis*. Four other species of freshwater turtle also inhabit the Roper River, 'Jarnamanjarr' (*C. rugosa*), 'Gorronani' (*Elseya dentata*), 'Marndirrin' (*Emydura 'australis'*) and 'Jabada' (Jesse Roberts, pers. comm.). Jabada is described as a flat-headed short-necked turtle and may possibly be *Elseya latisternum*, although *E. latisternum* has not been officially recorded from the Roper. Interestingly, Aboriginal people at Jinduckin claim that, contrary to other reports (e.g. John Bywater, cited in Georges & Kennett, 1989), the Pig-Nosed Turtle (*Carettochelys insculpta*) does not occur in the Roper, the nearest place they caught them was in the Victoria River at Timber Creek. The distribution of *C. insculpta* may be more restricted in the Roper River than in other drainages where it is found.

The eggs and hatchlings of *C. novaeguineae* (this study; Grossman, 1988) are similar in size and appearance to those of *C. longicollis* (Vestjens, 1969; Kennett & Georges, 1990). The bright orange stripes on the plastron of hatchlings may be aposematic which, allied with their pungent secretion, may act as a deterrent to predators. The colouration fades with age (Cann, 1981) and may not be as marked in captive raised juveniles (Grossman, 1988).

Our gravid specimen and a gravid female collected by John Cann (10 August, 1979) from the Gilbert River on the Cape York Peninsula north east Queensland (QM J37819) indicate that nesting may occur throughout the tropical dry season, equivalent to the temperate autumn and winter. If our observed incubation period of 120 days approximates the natural incubation period, then hatching would occur in the late dry or early wet season, equivalent to the temperate spring and summer. These results are in conflict with the conclusions of Legler (1981, 1985) who describes *C. novaeguineae* as a temperate breeder, nesting in spring with hatching before autumn. Legler (1981, 1985) recognizes two groups within the genus *Chelodina* and characterizes the groups as exhibiting a tropical reproductive pattern and a temperate reproductive pattern. *C. novaeguineae* effectively straddles both groups, with the small

egg size of the temperate pattern and the nesting and long incubation period of the tropical pattern. These data suggest that the reproductive pattern of *C. novaeguineae* may have changed as it has moved north from its hypothesised evolution in southern Australia (Legler, 1981, 1985) and that phylogenetic conclusions based on reproductive patterns may be unsound.

RE-EXAMINATION OF THE VENATION OF *OSMYLOPSYCHOPS SPILLERAE* TILLYARD FROM THE TRIASSIC OF QUEENSLAND

KEVIN J. LAMBKIN

Lambkin, K.J. 1992 06 29: Re-examination of the venation of *Osmylopsychops spillerae* Tillyard from the Triassic of Queensland. *Memoirs of the Queensland Museum* **32**(1): 183-188. Brisbane. ISSN 0079-8835.

The finding of new material has permitted re-examination of the venation of the Triassic neuropteran *Osmylopsychops spillerae* Tillyard. Many of the features of Tillyard's reconstruction of the forewing of the species are shown to be erroneous. □*Osmylopsychops spillerae, Neuroptera, Insecta, Triassic, Queensland.*

Kevin J. Lambkin, Honorary Research Fellow, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101; Correspondence to: 75 Alexandra St, Bardon, Queensland, Australia 4065; 22 November, 1991.

In the last of his 10 part series on the Mesozoic insects of Queensland, Tillyard (1923) described a broad-winged psychopsid-like lacewing from the Triassic of Denmark Hill in south-eastern Queensland (27°37'S, 152°47'E) as *Osmylopsychops spillerae* Tillyard. *Osmylopsychops* Tillyard was ascribed to the new family Osmylopsychopsidae by Martynova (1949) and, in 1953, Ellenberger et al. augmented the genus with their description of *O. radialis* from the Upper Triassic of France.

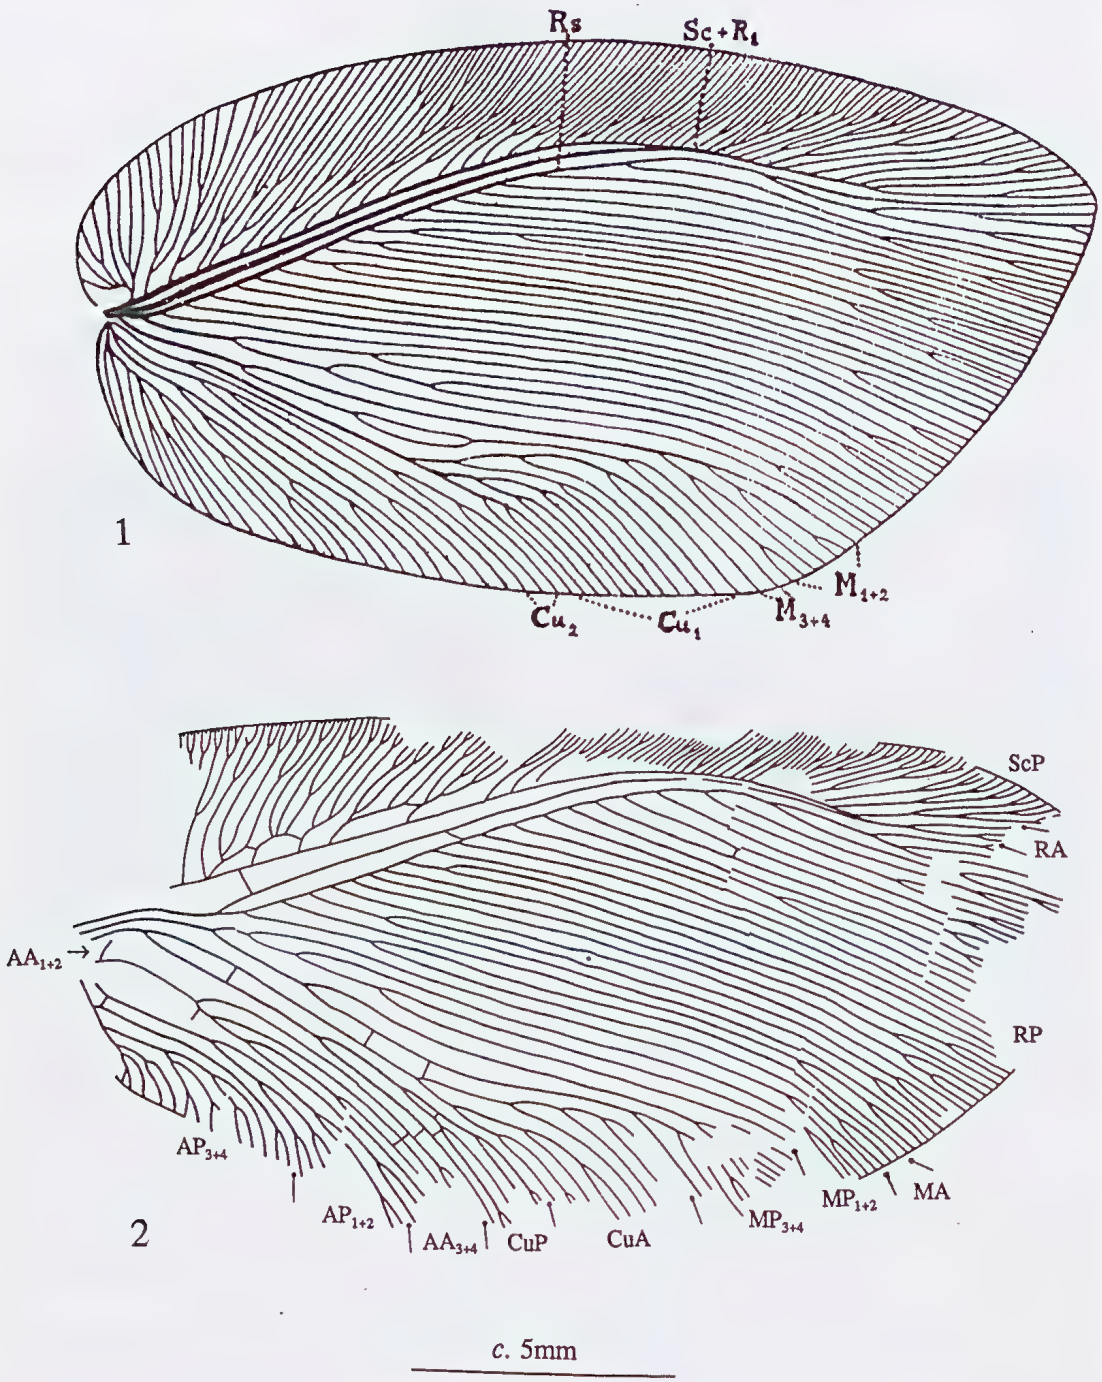
O. spillerae was based on two wing fragments (Tillyard, 1923, pl. XLIII, figs 39,40), from which Tillyard 'reconstructed' the forewing venation (Fig.1). Because of the fragmentary nature of this type material (Figs3,4), much of the reconstruction was notional and, as often happens with such 'best guess' reconstructions, its publication and subsequent reproduction (e.g. Riek, 1970) entrenched in the literature an assumed to be accurate 'complete' venational scheme that became a baseline for subsequent comparisons with similar species.

The purpose of the present work is to provide a more accurate view of the venation of *O. spillerae* and in so doing to exclude Tillyard's reconstruction, visually appealing though it may be, from the data set of fossil Neuroptera. The re-examination of the venation of the species has been made possible by the collection in more recent years of several specimens of *O. spillerae* from the Triassic of Mount Crosby in south-eastern Queensland (27°32'S, 152°48'E), from where the species was first recorded by Riek (1955). Examination of this new material as well as of Tillyard's original Denmark Hill specimens provides an almost complete picture of the forewing venation of the species (see Fig.2).

Tillyard's material was collected in grey shales of the Blackstone Formation that were exposed in a small quarry at Denmark Hill, a suburb of the town of Ipswich (Dunstan, 1916). Mount Crosby fossil insects occur in green shales of the Mount Crosby Formation and have been collected at five separate exposures designated as Fossil Insect Localities A, B, C, D and E (details in Allen, 1961). Both Formations are Late Triassic (Karnian) and form part of the Ipswich Coal Measures, with the Mount Crosby Formation lower in the sequence (Cranfield et al., 1976).

With one exception, the determination of whether the isolated wing fragments described herein are of fore- or hindwings has not been possible. The closest living species for comparative purposes is the psychopsid *Megapsychops illidgei* (Froggatt). In this species the basic venational patterns of the fore- and hindwings are very similar (see Tillyard, 1919, pl. LXXVII, fig.4; New, 1988, figs196,197) and, because of this similarity, I believe it is valid, for the sake of convenience of discussion, to regard all wing fragments of *O. spillerae* considered herein as probable forewings. The exception to this uncertainty is specimen UQDE CB14 (Fig.6). It has the proximal regions of AA_{3+4} and AP widely separated and the stem of AA_{1+2} clearly developed (both forewing characters of *M. illidgei* and other living psychopsids), and is therefore almost certainly a forewing.

The venational terminology used herein is that of Kukalová-Peck (1983, 1991; see also Lawrence et al., 1991). The following museum abbreviations apply: GSQ, Geological Survey of Queensland; QM, Queensland Museum; UQDE, University of Queensland, Department of Entomology.



FIGS 1,2. *Osmylopsychops spillerae*. 1, Tillyard's reconstruction (1923, text fig.93). 2, Composite of QM F18921 (Fig.5), UQDE CB14 (Fig.6), QM F18922 (Fig.7), and part of GSQ 283a (Fig.4) (proximal sections of ScP, RA, RP, CuA (thicker veins) not drawn to scale).

MATERIAL EXAMINED

Holotype GSQ 314 (central region of ?forewing), 'Osmylopsychops / ~~reevei~~ spillerae Till. / Holotype / Denmark Hill / Ipswich', '3149.9'; Heautotype [= autotype] GSQ 283a (apical $^2/_3$ of ?forewing), 'G', 'Osmylopsychops / ~~reevei~~ spillerae Till. / Heautotype / Denmark Hill / Ipswich / Trias.'; QM F18921 (central region of ?forewing), Mount Crosby Fossil Insect Locality D (collected by K J Lambkin, 20.viii.1972); UQDE CB14 (base of forewing), Mount Crosby Fossil Insect Locality B; QM F18922 (apex of ?forewing), 'L114 Mt Crosby shale / (910805-911805 Ipswich / 1 mile military map - upper bed) / 10.vii.1969 / E. Dahms', [Mount Crosby Fossil Insect Locality C]; QM F18923 (?forewing fragment), Mount Crosby Fossil Insect Locality B (collected by K J Lambkin, 24.viii.1974).

DESCRIPTION OF FOREWING VENATION (Figs 2-8)

Broad wing of psychopsid type, length c. 18.5mm (Fig.2); costal space quite broad basally, tapering apically (Figs4,5); costal crossveins irregular, mostly deeply forked and extensively branched, almost upright basally, becoming gradually more inclined apically, more closely spaced in 'pterostigmal' area, with a limited series of interconnecting crossveins basally just above ScP (Figs3-7); ScP converging and either ?fused or ?connected by a very short crossvein with RA apically (Figs4,7), entering margin before wing apex; 1 upright scp-ra just beyond radial fork (Figs5,6); ScP, RA and stem of RP curved apically (Fig.2), 1 inclined ra-rp at c. midlength (Fig.5); RP with at least 18 pectinate branches, a few of these forked basally or c. midlength, all with apical branches (Figs4,5,7,8); crossveins of RP field apparently few in number, only 1 or 4 detected (Figs 5,8); MA simple or deeply forked (Figs3,5,6,8); MP occupying a large central area of the wing, its primary forking very close to the base (before that of R - Fig.6), with 6 or 7 branches at midlength (Figs3,5,6), and extensively dichotomously forked apically (Figs5,7); MP_{1+2} dichotomous in holotype, but in some specimens tending to pectination, in UQDE CB14 this pectination mirroring that of RP (Fig.6); MP_{3+4} forking a little later than MP_{1+2} (Figs3,6,8), MP_4 of holotype with an enclosed cell at c. midlength (Fig.3); medial, cubital and anal fields with a few randomly placed crossveins as illustrated in Figs3,5,6,8 (possibly preservation dependent); CuA extensively dichotomously forked from c.$^2/_3$ length with branches curved anteriorly (Figs3,5); CuP occupying only a narrow area of the wing, more deeply dichotomously forked than CuA, CuP1 more deeply forked than CuP_2 (Figs3,5,6); AA_{1+2} developed as a short spur directed obliquely towards Cu (Fig.6); AA_{3+4} extensively dichotomously forked from c.$^1/_4$ length (Fig.6); AP1+2 dichotomously forked from c.$^1/_2$ length, less extensive than AA_{3+4} or AP_{3+4} (Fig.6); AP_3 joined to AP_2 by a short crossvein basally, simple for almost entire length, with 2 small branches apically (Fig.6); AP_4 extensive, occupying as much of the margin as AP_1, AP_2 and AP_3 combined, extensively dichotomously forked with branches directed apically (Fig.6); trichosors present, at least along fore margin (Figs5,6); 1 nygma detected, placed centrally between 2nd and 3rd branches of RP (Fig.5).

NOTES

Figure 2 is a composite of UQDE CB14 (Fig.6), QM F18921 (Fig.5), QM F18922 (Fig.7), as well as a small part of GSQ 283a (Fig.4) ('pterostigmal' region only). It illustrates the known features of the presumed forewing of *O. spillerae*. The major differences between this composite and Tillyard's reconstruction (Fig.1) are listed below. Certain features, such as the wing shape and the venation of the humeral region and parts of the fore, apical and hind margins, are not preserved in the material examined and remain unknown.

1. Structure of MP (= M of Tillyard's notation)

Because Tillyard's specimens did not show the important basal structures of the main veins (as now provided by UQDE CB14 - Fig.6), he conjectured that MP was of minor extent with its primary forking well beyond that of R (as is apparently the case in recent psychopsids). The new material indicates that MP forks very early (before the primary radial fork), is multibranched, and occupies a large central area of the wing. The veins shown by Tillyard as the first two branches of RP (Rs of his notation) are indeed part of MP.

The structure of MP in *O. spillerae* is especially interesting in providing a clue to the homology of 'MP' in the wings of living species of the Psychopsidae. In the forewing of these species there is a variably developed weak posterior branch leaving MP before the primary forking of R, in exactly the same position as MP_{3+4} in *O. spillerae*. In larger species (e.g. *M. illidgei*,

FIGS 3-8. *Osmylopsychops spillerae* (proximal sections of ScP, RA, RP, CuA (thicker veins) not drawn to scale). 3, GSQ 314 (holotype). 4, GSQ 283a ('heautotype'). 5, QM F18921. 6, UQDE CB14. 7, QM F18922. 8, QM F18923.

Psychopsis barnardi Tillyard) this branch exists as a very weak vein which peters out after running for a short distance along a fairly deep furrow in the membrane. In species of smaller size the furrow and a kink in the stem at the point of forking (e.g. *P. insolens* McLachlan), or simply the suggestion of a fold in the membrane (e.g. *P. coelivagus* (Walker)), is all that remains. Based on the structure of MP in *O. spillerae*, the much reduced extreme basal posterior branch of MP described above is the remnant of MP_{3+4} and the vein system usually labelled as 'MP' in living psychopsids is MP_{1+2} only.

2. Structure of Cu

In Tillyard's reconstruction the primary forking of Cu is a considerable distance from the base, and CuP forks at the same level as CuA and has only three branches. Specimen UQDE CB14 (Fig.6) shows that the primary fork of Cu is placed extreme basally (as occurs in the Psychopsidae and most Neuroptera), and that CuP forks much earlier than CuA and has at least six major branches.

3. Structure of A

The anal area in Tillyard's reconstruction is almost entirely conjectural and bears only marginal resemblance to that described herein (see especially Fig.6). The new information shows that the basal sections of Cu→CuP, AA_{3+4} and AP_{1+2} are much more widely spaced than in Tillyard's reconstruction; the basal section of AA_{3+4} is curved anteriorly, not posteriorly; AA_{3+4} and AP_{1+2} are not fused at the base; and AP_{3+4} is smaller in area and has fewer major branches which are directed apically rather than posteriorly.

4. Primary forking of R

Tillyard's reconstruction shows the primary forking of R very close to the base of the wing. UQDE CB14 (Fig.6) shows that R forks much further distally than this, well beyond the primary forkings of Cu and AA_{3+4}.

5. Marginal end-twigging of veins

End-twigging of veins is much more pronounced along the fore and hind margins (see Fig.2) than indicated by Tillyard.

6. Wing proportions

Comparison of Figures 1 and 2 indicates that the presumed forewing of *O. spillerae* is not as broad as suggested by Tillyard.

The relationships of *O. spillerae* (and *O. radialis* which, based on the figure of Ellenberger et al. (1953, fig.1), appears to be congeneric) remain problematical. *Osmylopsychops* is just one of a large number of diverse Mesozoic psychopsid-like wings (see Martynova, 1949, and numerous subsequent descriptions of additional species) that, as a group, requires critical re-examination and reappraisal. What can be said at this stage, however, is that *Osmylopsychops* does not possess the set of apomorphic wing features characteristic of the Psychopsidae (viz ScP, RA and stem of RP evenly spaced and braced by numerous crossveins; MP_{3+4} much reduced; CuA and CuP strongly posteriorly pectinate; crossveins mostly aligned into two or three gradate series) and is thus not attributable to that family (see also Riek, 1955).

ACKNOWLEDGEMENT

I am grateful for the assistance of Susan Parfrey of the Queensland Department of Resource Industries who arranged the loan of Tillyard's types.

NOTES ON *SPONDYLUS* LINNAEUS WITH DESCRIPTIONS OF TWO NEW SPECIES FROM WESTERN AUSTRALIA (MOLLUSCA: BIVALVIA: SPONDYLIDAE)

KEVIN LAMPRELL

Lamprell, K. 1992 06 29: Notes on *Spondylus* Linnaeus with descriptions of two new species from Western Australia (Mollusca: Bivalvia: Spondylidae). *Memoirs of the Queensland Museum* 32(1): 189-194. Brisbane. ISSN 0079-8835.

Two new species of Spondylidae, *Spondylus clarksoni* sp.nov. and *S. eastae* sp.nov., are described from Western Australia. Additional taxonomic notes are presented on other Recent *Spondylidae*. *Spondylus asperrimus* Sowerby, 1847 is elevated to specific rank; *S. butleri* Reeve, 1856 is removed from the synonymy of *S. longitudinalis*; *S. erinaceus* Reeve, 1856 is relegated to the synonymy of *S. gilvus* Reeve, 1856; *S. pratti* Parth, 1990 is placed in the synonymy of *S. pictorum* Schreibers, 1793; a reliable locality is established for *S. gravis* Fulton, 1915; *S. raoulensis* Oliver, 1915 (July) is given priority over *S. iredalei* Fulton, 1915 (October); and *S. prionifer* Iredale, 1931 is redescribed. □*Mollusca, Bivalvia, Spondylidae, Spondylus, new species, taxonomy, Western Australia.*

Kevin Lamprell, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 3 February, 1992.

Since publication of *Spondylus: Spiny Oyster Shells of the World* (Lamprell, 1987), I have studied type specimens in overseas museums and a range of new material from the Australian region. Two undescribed species of *Spondylus* from Western Australia were recognised and taxonomic information on several previously described species was updated.

Abbreviations used in text: AM = Australian Museum; QM = Queensland Museum; WAM = Western Australian Museum; MV = Museum of Victoria; pv = paired valves.

SYSTEMATICS

Family SPONDYLIDAE Gray, 1826
Spondylus Linnaeus, 1758

Spondylus clarksoni sp.nov.
(Fig. 1a-d)

ETYMOLOGY

For Mr Peter Clarkson who donated specimens for study.

MATERIAL EXAMINED

HOLOTYPE: WAM562-91, 1 pv, exposed on dead coral faces, 9-13m, Bennett Shoal, central Exmouth Gulf, W.A., 1991, P. Clarkson. Height 100mm, length 86mm, width 48mm.

PARATYPES: AMC167693, MVF6552, QMMO32909, 3 pv, exposed on sponge covered limestone reef in tide rip, 15-22m, S end South Muiron I., Exmouth Gulf, W.A., 1991, P. Clarkson.

OTHER MATERIAL: Four specimens from Pt Lefroy, southern end Exmouth Gulf, north W.A., P. Clarkson.

DIAGNOSIS

Shell pecten-shaped, slightly oblique, solid. Hinge typical for the genus. Top (left) valve moderately convex, more so umbonally; internally, slightly excavated under the hinge plate with a strong, wide, crenulated margin; hinge-line moderately wide. Sculpture of five, strong, rounded, principal radial ribs ornamented by strong, upright, spatulate spines which are channelled on the underside, narrow and strong at their bases, wide and flattened at their tips. Rib interstices with five to twelve minor radial ribs, central longer and stronger ornamented with dense, sharp, overlapping spines, and whose interstices contain smaller ribs which are ornamented with even smaller and finer spines or nodules. Lower (right) valve equally as convex as the top valve; cardinal area triangular and moderately deep; internally, moderately deep under the hinge plate with a strong, wide, crenulated margin. Sculpture (where not affixed) of thin concentric foliations with few, irregularly placed, strong spines. Area of attachment varying from 50-100% of the lower surface. Colouration pure white with pink-rose umbonally extending approximately one-third down the shell surface. Height 70-100mm, length 70-87mm, width 38-54mm.

HABITAT AND DISTRIBUTION

Covered in red sponge attached to low-profile limestone reefs, on a sandy bottom, among spon-

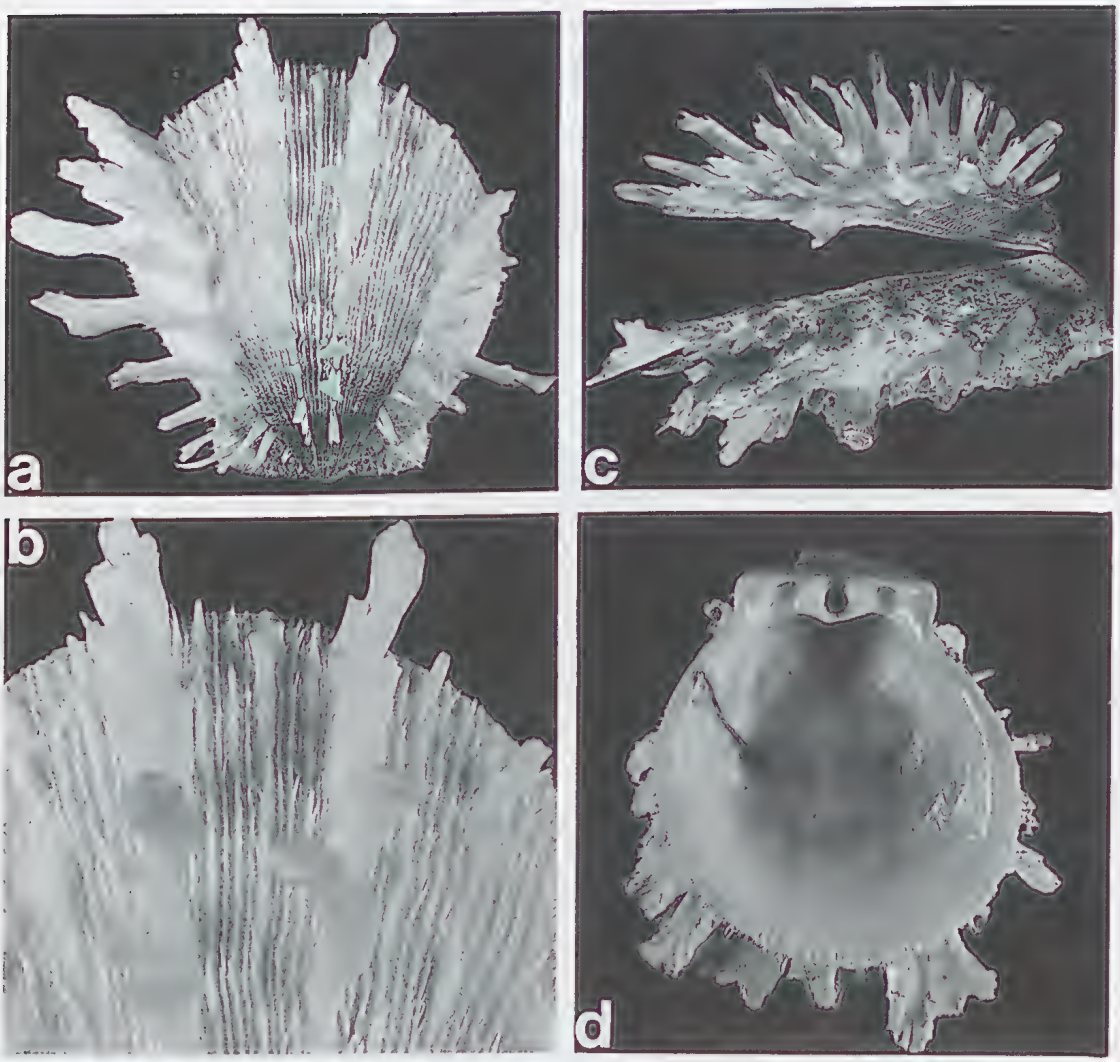

FIG. 1. *Spondylus clarksoni* sp.nov. a-d, Bennett Shoal, central Exmouth Gulf, Western Australia. WAM562-91, holotype. a, top valve. b, sculpture on top valve. c, side view. d, interior of lower valve.

ges and gorgonian corals. Apparently restricted to north Western Australia (Shark Bay to Broome).

REMARKS

Compared with *Spondylus clarksoni*, *S. sinensis* Schreibers, 1793 has fewer, stronger, interstitial ribs devoid of ornamentation, strong principal ribs on the lower valve (absent in *S. clarksoni*) and a very small attachment area. *Spondylus victoriae* Sowerby, 1843, which occurs sympatrically, has long, sharp to spatulate principal spines on both valves and fewer, stronger interstitial spines. Compared with *S. tenellus* Reeve, 1856, which occurs in southern Australia, *S. clarksoni* is larger and heavier, has stronger ribs, wide, spatulate spines and weaker interstitial spining. The spining and ribs in both valves of *S. tenellus* are always orange or pink whereas those of *S. clarksoni* are white.

Spondylus eastae sp.nov.
(Fig. 2a-d)

ETYMOLOGY

For Aileen East who has donated material for study.

MATERIAL EXAMINED

HOLOTYPE: WAM563-91, 1 pv, 7-11m, Schofield Shoal, SW Exmouth Gulf, W.A., 1991, P. Clarkson. Height 82mm, length 64mm, width 37mm.

PARATYPES: QM MO32910, AM C167694, MV F6553, 3 pv, exposed on sponge covered limestone reef

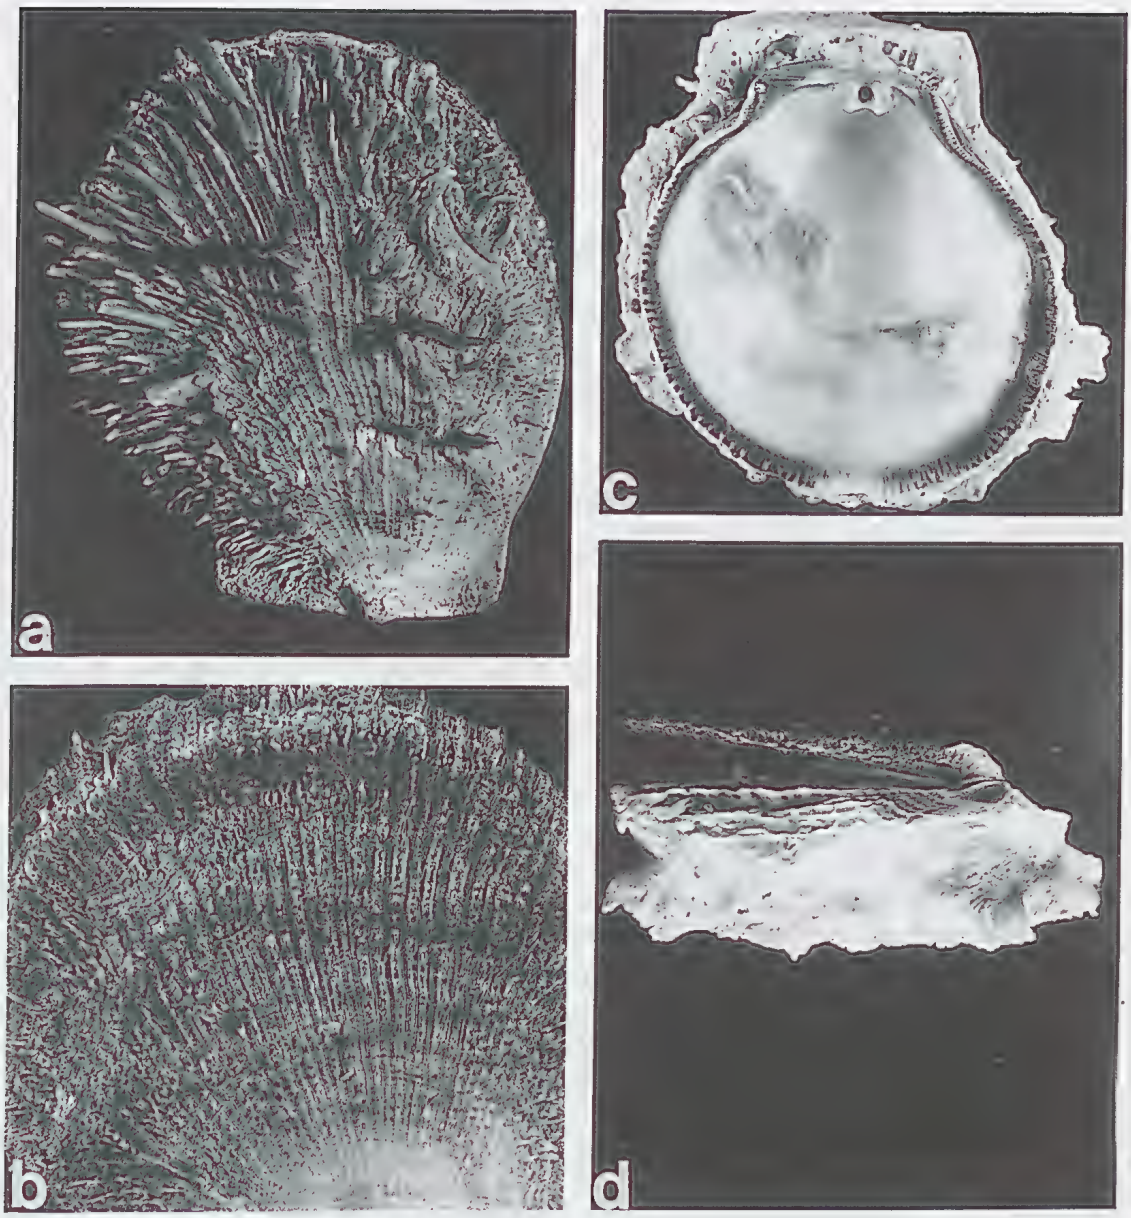

FIG. 2. *Spondylus eastae* sp.nov. a. Schofield Shoal, South West Exmouth Gulf, Western Australia. WAM563-91, holotype. b-d, Muiron I., Exmouth Gulf, Western Australia, paratype. a, top valve. b, sculpture of top valve. c, interior of lower valve. d, side view.

in tide rip, 15-22m, S end South Muiron I., Exmouth Gulf, W.A., 1991, P. Clarkson.

OTHER MATERIAL: Cape Keraudren, W.A., attached to rock at low tide, Sept. 1987, K. Lamprell; Port Hedland, W.A., attached to coral, low tide, Sept. 1987, K. Lamprell; Exmouth Gulf, Town Beach, 6m, attached to rocks, Sept. 1987, K. Lamprell and P. Spoor; Cape Keraudren, W.A., Sept. 1982, L. Marrow.

DIAGNOSIS

Shell ovate to pear-shaped; solid. Hinge typical for the genus. Top (left) valve moderately convex umbonally, remainder of surface depressed to moderately concave; internally smooth, slightly excavated under the hinge plate, with a strong, wide, moderately crenulated margin; sculpture of numerous, weak radial ribs, ornamented by short,

dense, strong, depressed, sharp spines and a few longer, irregular, flat, spatulate spines which are stronger at their bases. Rib interstices with a few irregular, obsolete radial ridges which are ornamented with dense, nodules or small spines. Lower (right) valve convex, moderately shallow to deep; cardinal area narrowly triangular, shallow; internally moderately excavate with wide, moderately crenulated margin; sculpture (where not affixed) of thin concentric foliations covering most of the surface, or otherwise with similar ribs and ornamentation to upper valve. Area of attachment varying from 10-70% of lower surface. Colouration typically brown/maroon to brick- red, orange or purple; umbones white with small flecks of brown; lower valve with similar colouration to top valve; internally blue-white centrally with deep purple-brown, red or orange margins and a dark brown margin towards the hinge. Height 72-93mm, length 57-79mm, width 30-42mm.

HABITAT AND DISTRIBUTION

Embedded in dead coral boulders and depressions on reef, among sponges and gorgonian corals; usually covered in red sponge. Restricted to north Western Australia.

REMARKS

Compared with *Spondylus eastae*, *S. barbatus* Reeve, 1856 has five or six strong, principal ribs with alternating, dense, sharp and spatulate spines, and colour bars or bands at the auricles. *Spondylus violascens* Lamarck, 1819 has been confused with *S. eastae* but has much stronger and denser spining on both valves, much less affixation and spatulate spines which are hollow rather than flat. The north-west Australian distribution given by Lamprell (1987) for *S. violascens* represents the range of *S. eastae*. *Spondylus multimuricatus* Reeve, 1856 is similar in shape and size to *S. eastae* but has stronger radial ribs ornamented with hollow, blunted spines (not spatulate) and with interstices that have few, irregular, smaller stout spines.

ADDITIONAL NOTES

Spondylus asperrimus Sowerby, 1847

REMARKS

Lamprell (1987: pl.3, fig. 1a-c) considered this species to be a form of *S. linguafelis* Sowerby, 1847. However it can be separated from that species by its more elongate shape, shorter spines and rows of fine nodulose spines in the interstices. It is usually affixed by almost the entire lower valve (or surface) whereas *S. linguafelis* is usually affixed by the cardinal area.

DISTRIBUTION

Philippines, north Western Australia and central Queensland coastal areas.

Spondylus butleri Reeve, 1856

REMARKS

Lamprell (1987: pl.4, fig. 2a-c) considered *S. longitudinalis* Lamarck, 1819 to be a prior name for the more widely used *S. butleri*. The type of *S. longitudinalis* (Museum of Natural History, Geneva) was examined and considered to be the same as *S. zonalis* Lamarck, 1819. Another specimen figured and referred to by Chenu (1845: pl.9, fig 2-2a) as *S. longitudinalis* (but not marked as a type), was even more similar to the type of *S. zonalis* . Fulton (1915:360, species 86) remarked, 'I have received a photograph of the shell figured by Chenu (*S. longitudinalis*), which is now in the Geneva Museum; the authorities there cannot say with any certainty that it is the actual type specimen'. *Spondylus butleri* should be used for the species figured in Lamprell (1987: pl.4, fig 2a-c).

DISTRIBUTION

Philippines, Madagascar, Micronesia and the Great Barrier Reef, Queensland.

Spondylus gilvus Reeve, 1856

S. erinaceus Reeve, 1856.

REMARKS

Although figured separately by Lamprell (1987: pl. 17, fig. 2a, b; pl. 17, fig. 1), types (British Museum Natural History) of *S. gilvus* and *S. erinaceus* revealed insufficient variation to maintain their separation.

Spondylus pictorum Schreibers, 1793

S. crassisquamatus Lamarck, 1819.
S. pratti Parth, 1990.

REMARKS

Three specimens of *S. pratti* from the type locality (Somalia) were compared with *S. pictorum*. Two were very mature but retained most of their sculpture; the third was younger with full sculpture. In describing *S. pratti*, Parth referred to

the two valves as unequal, the top valve larger and more gibbose. In all specimens examined, each valve was equally convex and gibbose. Parth also referred to both valves of *S. pratti* as equally sculptured with six principal ribs. In two of the specimens the top valve had six principal ribs while in the lower valve, one specimen had six and the other seven principal ribs.

While Parth (1990:6) only compared *S. pratti* with *S. americanus* 'because of its large size', numerous other *Spondylus* are equally as large or larger than this species: in particular, *S. pictorum* Schreibers, 1793 (Lamprell, 1987: pl. 23, fig. 1a-d), which shares a similar distribution to *S. pratti*, viz Somalia. *Spondylus pictorum* is equally as convex as *S. pratti*, has similar sculpture, rib count, interstitial sculpture and spining; and both have stout, upright principal spines that are channelled beneath, extending the full length of the spine. Colouration in specimens examined was similar to *S. pictorum*: white in base colour with bands of pink, red or brown and pink in the umbonal area. The juvenile specimen had white in the interstices and pink spines whereas, in some specimens of *S. pictorum*, the interstices are white and red or orange-brown. I am unable to find any features, apart from this interstitial colour variation, to separate *S. pratti* from *S. pictorum*.

Spondylus gravis Fulton, 1915

REMARKS

The type is in the British Museum (Natural History) without a specified locality. Recent trawling of several specimens (Lamprell, 1987: pl. 28, fig. 1) in 200-300m off Capo Ras Hafun, Somalia, gives reliable locality data.

Spondylus raoulensis Oliver, 1915

S. iredalei Fulton, 1915.

REMARKS

Lamprell (1987: pl. 29, fig. 4) incorrectly listed this species as *S. iredalei.* Fulton's work was published in two parts and the section naming *S. iredalei* was included in the second part printed in October 1915. The description of *S. raoulensis* by Oliver was published on the 12 July 1915 and thus has priority over *S. iredalei.*

Spondylus prionifer Iredale, 1931

REMARKS

Lamprell (1987: pl.25, fig.1) incorrectly listed *Spondylus prionifer* as a synonym of *S. tenellus* Reeve, 1856. The holotype (Australian Museum, Sydney) is immature and superficially similar to *S. tenellus*. However, numerous specimens recently collected on the Gneering Shoals, Mooloolooba, south Queensland, differed from *S. tenellus*. On the basis of this material, a more detailed description of *S. prionifer* follows. The species was figured by Lamprell (1987: pl. 25, fig. 3b; pl. 30, figs 1, 2).

DESCRIPTION

Shell height to 85mm, width to 65mm and depth of conjoined valves to 45mm, pecten-shaped. Top (left) valve slightly convex to depressed; lower (right) valve moderately deep, cup-like, cardinal area trigonal, moderately extended; internally with the margins strongly crenulated; area under the lunule and hinge plate, deep and extended; sculpture of both valves with 35-40 strong radial ribs with weaker intermediate ribs in the interstices; ribs ornamented with numerous depressed or hooked spines which vary from sharp to spatulate, stronger marginally and with a longitudinal furrow beneath and finely denticulate edges; interstitial ribs with two or three rows of fine spines or striae. Area of attachment of the lower valve variable but usually restricted to the umbonal area. Colouration variable, usually white with concentric bands of red and white ribs marginally, rarely all orange or red-brown; internally blue-white with margin crenulations variegated white and red or orange.

HABITAT AND DISTRIBUTION

Attached to corals or rock to 33m. Central Queensland (Capricorn Channel), south Queensland (Gneering Shoals) and Sydney Harbour, N.S.W.

ACKNOWLEDGEMENTS

Thanks are due to the Curators and staff of the British Museum (Natural History), Museum National d'Histoire Naturelle, Paris and the Museum of Natural History, Geneva for their assistance in examining essential study material; to Dr John Stanisic, Queensland Museum and Dr John Healy, Queensland University for critically reading the manuscript and for advice on manuscript preparation; to Mr Ian Loch, Australian Museum, for his research on *Spondylus iredalei/raoulensis*; and to Mr Luigi Bozzetti, Italy, for the loan of specimens.

This work was carried out through a grant from the CSIRO, Science and Industry Endowment

Fund. Overseas photographic expenses were partially met by funds received from the Keith Sutherland Award, Australian Museum, Sydney.

THE SUBTRIBE HICKSBEACHIINAE (PROTEACEAE) IN THE AUSTRALIAN TERTIARY

ANDREW C. ROZEFELDS

Rozefelds, A.C. 1992 06 29: The subtribe Hicksbeachiinae (Proteaceae) in the Australian Tertiary. *Memoirs of the Queensland Museum* 32(1): 195-202. Brisbane. ISSN 0079-8835.

Wilkinsonia bilaminata F. Muell., a fossil fruit from deep leads at Gulgong, New South Wales is similar to fruits of extant genera *Athertonia* and *Heliciopsis* (subtribe Hicksbeachiinae: Proteaceae). *Athertonioides* Rozefelds is considered a synonym of *Wilkinsonia*. Fossil evidence of *Wilkinsonia* in the mid-Tertiary demonstrates that the subtribe was more widespread than at present. *Wilkinsonia* is more closely related to *Athertonia*, the north Queensland rainforest endemic, than to the South East Asian genus *Heliciopsis*.□ *Proteaceae, Hicksbeachiinae, Athertonia, Heliciopsis, Wilkinsonia, Athertonioides, fossil fruit, Australia, Tertiary.*

Andrew C. Rozefelds, Queensland Museum, PO Box 3300, South Brisbane, Queensland, 4101, Australia; present address: School of Botany, University of Melbourne, Parkville, Victoria 3052, Australia; 30 January, 1991.

Mueller (1879, 1883) described *Wilkinsonia bilaminata* on the basis of woody fruits from deep leads (buried placer deposits) below basalts in the Orange and Gulgong gold mining areas of New South Wales. Mueller (1879, 1883) recorded *W. bilaminata* from Beneree, near Orange at a depth of about 110-130ft and in deep leads at Gulgong at a depth of 140-175ft (Fig. 1). He was unsure of the affinities of *W. bilaminata* but suggested (1879: 170) that it 'may perhaps have belonged to the order of Sapindaceae; but with the material at present available it is impossible to find its exact ordinal position, as no external resemblance indicates any close relationship to existing genera'. The only surviving specimen located is in the Museum of Victoria (NMVP53092) from the Gulgong locality in New South Wales.

Palynological studies of the Home Rule Kaolin Deposit which is part of one of the deep leads in the Gulgong area indicates they are of late early to middle Miocene age (McMinn, 1981). Potassium-Argon dates of 14.8 ± 1.2 and 13.8 ± 1.1my BP. for basalts that overlie deep leads in this area (Dulhunty, 1971) indicate a minimum mid-Miocene age for this flora.

Fruits from the Oligocene Glencoe locality in central Queensland were placed in a new form genus *Athertonioides* which closely resembles those of the north Queensland endemic *Athertonia*, and South East Asian genus *Heliciopsis*, (both in subtribe Hicksbeachiinae) (Rozefelds, 1990a). Re-examination of topotypic material of *W. bilaminata* F. Muell. from the Gulgong locality also suggests inclusion in Hicksbeachiinae (Fig. 2).

In this paper *W. bilaminata* is redescribed and it's affinities discussed. The status of *Athertonioides* Rozefelds is also re-examined. Fruit anatomy of extant genera *Heliciopsis, Athertonia* and *Hicksbeachia* is also figured and the fossil record of Hicksbeachiinae in Australia is reviewed.

METHODS AND MATERIALS

To permit comparison with the fossil material, the soft outer exocarp and mesocarp layers of modern fruits were removed. Persistent fibres attached to the stony layer (endocarp) of the fruit were removed with a nylon brush. The endocarp was sectioned with a coping saw and the transverse sections polished with 1200 grit 'wet and dry sandpapers'. The sections were photographed with a Carl Zeiss DRC Stereo Microscope with MC63 camera attachment. Comparative modern Australian material figured in this paper will be donated to the Queensland Herbarium (BRI).

The term endocarp is used here in a descriptive sense and follows that of Sleumer (1955a,b), (Smith & Haas, 1975) and Filla (1926). Johnson & Briggs (1975), however, have concluded that this inner stony layer is part of the mesocarp. The mesocarp consisting of an outer zone of parenchymatous tissue with radial fibres and inner dense hard zone of tangentially oriented fibres.

Silicified fossil material from Glencoe (Queensland Museum locality QML511) is preserved as moulds with little or no internal cellular preservation. Gulgong and other deep leads fruits approach fusanites in appearance, which

suggests they have been subjected to considerable heat and pressure. During fossilization, the more volatile endocarp wall constituents are lost, leaving only the ligneous structure of the fruit. In modern fruits the volatile endocarp wall constituents are still present making comparisons difficult.

SYSTEMATIC PALAEOBOTANY

Family PROTEACEAE
Tribe MACADAMIEAE
Subtribe HICKSBEACHIINAE

Rozefelds (1990a) erected *Athertonioides glencoensis* for fossil fruits collected from the Glencoe locality in central Queensland. Re-examination of *Wilkinsonia bilaminata* also indicates close affinities with *Athertonia*. It is not warranted to maintain two form genera for fossil *Athertonia*-like fruits and so *Athertonioides* is here reduced to a synonym of *Wilkinsonia*. In his diagnosis of *Wilkinsonia*, Mueller (1879, 1883) drew prominent attention to the flattened nature of the endocarp and the ridging which are features, that are in part, due to compression during fossilization. An emended diagnosis of *Wilkinsonia bilaminata* is provided. The original specimen figured by Mueller (1879: pl. 3, fig. 4a,b) has not been located in the Museum of Victoria, Geological Survey of New South Wales or Australian Museum collections. It seems likely that as the original material was obtained by C.S. Wilkinson (Geological Survey, New South Wales), the figured specimen would have been lodged in their collections, but may have been subsequently lost in the Garden Palace fire, Sydney, 1882 (J. Pickett, pers comm. 1992). A neotype is erected here, which is probably the specimen figured by Mueller (1883: pl. 3).

Geological Survey of New South Wales specimens (MMF31337-31343) from the Newstead Mine, Elsmore, northern NSW have been tentatively compared with *Wilkinsonia* (Pickett et al., 1990). These compressed fruits however lack the reticulate lacunose ornamentation and longitudinal ridges characteristic of this genus. The affinities of these fruits remain unknown.

Wilkinsonia (F. Muell., 1879) emend.

TYPE SPECIES

Wilkinsonia bilaminata F. Muell., 1879.

FIG. 1. Localities mentioned in text and distribution of modern genera and species of Australian Hicksbeachiinae.

EMENDED DIAGNOSIS

Endocarp indehiscent, variable in shape and size, with variable development of longitudinal ridges, reticulate lacunose surface consisting of irregular depressions. Depressions variable in size. Base of depressions confluent with internal wall of endocarp. Incipient curved longitudinal ridge continuous from apex to base of endocarp. Irregular rows of small depressions between incipient ridge and edge of endocarp. Monolocular.

FIG. 2. Reproduction of Mueller's (1883) original figure of *Wilkinsonia bilaminata*, × 0.7. The specimens were originally illustrated by Mueller at natural size.

Wilkinsonia bilaminata (F. Muell., 1879) emend. (Figs 2, 3A-D).

1879. *Wilkinsonia bilaminata* F. Muell., p. 170, pl. 3, fig. 4a,b.
1883. *Wilkinsonia bilaminata* F. Muell., p. 7, pl. 3 (refigured herein).

MATERIAL EXAMINED

NEOTYPE: NMVP53092 (here designated), Black Lead, 140-170ft below basalt, Gulgong, NSW (Fig. 3A-D).

EMENDED DIAGNOSIS

Large round monolocular endocarp, with reticulate lacunose ornamentation consisting of longitudinal ridges with ramifying supporting lateral ridges. Approximate size of endocarp (due to fraying of edges), length 46.3mm, width 45.9mm. A prominent incipient lateral ridge extends from the apex to the base of the endocarp. A broad lateral field occurs between incipient ridge and edge of endocarp with minor accessory lateral ridges and irregular rows of small depressions. Endocarp thinly elliptical in lateral view, although this is due to lateral compression. Multiple irregular rows of depressions and secondary ridges occur between the lateral ridge and the edge of the endocarp. The endocarp wall which is 2-3 mm in thickness, con-

sists of tangentially oriented interweaving fibres. Evidence of radial fibres around lacunae is missing but as these fibres are not strongly lignified they are unlikely to be preserved in fossil material.

Wilkinsonia glencoensis (Rozefelds) comb. nov. (Fig. 4A-C).

1990a. *Athertonioides glencoensis* Rozefelds, pp. 123-4, fig. 3,A- C,D(left figure), E,H.

MATERIAL EXAMINED

Holotype, QMF17212 and additional specimens from the mid-Tertiary Glencoe locality (QML511), near Capella, CQ, figured by Rozefelds (1990a).

DIAGNOSIS

Endocarp variable in size, broad to suboval or rounded in outline, with prominent reticulate lacunose ornamentation, ridging poorly developed, length 36-43mm; width 25-34mm, height 14-21mm. A narrow lateral field with multiple irregular rows of depressions occurring between incipient ridge and edge of endocarp. Endocarp wall thick, but ligneous structure not preserved.

REMARKS

The two *Wilkinsonia* species differ in the width of the lateral field between the incipient ridge and edge of the endocarp. In *W. bilaminata* this zone is broad while in *W. glencoensis* and closely related modern genera of the Hicksbeachiinae, it is narrow. This broad field in *W. bilaminata* is reflected by the presence of multiple irregular rows of small depressions with accessory ridges between the incipient ridge and edge of the endocarp. *W. bilaminata* also appears to possess more pronounced longitudinal ridges than *W. glencoensis,* but these ridges along with the flattened appearance of the endocarp are in part, due to compression.

ENDOCARP MORPHOLOGY OF EXTANT GENERA IN THE HICKSBEACHIINAE

The endocarps of *Wilkinsonia* are strongly lignified which helped facilitate fossilization. The endocarp wall in *Heliciopsis* and *Athertonia* consists of tangentially and radially oriented fibres. In *Athertonia* the tangentially oriented fibre bands are numerous and diffuse while in *Heliciopsis artocarpoides*, the endocarp wall is thin and there are areas of lignified parenchyma interspersed around the tangentially oriented fibres (Fig. 4F, J). The radial fibres in *Athertonia* and *Heliciopsis* tend to be perpendicular to the outside edge of the endocarp. In *Heliciopsis* the radial fibres around the lacunae are variously oriented, and sometimes oblique to the endocarp wall (Fig. 4F-G,J-K).

In *H. artocarpoides* (Elm.) Sleumer the reticulate lacunose ornamentation is less developed and the ridging is less prominent than in *Athertonia* (Fig. 4H-I). Most species of *Heliciopsis* conform to the endocarp morphology in *H. artocarpoides* although material from Sumatra, figured as *Heliciopsis* sp. and tentatively compared with *H. incisa* by Sleumer (1955a:191,194) resembles *Athertonia* in having more thickly walled and more strongly ornamented endocarps. The endocarp wall of *Heliciopsis* sp. also lacks the internested lacunae typical of *H. artocarpoides* (Sleumer, 1955a).

Hicksbeachia is the only other genus of this subtribe in Australia with two allopatric species in eastern Australia (Weston, 1988). The endocarp of *Hicksbeachia pinnatifolia* lacks reticulate lacunose ornamentation. In the specimens of *Hicksbeachia* available there is not a clear separation between the inner ligneous (endocarp) and outer fleshy mesocarp. The endocarp in *Hicksbeachia*, in transverse section has prominent vascular bundles that are oriented longitudinally, (absent in *Heliciopsis* and *Athertonia*) and poorly lignified radial fibres extend from the outer edge of the endocarp into the fleshy mesocarp (Filla, 1926; Fig. 4L, M). Similarly in *Athertonia* and *Heliciopsis* radial fibres extend from the endocarp into the mesocarp, with persistent radial fibres evident around the lacunae. The endocarp (inner mesocarp of Weston, 1988) in *Hicksbeachia* consists of tangentially oriented fibres and lignified parenchyma.

The remaining genera in the Hicksbeachiinae; *Virotia* from New Caledonia lacks reticulate lacunose ornamentation of the endocarp while the fruit morphology of *Malagasia* from Madagascar is unknown (Johnson & Briggs, 1975; Virot, 1968).

CONCLUSION

The large endocarp, incipient ridge extending from the apex to the base and prominent reticulate ornamentation and arrangement of tangential fibres in *Wilkinsonia* strongly suggest affinities with genera in the subtribe Hicksbeachiinae (Sleumer, 1955 a,b; Rozefelds, 1990a). These external endocarp features are shared with *Athertonia* and *Heliciopsis* but are absent from *Hicksbeachia* and *Virotia.*

Wilkinsonia is more closely related to *Athertonia* than to *Heliciopsis.* In *Heliciopsis* the depressions on the endocarp wall tend to consist of internested small lacunae while in *Athertonia* and *Wilkinsonia* they tend to be separate and not internested. The endocarp wall in *W. bilaminata* is strongly ornamented, consists of separate lacunae surrounded by tangentially oriented fibres. The endocarp wall is relatively thin and the simple perpendicularly oriented lacunae in *Wilkinsonia* are similar to *Athertonia.* The internal ligneous structure of *W. glencoensis* is not preserved although the endocarps are thick and woody, have perpendicularly oriented lacunae as in *Athertonia* and differ from the relatively thin walled endocarps of *Heliciopsis* (Rozefelds, 1990a) (Fig. 4).

The fossil distribution of *Wilkinsonia* demonstrates that the subtribe Hicksbeachiinae was more widespread than at present (Fig. 1). *Wilkinsonia* is most closely related to *Athertonia* which is presently restricted to rainforest communities on the Atherton Tablelands of north eastern Queensland. Similarly the allopatric distribution of *Hicksbeachia,* and restriction to widely separated mesic rainforest communities is suggestive of a more widespread range for this genus during the Tertiary, which may have encompassed much of eastern Australia (Fig. 1). The close relationship of *Wilkinsonia* to *Athertonia,* and the presence of *Elaeocarpus* (Rozefelds 1990b) in this flora suggests that the Gulgong area during the mid-Miocene was dominated by rainforest. The taxonomic diversity and structure of these mid-Tertiary rainforests will be more fully understood when the affinities of the remaining fruits and seeds described by Mueller (1879, 1883) are recognized. This will only be achieved by the concurrent study and description of fruits and seeds of the contemporary Australian flora.

ACKNOWLEDGEMENTS

The Jabatan Perhutanan Herbarium, Sandakan, Sabah, Malaysia provided material of *Heliciopsis artocarpoides* (SAN 28114) for study. *Athertonia* and *Hicksbeachia* fruits were supplied by T. Irvine and P. Weston respectively. P. Jell and A. Drinnan gave helpful advice and comments on this paper. The Museum of Victoria provided funding for my visit, allowing access to collections and photographed the original plates from Mueller's papers. Most of the remaining photographs were taken by the photography section at the Queensland Museum. Information and/ or access to collections was provided by R. Jones (Australian Museum), E. Thompson (Museum of Victoria) and J. Pickett (Geological Survey of New South Wales).

TERTIARY OCCURRENCE OF THE FERN *LYGODIUM* (SCHIZAEACEAE) IN AUSTRALIA AND NEW ZEALAND

A.C. ROZEFELDS, D.C. CHRISTOPHEL AND N.F. ALLEY

Rozefelds, A.C., Christophel, D.C. & Alley, N.F. 1992 06 29: Tertiary occurrence of the fern *Lygodium* (Schizaeaceae) in Australia and New Zealand. *Memoirs of the Queensland Museum* 32(1): 203-222. Brisbane. ISSN 0079-8835.

Lygodium is ubiquitous in early Tertiary floras of Australia. Sterile and fertile leaves of the climbing fern *Lygodium* are found in Eocene deposits from Anglesea (Victoria), Maslin Bay and Golden Grove (South Australia) and in the early Tertiary from Dinmore in Queensland (*L. dinmorphyllum* Churchill, 1969). Sterile material is known from Late Eocene/Early Oligocene sediments at Cethana (Tasmania) and the Middle Eocene at Temuka, in New Zealand.

New material from the Golden Grove, Maslin Bay and Anglesea localities including sterile and fertile pinnules, spores, and cuticular structure is referred to *L. dinmorphyllum*. The fertile pinnae contain spores of *Cyathidites splendens* Harris, 1965. This palynomorph has a Late Cretaceous (Maastrichtian) to Pliocene range in southern Australia. The Australian species is very similar to the Eocene Chilean *L. skottsbergii* Halle, 1940, in sterile and fertile pinnule morphology. Heterophylly presents problems in interpreting variation in fossil *Lygodium*.

☐*Lygodium, Schizaeaceae, Cyathidites splendens, Tertiary, palynology, palaeobotany, biogeography, Australia, New Zealand.*

Andrew C. Rozefelds, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; present address: School of Botany, University of Melbourne, Parkville 3052, Victoria, Australia; D. C. Christophel, Botany Department, University of Adelaide, PO Box 496, Adelaide 5001, South Australia, Australia; N. F. Alley, South Australian Department of Mines and Energy, PO Box 151, Eastwood 5053, South Australia, Australia; 25 June, 1991.

Extant *Lygodium* is a pantropical climbing fern with temperate outliers occurring in New Zealand (*L. articulatum* A. Rich.), eastern United States (*L. palmatum* (Bernh.) Swartz and Japan [*L. japonicum* (Thunb.) Sw.]. About 40 species are known world wide with four occurring in Australia (Holttum, 1959). The Australian species *L. japonicum* (Thunb.) Sw., *L. flexuosum* (L.) Sw., *L. microphyllum* (Cav.) R. Br. and *L. reticulatum* Schkuhr are tropical occurring in northern and eastern Australia. In this paper, fossil *Lygodium* leaves including sterile and fertile pinnules are described from Dinmore (Queensland), Maslin Bay and Golden Grove (South Australia) and Anglesea (Victoria) and a number of other localities in southern Australia and New Zealand (Fig. 1). Previous records of *Lygodium* or *Lygodium*-like ferns are reviewed. Problems inherent in classifying and describing variable taxa are discussed.

PREVIOUS RECORDS OF FOSSIL *LYGODIUM* IN AUSTRALIA AND NEW ZEALAND

Lygodium or *Lygodium*-like fossils have been reported by Johnston (1894), Ettingshausen (1886, 1888), Shirley (1898), Churchill (1969), Hill et al. (1970), Douglas (1978), Peters & Christophel (1978) and Christophel & Greenwood (1987). Churchill's material was the first unequivocal fossil evidence of the genus in Australia. The taxa described in the 19th century were based on fragmentary sterile pinnules but none can be confidently assigned to *Lygodium* (Churchill, 1969). Of these taxa the type of *Osmunda tasmanica* Johnston from Glenora, could not be located in collections in Tasmania (R. S. Hill & N. Kemp, pers. comm.). The holotype of *L. strzeleckii* Ettingshausen, 1886, collected from the Vegetable Creek locality was restudied and prepared further (Fig. 3A) but referral to *Lygodium* is dubious because it is based upon small pinnule fragments with abraded margins. The Late Triassic *Lygodium antiquorum* Shirley, 1898 from the Ipswich Coal Measures is based upon a trilobate seed fern or fern pinnule (Fig. 3F) with no evidence of sporangia, and is not referable to *Lygodium* as Walkom (1917) indicated.

Churchill (1969) described *L. dinmorphyllum* based upon two fertile pinnules from the early Tertiary Redbank Plains Formation at Dinmore in south eastern Queensland. Hill et al. (1970) recorded sterile *Lygodium* pinnules from Dinmore, which they referred to *L. skottsbergii*. Douglas (1978) figured a fertile *Lygodium* pinna

from Anglesea in Victoria. A fern frond tentatively compared with *Lygodium* has also been figured from the Cenomanian Winton flora of Western Queensland (Peters & Christophel, 1978). Christophel & Greenwood (1987) recorded *Lygodium* from the Golden Grove locality.

Additional material was collected from Dinmore and Anglesea by ACR and DCC respectively over a number of years. *Lygodium* has also been recently collected from the Middle Eocene Maslin Bay and Golden Grove floras (South Australia) and the Late Eocene/Early Oligocene Cethana flora of Tasmania (R. Carpenter, pers. comm.). *Lygodium* pinnae have also been recognized from Temuka in New Zealand (D. Mildenhall, pers. comm. 1986).

LOCATION OF SITES AND AGES OF FLORAS

The Dinmore site in the Redbank Plains Formation, south eastern Queensland is of Paleocene/Eocene age (Day et al., 1983). This largely undocumented flora includes ferns, Podocarpaceae and dicotyledonous leaves (Hill et al., 1970; Selling, 1950).

The diverse Anglesea flora occurs in the Middle Eocene Eastern View Coal Measures, and while *Lygodium* occurs in most lenses the majority come from the *Gymnostoma* lens (Christophel et al., 1987). Elements of the Maslin Bay flora were described by Blackburn (1981) from a carbonaceous clay lens in the Middle Eocene North Maslin Sands (McGowran et al., 1970; Alley, 1987). A well preserved flora from the North Maslin Sands at Golden Grove, north of Adelaide is also Middle Eocene in age. A recent overview of the flora has been provided by Christophel & Greenwood (1987).

The Late Eocene/Early Oligocene Cethana flora has yielded *Nothofagus* leaves (Hill, 1984), and the remaining flora, which includes 'tropical'

rainforest elements is presently being studied (R. Carpenter, pers. comm., 1987). The geology and stratigraphic information on the Temuka potteries clay pits in New Zealand indicates an Eocene age for this flora (Wellman, 1953; Gair, 1967). Specimens from these two localities were not available for study.

METHODS AND PRESERVATION OF FOSSILS

The Dinmore, Cethana and Vegetable Creek materials are preserved as impressions in fine grained mudstones lacking cuticle. Latex peels of the surface of sterile *Lygodium* pinnules from Dinmore, examined with a SEM, yielded no cellular information (D. Dilcher, pers. comm.). However, SEM examination of fragments of the original specimen do show some cellular information (Fig. 11A,B). The Maslin Bay and Anglesea specimens are preserved as compressions or impressions while *Lygodium* leaves and sorophores from Golden Grove are 'mummified'. The method for preparing 'mummified' leaves follows that of Christophel (1984). The Golden Grove *Lygodium* leaves are usually opaque and could not be studied using the fluorescence technique of Friedrich & Schaarschmidt (1977). Small areas of venation in these specimens were illuminated using narrow beams of light from cold light sources.

The mummified sorophores and small fragments of leaf cuticle from Golden Grove were cleaned with concentrated HF acid for a few days and the sporangia were gently macerated to release spores. Spores were studied and photographed with a Zeiss Photomicroscope 111. Fragments of cuticle from the sorophores and leaves were washed in distilled water, airdried and sputter coated with platinum. Material was examined with a JEOL JSM 840 scanning electron microscope with lanthanum hexaboride filament at 5kv.

Lygodium examined in this paper (Appendix A) includes material from the Queensland Museum (QMF), Geological Survey of Queensland (GSQF), University of Queensland (UQF), Museum of Victoria (NMVP), University of Tasmania (UTC), University of Adelaide (Maslin Bay, UAS; Golden Grove, UAG), and Geological Survey of New Zealand (GSNZ). Modern *Lygodium* material collected by ACR for this study, will be donated to the Queensland Herbarium (BRI).

SYSTEMATIC PALAEOBOTANY

Family SCHIZAEACEAE

Lygodium Sw.

The new *Lygodium* material from the various Australian localities is considered to be conspecific with *L. dinmorphyllum* Churchill from Dinmore in south eastern Queensland. An emended diagnosis of this taxon including information on spores, cuticle and foliar heteromorphism is given, as Churchill's description only covered the gross morphology of the fertile pinnules.

(Figs 4-10)

1969 *Lygodium dinmorphyllum* Churchill, pp. 257-265, fig.2.
1970 *Lygodium skottsbergii* Halle, Hill et al., pl. Czll, fig. 1.

EMENDED DIAGNOSIS

Sterile pinnules asymmetrical, usually 2-3 lobed, although unilobate, quadrilobate and pentalobate pinnules occur. Lateral lobes tend to be longer than central lobes. Pinnule base is cuneate to truncate, apex rounded to acute. Pinnules petiolate, lacking abscission node at pinnule base. Venation palmate, dichotomously branching from the central vein, on each lobe, two to three times before reaching leaf margin. Leaf length variable, maximum lobe length about 110mm. Pinnule margin variable, undulose in larger specimens, smooth in small pinnae, rarely lobed. Pinnules probably hypostomatic. Anticlinal walls of abaxial epidermis strongly sinuous, stomata anomocytic. Stomatal apparatus 30μm long, (29-32μm) and 27μm wide (25-32μm).

Fertile pinnules in branched axes often lack lamina, although lamina sometimes present as narrow wing or flange at the base of sorophores. Individual sorophores variable in size, ranging

from about 4.0-14.0mm in length, often united in groups of 2-4. Spores referable to *Cyathidites splendens* Harris, 1965. Sinuosity of anticlinal walls of epidermis on sorophore lamina not as pronounced as in sterile pinnules.

REMARKS

The Golden Grove and Anglesea localities have yielded *Lygodium* sorophores containing *C. splendens* spores. *C. splendens* is also a common palynomorph in the Maslin Bay palynoflora. While spores have not been isolated from the Dinmore sorophores and the cuticle is poorly known, it seems preferable to refer the new material to *L. dinmorphyllum* than erect a doubtfully distinct taxon. Based upon the widespread distribution of *C. splendens* in the early Tertiary and Late Cretaceous in Australia it seems likely that the Dinmore sorophores also had *C. splendens* spores. *Lygodium dinmorphyllum* is closely comparable with *L. skottsbergii* but is considered distinct based upon spores and cuticular information. Halle (1940: 259) noted that the spores of *L. skottsbergii* are finely punctate or almost smooth and hence differ from *C. splendens*.

The only contra-indication that the *Lygodium* material from Australia may include a number of taxa is the variation in the angle of lower order branching in the fertile axes at different localities. In a relatively complete non-distorted specimen from Anglesea (Fig. 8D), the angle of branching is (130-150°), which is similar to that of modern *L. articulatum* (Fig. 2). The Dinmore material typically has acutely angled lower order branching in the fertile pinnae, i.e. (75-85°) (Fig. 4A, G,H). Relatively complete and undistorted fertile axes have not been collected from Golden Grove or Maslin Bay so the angle of branching in the fertile axes from these localities is unknown. The systematic implications are difficult to assess because insufficient material has been collected from enough localities to assess variation.

FOLIAR HETEROMORPHISM IN EXTANT *LYGODIUM*

Foliar heteromorphism is the production of morphologically variable leaf types on the same individual (Eckenwalder, 1980). Changes in the size and shape of successive leaves can be due to heteroblastic development (Wareing & Phillips, 1982). This may occur in the transition from juvenile to adult leaves or may result from environmental factors. In *Lygodium*, transition from sterile to fertile pinnae results in morphologically distinct pinnae. Pinnae intermediate in character between sterile and fertile pinnules occur in *L. articulatum* and *L. palmatum*. The lamina in the fertile pinnae of the extant species *L. articulatum* and *L. palmatum* is very reduced and the pinnules are strongly dimorphic (Fig. 2; Manchester & Zavada, 1987, figs 9,11). The degree of lamina reduction varies in fertile leaflets of *L. articulatum* (Fig. 2).

In *Lygodium*, there is great plasticity of form in sterile and fertile pinnae, and fusion of pinnules occurs. Sterile leaflets in extant *L. articulatum* are characteristically unilobate although fused bilobate pinnules also occur. Fusion of pinnules may explain some variation in fossil material from Australia.

Aberrant pinnules with accessory lobing were collected from Dinmore, Maslin Bay and Golden Grove (Fig. 9G,H) and were also figured for *L. kaulfussi* Heer, 1861 by Manchester & Zavada (1987). In modern *L. reticulatum* from north eastern Queensland similarly deformed leaves also occur.

FOSSIL *LYGODIUM* MORPHOLOGY

Taxonomic treatments of extant *Lygodium* are based upon the form of sterile and fertile pinnules, spores, venation and mode of branching. Holttum (1959: 39) commented that 'there is so much variation in leaflet form due to the age of the plant,

height above ground and perhaps polyploidy and hybridization that even with ample material it is not easy to give specific limits'. Fossil *Lygodium* presents further problems due to the incomplete and fragmentary material available for study. The overlap in morphology and variation in sterile *Lygodium* pinnules from sites in Australia and New Zealand is presented in Table 1. As Dinmore and Golden Grove have yielded the largest amount of vegetative and fertile material, discussion centres on material from these two localities. The strongly dimorphic sterile and fertile pinnules occur in association at Dinmore, Golden Grove, Anglesea and Maslin Bay. Material from Dinmore indicates that the sterile and fertile *Lygodium* pinnules can be referred to the same plant (Fig. 4E-F).

Sterile Pinnule Morphology

Fossil *Lygodium* pinnules from the various sites are asymmetrical and palmately lobed. The number of lobes in sterile *Lygodium* was used by Berry (1930) to define new fossil taxa, although it is an extremely variable feature. *Lygodium* pinnules at most sites, but particularly at Dinmore and Golden Grove, exhibit considerable variation in the number and degree of lobation (Table 1). At Dinmore, unilobate and trilobate and bilobate and trilobate pinnules have been found in organic connection (Figs 5E,H,6C). In the extant New Zealand species *L. articulatum*, unilobate pinnules predominate but fused bilobate pinnules occur. Similarly, in fossil *Lygodium* from Dinmore, bilobate and trilobate pinnules are the most common, although rare quadrilobate and pentalobate pinnules occur (Fig. 5B,I). These are interpreted as resulting from the fusion of trilobate with unilobate and bilobate pinnules. Bilobate and trilobate pinnules also predominate in the Golden Grove, and Maslin Bay localities (Table 1). The Australian fossil *Lygodium* pinnules resemble extant *L. palmatum* in having multilobate pinnules but like *L. kaulfussi* Heer, they differ in their larger, more elongate pinnules.

All the major localities in Australia have yielded sterile pinnules with petiolules. In most specimens the petiolules are short (<3.0mm long), except a few specimens from Dinmore which have a preserved petiolule length of up to 15.0 mm (Fig.

TABLE 1. Comparison of the morphology of sterile *Lygodium* pinnules from localities in Australia and New Zealand.

LOCALITY	PINNULE SHAPE	VENATION	PINNULE APEX	PINNULE BASE	REFERENCES
L. dinmorphyllum					
Dinmore, Queensland	asymmetrical/palmate; bi., tri., quad., pentalobate	dichotomous	acute, obtuse, retuse	cuneate, truncate	Churchill, 1969; Hill et al., 1970
Anglesea, Victoria	asymmetrical/palmate; bilobate, quadrilobate	dichotomous	acute, obtuse, retuse	cuneate	Douglas, 1978
Maslin Bay, S. Aust	asymmetrical/palmate; uni., bi., trilobate	dichotomous	acute, obtuse	cuneate, truncate	—
Golden Grove, S. Aust	asymmetrical/palmate; uni.,bi., trilobate	dichotomous	acute, obtuse, retuse	cuneate, truncate	Christophel and Greenwood, 1987
Lygodium sp.					
Cethana, Tasmania	asymmetrical/palmate?; uni., bilobate	dichotomous	acute?, obtuse	cuneate	—
Temuka, New Zealand	asymmetrical/palmate?; uni., trilobate	dichotomous	obtuse, acute	truncate	
Vegetable Creek, N.S.W (*L.strzeleckii*)	unilobate	dichotomous	obtuse	—	Ettingshausen, 1886
L. skottsbergii					
Chile (fossil)	asymmetrical/palmate; bi., trilobate	dichotomous	acute, obtuse	truncate, broady cuneate	Halle, 1940
L. articulatum					
New Zealand (extant)	usually unilobate, rarely bilobate	dichotomous	acute	cuneate	

6B). The end of the petiolule in the Golden Grove material is frequently enlarged indicating a point of attachment and probably also dehisence (Fig. 9B-E,H). In extant *L. articulatum*, sterile and fertile pinnules lack a petiolule, and the abscission node occurs at the leaf base (Fig. 2). This feature also occurs in the fossil *L. kaulfussi* and was used by Manchester and Zavada (1987) to differentiate between *L. kaulfussi* and *L. skottsbergii*. *Lygodium skottsbergii* and the fossil Australian material resemble extant *L. palmatum* in that their leaflets are firmly affixed to short petiolules (Manchester & Zavada, 1987).

The pinnule margins in *L. dinmorphyllum* are entire to undulose with some specimens showing irregular lobation (Fig. 9G,H). One of the Cethana specimens (Fig. 3B) is irregularly serrate and is tentatively referred to *Lygodium*. The serration is accentuated by tearing of the leaf lamina and margins during fossilization. The other specimen is asymmetrical and bilobate (Fig. 3C) and comparable to other *Lygodium* material. The concavely curved basal margin of the pinnule is similar in both specimens. This feature occurs consistently in most of the Tertiary *Lygodium* material in Australia. The base of the pinnule is typically cuneate or truncate while in *L. kaulfussi* it is rounded to obtuse or cordate (Manchester & Zavada, 1987).

The venation in the fossil Australian and New Zealand material is dichotomous, branching 2-3 times before reaching the margin. The venation of the Australian *Lygodium* material appears indistinguishable from *L. kaulfussi* from the Eocene material from Wyoming figured by Manchester & Zavada (1987). Dichotomous venation is typical of most *Lygodium* species except those with reticulate venation, e.g. *L. reticulatum*.

Preservation of the mode of branching and evidence of the climbing habit which is characteristic of modern species in this genus is rare in the fossil record and is unlikely to occur in those species whose pinnules dehisce at senescence. The only evidence of the mode of branching in fossil *Lygodium* comes from impressions at Dinmore.

Fertile Pinnule Morphology

The sorophores of *L. dinmorphyllum*, like those

of *L. kaulfussi* and the extant species *L. palmatum* and *L. articulatum*, are produced terminally on branched axes. The sorophores vary in size, reflecting their position on the plant and stage of development. *Lygodium skottsbergii*, *L. articulatum* and *L. dinmorphyllum* all show variation in reduction of lamina in fertile pinnae. The fertile pinnae of *L. articulatum* vary in the free lamina between sorophores (Fig. 2) and *L. skottsbergii* shows similar variation in the amount of leaf lamina between sorophores (Halle, 1940: pl. 1, figs 4-8). *Lygodium dinmorphyllum* pinnae from Dinmore exhibit similar ranges of variation (Fig. 4) with some fertile pinnae 'free' of lamina, and others bearing extensive laminae between the sorophores (Churchill, 1969: fig. 2). In most of the Golden Grove, Maslin Bay and Anglesea material the fertile pinnae are nonlaminar. Fertile pinnae of *L. kaulfussi* are also nonlaminar although pinnules intermediate in character between sterile and fertile pinnules are preserved (Manchester & Zavada, 1987: fig. 8). The sorophores attached to the sterile pinnule from Dinmore can similarly be explained as a 'leaflet' intermediate in character between sterile and fertile pinnules (Fig. 4E-F). The annulus on the sporangia is not preserved in material from any site. Halle (1940) and Manchester & Zavada (1987) noted that the annulus could not be discerned in *L. skottsbergii* and *L. kaulfussi* respectively.

Spore Morphology

Spores from complete sorophores of *L. dinmorphyllum* are known from Anglesea (Douglas, 1978) and have been extracted from Golden Grove material. The spores broadly resemble those from fossil *Lygodium* (excluding *L. poolensis* Chandler, 1955) described from the Northern Hemisphere (Buzek & Konzalová, 1983; Chandler, 1955; Manchester & Zavada, 1987). Although spores were recovered from *L. dinmorphyllum* from a number of sites the best preservation is in the Golden Grove material and descriptions are based on this material. In general, the spores possess a subtriangular amb with convex to straight (occasionally concave) interradials and rounded radials. The laesura are slightly sinuous, often open and gaping, and extend two thirds of spore radius towards the amb. The laesura are bordered by labra 5-7μm wide and raised 6-8μm. Spore exine is approximately 2μm thick and thickened in the radial areas to 5μm. Ornamentation is best developed on the distal surface and comprises low verruca, short rugula and low sinuous to bifurcating ridges enclosing short irregular lumina; ornamentation is reduced on the proximal surface, particularly in the proximal polar area (Fig. 10). In optical section the amb is gently undulating. Some specimens appear to bear remnants of an irregular perisporum. Based upon measurements from 15 specimens the equatorial diameter of the spores is 67 (82) 95μm and polar diameter is 59 (75) 90μm.

The spores from *L. dinmorphyllum* sorophores are identical to the form species *Cyathidites splendens* Harris, 1965. The holotype of *C. splendens* was examined but the mounting medium and spore are too dehydrated to provide useful morphological information and comparisons were limited to photographs and published descriptions. However free spores of *C. splendens* occur consistently in the Golden Grove and Maslin Bay carbonaceous lenses as well as other Australian early Tertiary sediments (Fig. 10). *Cyathidites splendens* has also recently being recognized in Late Cretaceous (Maastrichtian) sediments from the offshore Bight and Duntroon Basins, off South and Western Australia (NA, pers. obs). Spores of the form species *C. gigantis* (Cookson) Harris, 1965 also bear some similarity to the spores extracted from the *L. dinmorphyllum* sorophores. However the holotype of *C. gigantis* and other free spores from early Tertiary sediments were examined and found to be smaller, possess a much thickened exine with prominently thickened radials, and coarse ornamentation in the proximal polar area, diminishing greatly in the equatorial interradial areas. The *L. dinmorphyllum* spores therefore correlate with the form species *C. splendens* Harris, 1965.

Cuticle Morphology

Attempts to prepare cuticle from the mummified Golden Grove leaves have proved difficult but small fragments were obtained. *Lygodium dinmorphyllum* pinnules from Golden Grove are probably hypostomatic as is modern *L. articulatum*. The stomata of *L. dinmorphyllum* from Golden Grove are anomocytic, as in extant *Lygodium* (Clifford & Constantine, 1980) and the anticlinal epidermal walls are strongly sinuous (Fig. 11 F,H). The stomata appear to be irregularly oriented on the leaf surface as in modern *L. articulatum* (Fig. 11D). SEM micrographs of impressions of Dinmore material also demonstrate sinuous anticlinal epidermal walls but stomata are not evident (Fig. 11 A,B). *Lygodium kaulfussi* has sinuous anticlinal epidermal walls and stomata comparable in size to those of *L. dinmorphyllum*. Unlike *L. dinmorphyllum* the stomata in *L. kaul-*

fussi are diacytic, arranged in rows and the anticlinal epidermal walls are not as strongly sinuous (Kräusel & Weyland, 1950). The stomata in *L. kaulfussi* are oriented between two epidermal cells, while in *L. dinmorphyllum* the stomata are surrounded by four or five cells.

The cuticle of *L. dinmorphyllum* sorophores indicates that the anticlinal epidermal walls are sinuous but not to the same extent as the leaves (Fig. 11G). No stomata were seen.

CONCLUSION

Even with ample material as provided by the Golden Grove and Dinmore localities, species assessment is difficult, as the material is extremely variable. The limited material from Cethana or Temuka is therefore difficult to interpret particularly with only photographic evidence available. Similarly early records of *Lygodium* (such as Ettingshausen, 1886, 1888), which are based solely on sterile foliage are also not presently resolvable. Northern Hemisphere species based on limited material present similar problems as Manchester & Zavada (1987) have shown.

Palaeobiogeographical speculation on the radiation and evolution of *Lygodium* is difficult because of the cosmopolitan distribution and extensive Tertiary fossil record (Kräusel & Weyland, 1950; Reed, 1947). The extensive fossil record of *Lygodium* in Australia suggests that the extant Australian species may be derived from these early Tertiary forms. However, as fossil *Lygodium* is also known from the Miocene Notonakajima flora of Japan and Oligocene floras of Manchuria (Matsuo, 1963; Florin, 1922) it is equally possible that the modern northern Australian species *L. japonicum*, *L. flexuosum*, *L. microphyllum* and *L. reticulatum* are recent arrivals from Asia as Page & Clifford (1981) speculated. These species are all widely distributed within the Malesian region (Holttum, 1959). The weakly dimorphic fertile foliage of most of the Malesian species, i.e. the fertile pinnules resemble the sterile pinnules, suggests a closer affinity to *L. mioscandens* Matsuo(1963) from Japan than with the fossil material from the early Tertiary of Australia. Manchester & Zavada (1987) suggested that species with lamina surrounding the sorophores, e.g. *L. japonicum* and *L. flexuosum* are relatively recent in origin. The high diversity of *Lygodium* species in the Malesian area may be due to a relatively recent and rapid speciation and radiation in this region. This may explain, in part, Holttum's (1959: 39) difficulties in defining modern species within the genus.

Cyathidites splendens ranges from the Late Cretaceous through to the Pliocene in southern Australia. In the early Tertiary Eyre Formation of the Lake Eyre Basin *C. splendens* is common and can be locally more frequent in parts of the Paleocene section. The frequency of the spore in palynomorph assemblages, however, decreases through the Tertiary and *C. splendens* is rare in Pliocene assemblages. *Cyathidites splendens* is commonly associated with palynofloral assemblages that are indicative of rainforest communities. The gradual decrease in the frequency of *C. splendens* through the Tertiary in southern Australia may be related to the overall decline in temperature and precipitation during this interval.

ACKNOWLEDGEMENTS

We thank the following institutions and staff for access to collections, loan of material or photographs: Museum of Victoria, Geological Survey of Victoria, Geological Survey of Queensland, University of Queensland, Geological and Mining Museum, Sydney, University of Tasmania, New Zealand Geological Survey, Dominion Museum, Auckland, Department of Scientific and Industrial Research Organization, Christchurch, New Zealand, and Swedish Museum of Natural History. J. Baker photographed and drafted Figs 1 and 9. The remaining photographs were taken by staff at the Queensland Museum and the South Australian Department of Mines and Energy.

Our special thanks to G. Atherton, J. Webb, T. Poole and R. Naumann who donated specimens to the Queensland Museum. We also thank Alcoa (Australia) and Monier Ltd for access to the Anglesea and Golden Grove localities respectively and for grants which enabled early collections to be made. M.E. Dettmann and H.T. Clifford provided Figs 11A,B. A. Drinnan and J. Conran provided advice on this paper. N.F. Alley publishes with the permission of the Director-General, South Australian Department of Mines and Energy.

BRYOZOA FROM HERON ISLAND, GREAT BARRIER REEF

J.S. RYLAND AND P.J. HAYWARD

Ryland, J.S. & Hayward, P.J. 1992 06 29: Bryozoa from Heron Island, Great Barrier Reef. *Memoirs of the Queensland Museum* **32**(1): 223-301. Brisbane. ISSN 0079-8835.

Eighty-one species of Bryozoa are described from shallow reef habitats around Heron Island, Queensland. Fourteen new species are described: *Puellina decipiens, P. egretta, P. vulgaris, Celleporaria desperabilis, Robertsonidra novella, Parasmittina galerita, P. onychorrhyncha, P. turbula, Pleurocodonellina clavicula, Microporella fimbriata, Celleporina reginae, Rhynchozoon ardeolum, R. limatulum* and *R. scopulorum*. Twenty four species are recorded for the first time from Australian waters. □*Heron Island, Great Barrier Reef, Bryozoa, taxonomy, new species.*

J.S. Ryland and P.J. Hayward, Marine, Environmental and Evolutionary Research Group, School of Biological Sciences, University of Wales, Swansea, Singleton Park, Swansea SA2 8PP, United Kingdom; *10 June, 1991.*

The coral-associated bryozoan fauna of the Great Barrier Reef (GBR) is undoubtedly very diverse, probably comprising several hundred species. It is, however, poorly known. Thus, in the late 19th century, when the rich bryozoan fauna of Victoria and, to a slightly lesser degree, of New South Wales and South Australia, was being described, the GBR bryozoans were known only by a few specimens from HMS Rattlesnake (Busk, 1852a), from Port Denison and Holbourne Island (Haswell, 1881) and from A.C. Haddon's collections in Torres Strait (Kirkpatrick, 1890a). This lack of study continued through most of the 20th century, with coastal Queensland or GBR bryozoans being described in only a few short papers (Livingstone, 1926; Hastings, 1932; Silén, 1942; Ross, 1974; Ryland, 1974, 1984) and lists (Livingstone, 1927; Dall & Stephenson, 1953; Hall, 1984; Winston, 1986). Consequently, the view prevailed that bryozoans were poorly represented in coral reefs generally and in the GBR particularly (Ryland, 1974). That this must have been erroneous was evident from Maxwell's (1968) study of sediments in which bryozoan fragments, representing a wide diversity of species, formed an important constituent. Recent semi-popular descriptions of the GBR have been given by Bennett (1971), Endean (1982) and Talbot (1984), providing useful background information on the fauna generally but little on the Bryozoa specifically.

The GBR is extensive, stretching some 1900km from Lady Elliot Reef (24°07'S), slightly south of the Tropic of Capricorn, to the Warrior Reefs and Bramble Cay in the Gulf of Papua (9°09'S). The reefs are dispersed over, and along the edge of, the continental shelf and occupy an area of some 215,000km^2. It is to be expected that the bryozoan fauna will vary with latitude and, most species being essentially subtidal, would be appropriately studied and collected by scuba. The present contribution, in which we describe 81 species, is manifestly preliminary being based on a still incomplete examination of specimens collected intertidally on Heron Island reef, one of the southernmost in the GBR, mainly over a few days in 1972.

Heron Reef is one of 16 comprising the Capricorn Group which, together with four of the Bunker Group, lie between latitudes 23° and 24°S, at the southern end of the GBR. These reefs are separated from Breaksea Spit (Sandy Cape) to the southeast and from the mainland coast in the neighbourhood of Gladstone by Curtis Channel, while the Swain Reefs lie about 150km northwards across the Capricorn Channel. The 200m isobath lies some 16-25km east of the Capricorn Group, whilst the mainland is about 70km to the southwest. A map of the group, with bathymetry, is given by Jell & Flood (1977) and Mather & Bennett (1984).

Mean water temperatures are 26-27°C in summer dropping to 20-21°C in winter, but temperatures over the reef flat may exceed 32°C or drop to 17°C, or even lower (Endean et al., 1956). Prevailing winds are southeasterly, or from between southeast and east during summer. Low-amplitude ocean swells thus approach predominantly from roughly the southeast. The East Australian Current outside the shelf edge flows polewards but there is little information on the current patterns within the southern GBR. In the central GBR the residual flows are determined by prevailing winds, setting northerly

during periods of steady tradewinds but southerly during light or variable breezes (Wolanski & Pickard, 1985). Releases of surface drifters in the Capricorn Channel suggested a nett southerly movement (Woodhead, 1970). Tides are semi-diurnal, though successive tides frequently differ in height; mean amplitudes are 2m on springs and 1m on neaps. Tidal currents set westerly on the flood, easterly on the ebb.

Heron Island, the cay (23°27'S, 151°55'E), is situated at the leeward (western) end of an egg-shaped lagoonal platform reef (Jell & Flood, 1977), roughly 8.5 by 4km with the long axis orientated ESE-WNW (Fig. 1). At its eastern end, Heron Reef is separated from the smaller Sykes Reef, with which it shares a reefal platform, by a 3km wide channel of about 15m depth (map in Jell & Flood, 1977). The southwestern quarter of Heron Reef is separated by a channel, about 700m wide and 30m deep, from Wistari Reef. The disposition of the two reefs ensures that the western extremity of Heron Reef, and especially the northern aspect of it, is well sheltered from direct impact of the tradewind swells, although waves from the southeast are refracted around the reef. Wave-transported particles are deposited in the vicinity of the cay (Flood, 1974). During the ebb, water from the reef drains in a radial manner (except near the boat channel, see below) until the rim becomes exposed. A shallow lagoon occupies the east-central area of the reef. At spring tides there is an extensive peripheral reef flat, especially at the western end, covered by 0.5m of water or less. The edge of the reef is then accessible from the cay by wading. Access to other parts of the reef edge at low tide, and to the drop off for scuba, must be by boat.

Most descriptions of Heron Island refer more to the cay than to the reef (e.g. Steers, 1938) but brief accounts of the reef have been given by Endean et al. (1956), Cribb (1966), Jell & Flood (1977) and Mather & Bennett (1984). Important man-made features are the boat channel and the cay's western retaining wall. Marine engineering works up to 1980 were summarized by Gourlay & Flood (1981), with particular reference to the stability of the cay, although there have been consequences on the reef flat to the south of the cay. In 1945 a gap was blasted in the reef rim, opposite the northern tip of Wistari Reef, to provide access for small boats. A wreck (still there) was positioned to provide shelter. The gap was extended in 1966-67 to provide a dredged boat channel and harbour. The channel has subsequently been filled with sand mobilized by cyclones, e.g. 'Emily' (Apr 1972), 'David' (Jan 1976) and 'Simon' (Feb 1980), each time being dredged clear afterwards. The boat channel was extended in 1987-88 (Flood, 1989) and is now associated with a long and substantial jetty. These developments have affected sediment deposition (Gourlay & Flood, 1981), a symptom of a substantially altered flow regime over the southern cay-side flat. Most of the Bryozoa described in this paper were collected from this area in 1972. Water no longer drains radially from the reef here but (1988) flows strongly along the flat towards the channel. The reef flat provided a rich collecting area in 1972 but seemed to have deteriorated markedly by 1988, even before the consequences of the 1986-87 developments (already apparent on water flow) could have affected the living coral framework.

The reef flat extends seawards from the cay to the inner side of the reef rim. At low water springs, away from the boat harbour, water drains through gaps and channels in the rim, but the flat never wholly dries. The inner part of the flat is largely sandy, with patches of coral rubble and some living coral, e.g. *Porites cylindrica*. The outer flat is characterized by living coral, extensive development of crustose coralline algae, and drifts of coral shingle; sand is restricted to small pools and narrow channels. In 1972 the flat at the western end (beyond the boat harbour) was extensively carpeted with a level forest of *Acropora* but shingle has increasingly accumulated since then.

The reef rim is higher than the upper level of live coral on the outer flat. Its surface is cemented with crustose coralline algae, and zoanthids (especially *Palythoa* spp.) are conspicuous. Coral shingle, coral boulders (derived from *Acropora hyacinthus* heads), and sometimes large blocks derived from bommies (plate 30B in Saville-Kent, 1893), accumulate on and just inside the rim. While the rim pavement is devoid of habitats suitable for bryozoans, the boulders constitute the richest intertidal habitat for them.

The reef slope is the sublittoral extension of the reef rim. On the windward (southeastern to southwestern) side of the reef, the upper slope has spur and groove form and the gradient varies from 1 in 20 in the southeast to 1 in 4 southwest of the cay (Jell & Flood, 1977). When accessible in calm weather the coral growing on the spurs would undoubtedly prove a rich habitat for Bryozoa. On the lee side of the reef the spur and groove formation does not develop; rather there is extensive growth of tabular corals, such as *Acropora hyacinthus*. In 1972 some bryozoans

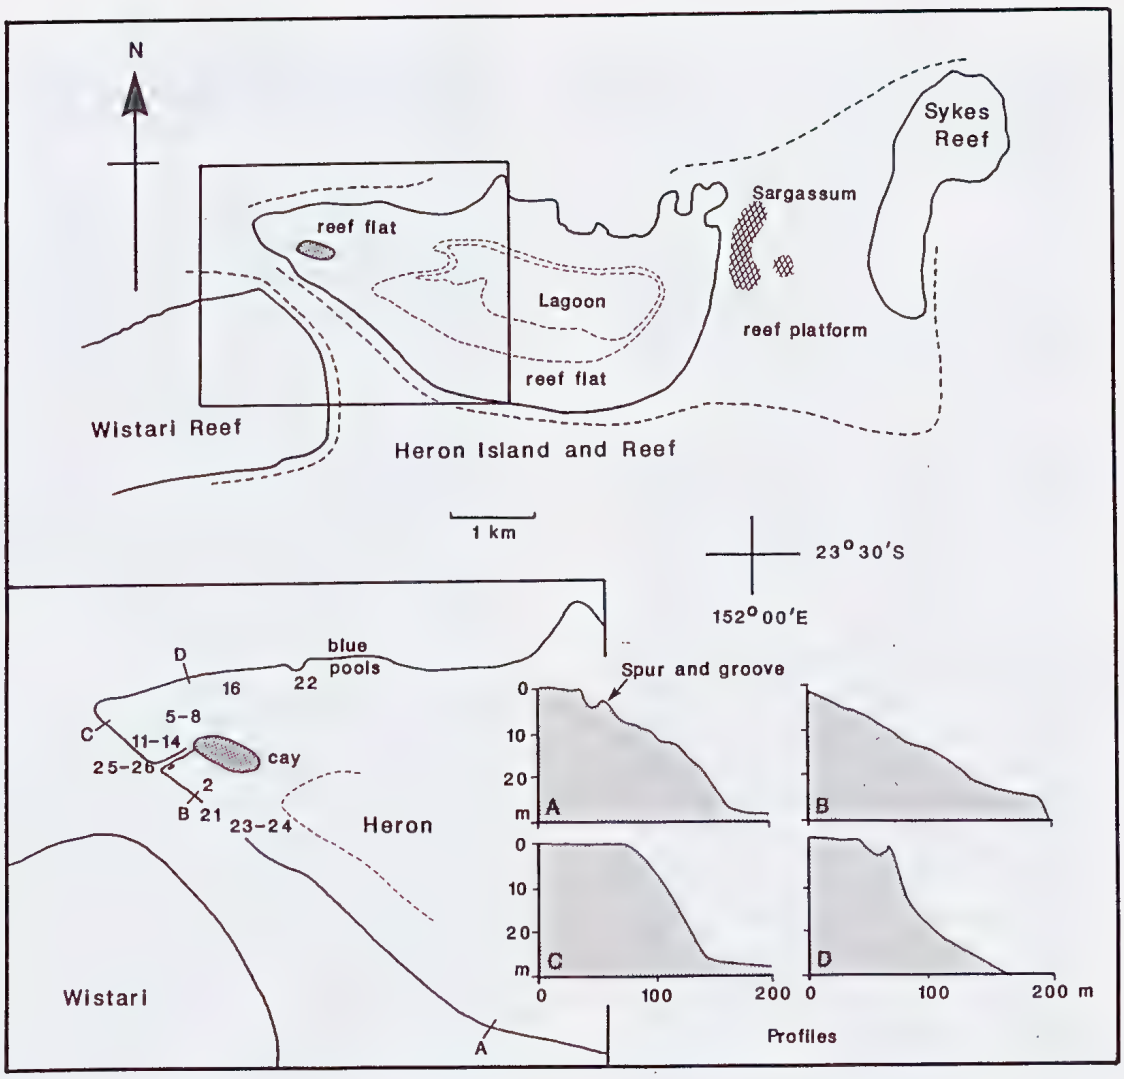

FIG. 1. Heron Island and Reef, showing location of samples. Profiles from Jell & Flood (1977).

were collected by snorkelling and scuba from under such tables, and photographs show the richness there of sessile fauna. It is such tables that, when struck by tropical cyclones, are broken free and hurled onto the edge of the reef. They ultimately settle in the only stable position, with the former attachment facing upwards. The cryptic surface is usually somewhat concave, such that the boulder rests on its rim; irregularities ensure that water circulates through the space, keeping the boulder surface clear of sediment. In this dark, protected habitat ascidians, bryozoans and sponges develop in profusion. Thus the boulders in the Blue Pools area, north of the cay, which were deposited by cyclone 'Emily' (Apr 1972), by 1988 had developed an abundant and colourful sessile fauna of great diversity.

In 1988 occasional pieces of drift *Sargassum* heavily colonized with bryozoans such as *Aetea, Crisia, Lichenopora* and *Membranipora* and hydroids *Eudendrium* and *Plumularia* were collected on the beach of the cay. At the time it was not known where the *Sargassum* was growing. Subsequently, a bed of *Sargassum* has been located by Lin Baldock and Myriam Preker in 10-15m water in the channel between Heron and Sykes reefs. The species here differ from those of boulders and discovery of the *Sargassum* bed should greatly benefit future studies on the Bryozoa.

MATERIALS

With the exception of two species of *Bugula* found on boulders near Blue Pools in 1988, the bryozoans described in this paper are from 14 of the 28 samples obtained by JSR in 1972. These are identified by sample numbers (Fig. 1) as follows:

2. 9 Apr, 1972. On the reef flat south of the cay. Bryozoa were collected on pieces chipped off tabular *Acropora*, in situ, or from dislodged heads resting on the sand. Bryozoans were present on under surfaces, though rarely abundant, and less common than sponges.
5. 11 Apr, 1972. On the reef flat WNW of the cay. Flat plates of coral, the outer parts spread as horizontal laminae, the inner were convoluted, forming recesses and clefts sheltering *Margaretta*, lace corals (Phidoloporidae), and cellularines.
6. 11 Apr, 1972. Near 5 on the reef flat WNW of the cay. Plates of *Echinopora* with encrusting bryozoans on the lower surface.
8. 11 Apr, 1972. Near 5 and 6. The flat here was a level platform of abraded *Acropora* with a maze of cavities underneath, and coral 'fingers' rising from the surface. The encrusting fauna seemed poorer than under individual tables.
11. 12 Apr, 1972. On the reef flat west of the cay, to the north of the boat channel. Part of a well-developed *Acropora* head which had tipped when stepped on. The outer parts were coated with a thin, filmy prussian blue sponge. Several *Reteporella graeffei* and incrusting species were present.
12. 12 Apr, 1972. On the reef flat, near 11. Below the actively growing *Acropora* head, supported by a slender pedestal, was a layer representing an earlier growth level, 3-5cm thick, with sediment lying on its upper surface. The lower surface was white, lacking encrusting coralline algae, but bearing *Tubastrea*, sponges, *Filograna*, a brachiopod, and bryozoans. Below this was coral rubble.
14. 12 Apr, 1972. Near 12. Pieces broken from a large *Acropora* head which had become free and turned upside down, though continuing to grow.
16. 13 Apr, 1972. Crest to the west of the cleft in the reef edge, northeast of the cay. The crest here was strewn with boulders deposited (or redistributed) by cyclone 'Emily' (1-2 Apr). The sessile fauna on the *Acropora* was protected by the knobbly surface of the pedestal. Fragments of typically subtidal erect Bryozoa, such as *Triphyllozoon* and violet *Iodictyum*, were also picked up here. (These boulders were examined in 1988, having been on the reef for 16 years. The fauna is still being studied).
21. 14 Apr, 1972. Reef crest south of the cay. Most of the flat approaching the crest at this point was level, easy to walk on, rather than being a forest of heads. Several coral boulders derived from *Acropora* heads were present. The living coral of the crest tended to form layers (almost shelves). While water on the flat appeared to ebb over the coral, on the crest it noticeably percolated through the coral. The space matrix would seem ideal for bryozoans being fairly dark and with long periods of water flow. The coral heads typically, though not invariably, displayed a lower surface zonation, with the peripheral fingers covered with lithothammion and the centre region white, with *Filograna* tubes, sponges, compound ascidians and Bryozoa. The sample was a piece of boulder showing a coral/bryozoan interface.
22. 15 Apr, 1972. Reef crest at the cleft, northeast of the cay. The crest here is more complex than at 21. There is the actual edge, marked by surf, then a moat; the coral then rises onto the crest which merges into the zone of coral boulders and rubble (see profile D, fig. 1, from Jell & Flood, 1977). Along the crest coral was dying back, apparently because cyclone 'Emily' had altered the drainage pattern, leaving the coral heads dry and dying; or live coral had been flattened by pounding with the *Acropora* boulders produced by the cyclone. Sample was from these boulders, though most *Iodictyum* fragments were unattached.
23. 16 Apr, 1972. Reef crest south of the cay; collection made by turning boulders. Tide poor; reef edge not exposed; water running off the reef as a sheet.
24. 17 Apr, 1972. Near 23; from well-incrusted boulders.
25. 18 Apr, 1972. Collection from 4.5-9m at bommie made by D.R. Robertson. Included *Bugula dentata, Nellia simplex* and Phidoloporidae.
26. 18 Apr, 1972. Near 25, about 3m depth on the slope.

Holotypes and paratypes of the new species described here are in the Queensland Museum.

ACKNOWLEDGEMENTS

We are grateful to the Nuffield Foundation for the provision of a Travelling Fellowship to JSR in 1971/72, to the Royal Society for a travel grant in 1988, and to the Australian Biological Resources Survey for generous financial support for our research. Thanks are also due to the Director of the Heron Island Research Station, Dr Ian Lawn, and to Miriam Preker, who kindly supplied data on the distribution of *Sargassum*, and Dr P.G. Flood for freely given advice and information on the physical environment of Heron Island. P.J. Chimonides and Mary E Spencer-Jones (Natural History Museum, London) were most helpful in facilitating the loan of type specimens. Dr M.R. Fordy (School of Biological Sciences, University of Wales, Swansea) is especially thanked for his valued expertise in scanning electron micrography.

SYSTEMATIC ACCOUNTS

The taxonomic order adopted here follows that established by Gordon (1984, 1986, 1989b). Taxonomic diagnoses are provided at family and genus level, and the species descriptions and measurements are based on Heron Island specimens. The synonymies given for each species are deliberately selective, being limited to the original description and the most useful, recent accounts. Unverified synonymies have been avoided. The occurrence of each species at Heron Island, and its wider geographical distribution, are briefly noted. It is intended that a more precise account of the ecological distribution of the bryozoan fauna will be prepared after the completion of the present, continuing research project.

Class STENOLAEMATA Borg, 1926
Order CYCLOSTOMIDA Busk, 1852a
Family LICHENOPORIDAE Smitt, 1867

Colony encrusting, regularly circular or oval, occasionally developing as a cylinder around erect substrata; concave or domed, nodular or mamillate, often lobed; bordered by a peripheral lamina of common basal wall. Autozooids radiating from centre of colony, sometimes in irregular quincuncial series, more usually in connate, uniserial or multiserial rows. Extrazooidal space between zooid rows divided by calcified struts, defining polygonal spaces referred to as alveoli. Brood chambers originating in centre of colony, with lobes extending between zooid rows, roofed by finely granular calcification; ooeciostomes situated at edges of brood chamber, between zooid rows.

Lichenopora Defrance, 1823

With the characters of the family.

Type species: *Lichenopora turbinata* Defrance, 1823.

Lichenopora novaezelandiae (Busk)
(Fig. 2a,b)

Discoporella novaezelandiae Busk, 1875: 32, pl. 30, fig. 2.

Lichenopora novaezelandiae: Brood, 1976: 299, figs 17A-C (not figs 17G-I, = *Disporella sibogae* Borg); Hayward & Cook, 1983: 137.

DESCRIPTION

L. novaezelandiae, as described and figured by Busk (1875) and Harmer (1915), has uniserial zooid rows and a simple, rounded ooeciostome. Brood (1976) appears to have confused his figures with those of *Disporella sibogae*, a superficially similar species in which the zooid rows are always biserial. Colonies are typically oval and domed, and may reach 10mm in length. This species is probably quite common in shallow reef environments, but it is generally inconspicuous. Several large colonies were present in the interstices of *Acropora* in sample 2.

DISTRIBUTION

It is distributed throughout the western Pacific, from New Zealand to Japan, and westwards to the east coast of Africa.

Class GYMNOLAEMATA Allman, 1856
Order CHEILOSTOMIDA Busk, 1852a
Suborder ANASCINA Levinsen, 1909
Superfamily MEMBRANIPOROIDEA Busk, 1854
Family CALLOPORIDAE Norman, 1903

Colony encrusting, forming coherent or disjunct sheets, or reticulate to uniserial runners; or erect, developing bilaminar plates or arborescent, vinculariiform growths, attached by an encrusting base. Frontal wall of autozooids with extensive membrane, sometimes overarched by spines but always conspicuous; gymnocystal and/or cryptocystal calcification usually present, often well developed. Spines present or absent.

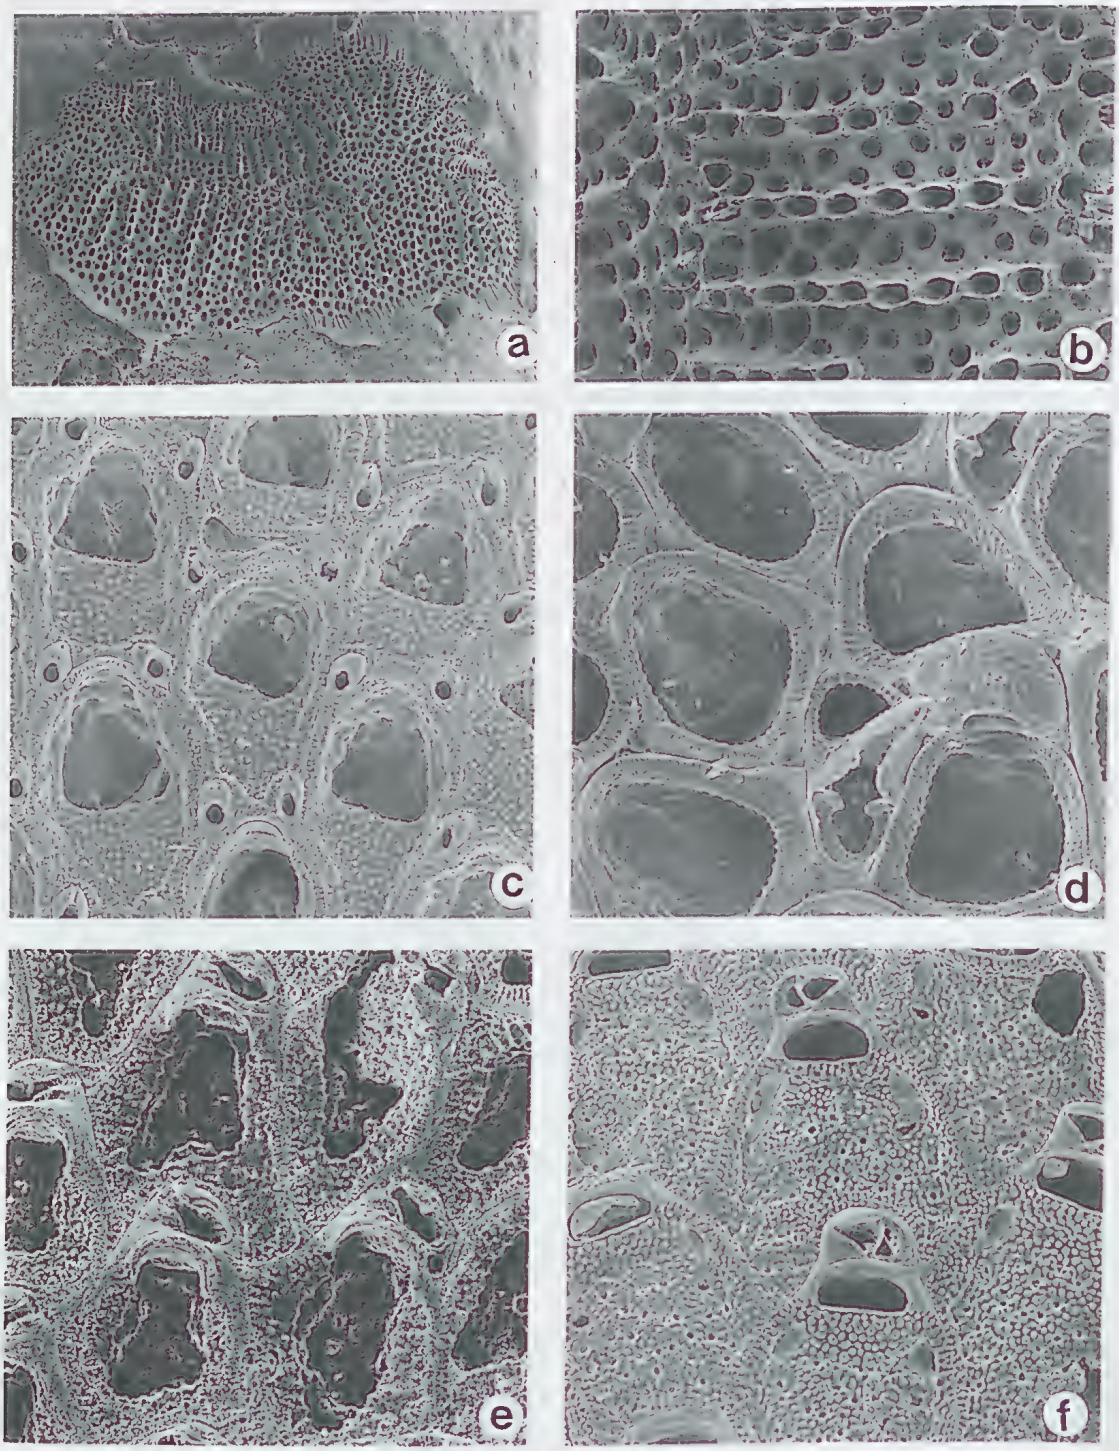

FIG. 2. a,b, *Lichenopora novaezelandiae*; a, whole colony, ×9; b, detail showing oeciostome between two zooid rows, ×30. c, *Antropora granulifera*, ×80. d, *Parellisina curvirostris*, ×60. e, *Cranosina coronata*, ×50. f, *Micropora variperforata*, ×75.

Avicularia adventitious and/or vicarious, sometimes lacking. Ovicells generally present, hyperstomial, or partly immersed, reduced. Vertical walls with large basal pore chambers, or mural septula.

Antropora Norman, 1903

Colony encrusting. Autozooids with well developed cryptocyst; gymnocyst negligible or absent. No spines. Avicularia interzooidal, small, sometimes lacking. Ovicell endozooidal, its presence indicated by a slight thickening at the distal end of the autozooid. Basal pore chambers present.

Type species: *Membranipora granulifera* Hincks, 1880b.

Antropora granulifera (Hincks) (Fig. 2c)

Membranipora granulifera Hincks, 1880b: 72, pl. 9, fig. 4.
Antropora granulifera: Harmer, 1926: 232, pl. 14, figs 11-14; Cook 1968a: 138, text-fig. 9.

DESCRIPTION

Colony forming flat, unilaminar sheets. Autozooids irregularly oval to hexagonal, each with a raised crenellated rim; 0.4-0.5×0.2-0.3mm. Cryptocyst occupying about half total autozooid length, flat or slightly concave, coarsely beaded; opesia subtriangular. At the distal end of each autozooid is a pair (rarely one) of small, interzooidal avicularia, each budded from a disto-lateral pore chamber; rostrum acute to frontal plane, directed distally or disto-medially, 0.07mm long, with a short triangular mandible.

DISTRIBUTION

Antropora granulifera is possibly circumtropical in distribution. It has been reported from Madeira, West Africa, Sri Lanka, Indonesia and the tropical eastern Pacific, but has not been recorded previously from the Great Barrier Reef. It was found at two stations on Heron Island (samples 2 and 16), on the reef flat to the south of the cay, and on the reef edge to the northeast.

Parellisina Osburn, 1940

Colony encrusting. Autozooid with narrow cryptocystal rim, and minimal area of gymnocyst. Spines reduced or absent. Avicularia vicarious, large, each associated with a small kenozooid. Ovicell prominent, hyperstomial. Basal pore chambers present.

Type species: *Membranipora curvirostris* Hincks, 1862.

Parellisina curvirostris (Hincks) (Fig. 2d)

Membranipora curvirostris Hincks, 1862: 29; 1880a: 153, pl. 20, figs 5,6.
Ellisina curvirostris: Harmer, 1926: 228, pl.14, fig. 7.
Parellisina curvirostris: Cook, 1968a: 156, text-fig. 16; Winston, 1984: 7, fig. 14; Winston & Heimberg, 1986: 6, figs 7,8.

DESCRIPTION

Colony forming small, unilaminar patches. Autozooids broadly oval or pear-shaped, commonly 0.5×0.3mm, the extensive frontal membrane bordered by a raised mural rim; a pair of delicate, evanescent, distal oral spines present in early ontogeny. Avicularia frequent; distinctive: rostrum acute to frontal plane, 0.25mm long, laterally curved; associated with a kenozooidal polymorph, with a rounded opesia, visible distal to the rostrum. Ovicell relatively small, the ectooecium membranous frontally, exposing granular entooecium.

DISTRIBUTION

This familiar species has a pantropical distribution, ranging into temperate regions in the north-east Atlantic and perhaps elsewhere. It forms small, and generally inconspicuous, colonies on hard substrata, particularly biogenic carbonates. It is common at Heron Island, occurring in seven of the sample stations reported here.

Crassimarginatella Canu, 1900

Colony encrusting; or erect, attached by an encrusting base, bilaminar or vincullariiform. Autozooids with extensive opesia, bordered by a narrow, granular cryptocyst; gymnocyst variably developed. Spines present or absent. Avicularia vicarious. Ovicell prominent, hyperstomial, or small and cap-like. Vertical walls with basal pore chambers or mural septula.

Type species: *Membranipora crassimarginata* Hincks, 1880b.

Subgenus **Corbulella** Gordon, 1984

Autozooids with well developed gymnocyst, and numerous marginal spines.. Avicularia

vicarious, with proximal opesia bordered by spines. Ovicell prominent, hyperstomial, with a broad frontal fenestra.

Type species: *Membranipora corbula* Hincks, 1880c.

Crassimarginatella (Corbulella) corbula (Hincks) (Fig. 3)

Membranipora corbula Hincks, 1880c: 378, pl. 17, fig. 6.

Crassimarginatella (Corbulella) corbula: Gordon, 1984: 29, pl. 3, figs D,E; 1986: 32, pl. 5, fig. A.

DESCRIPTION

Colony encrusting, forming a small, flat, unilaminar sheet. Autozooids oval, 0.5× 0.35mm, with large oval opesia, a narrow, granular cryptocyst and a reduced, smooth gymnocyst. Twelve to 18 pairs of spines distributed around the opesia, the distal one or two pairs stout, erect, the rest thin, incurved over the frontal membrane. Ovicell spherical, with a transversely oval frontal fenestra, its distal edge often developing a short umbo. Avicularium slightly larger than autozooids, its distal half comprising a raised, smooth-edged rostrum, supporting a semielliptical mandible; proximal half consisting of a shortened opesia bordered by three or four pairs of curved spines.

DISTRIBUTION

This species is widely distributed in the western Pacific from Japan to New Zealand. A single colony was present in sample 16, from the reef edge northeast of the cay.

Cranosina Canu & Bassler, 1933

Colony encrusting. Frontal membrane of autozooid underlain by a broad, peripheral cryptocyst; gymnocyst absent. No spines. Avicularia interzooidal, typically one budded from each autozooid; mandible setiform. Ovicell reduced, endozooidal, or lacking. Large basal pore-chambers present.

Type species: *Membranipora coronata* Hincks, 1881a.

Cranosina coronata (Hincks) (Fig. 2e)

Membranipora coronata Hincks, 1881a: 147, pl. 10, fig. 1.

FIG. 3. *Crassimarginatella (Corbulella) corbula.*

Cranosina coronata: Winston & Heimberg, 1986: 6, figs 3-6; Hayward, 1988: 281.

DESCRIPTION

Colony forming flat, unilaminar sheets. Autozooids irregularly oval to hexagonal, separated by distinct grooves; 0.65-0.7×c.0.4mm. Cryptocyst coarsely beaded, the beads aligned in ridges, directed medially and imparting a crenulate edge to the cryptocyst. Distal end of autozooid raised, with a hood-like border of smooth, gymnocystal calcification supporting the operculum. Avicularium developed from the distal pore chamber of each autozooid, its cystid not clearly distinguishable from the distal wall of the autozooid; rostrum transversely orientated, at a slight angle to the frontal plane, constricted medially, its distal end flared; mandible setiform, very finely toothed, about 0.4mm long.

DISTRIBUTION

A single small colony of this species was present in sample 16. It is distributed throughout the Indo-West-Pacific region, from the Philippines to Sri Lanka and Mauritius. Also reported

from Puerto Rico (Osburn, 1940) and Venezuela (Winston, 1986).

Family QUADRICELLARIIDAE Gordon, 1984

Colony erect, branching, jointed. Autozooids elongate, opesiae extensive; cryptocyst moderately to well developed; gymnocyst reduced. Avicularia adventitious, or absent. Ovicells present or absent. Ancestrula resembling later autozooids, but with a tubular proximal portion rising from an uncalcified stem.

Nellia Busk, 1852b

Colony erect, branching, jointed; internodes square-sectioned, consisting of four longitudinal series of autozooids, arranged in alternating, back-to-back pairs. Autozooids with well-developed gymnocyst; opesia with broad, proximal border of cryptocyst and surrounded by raised mural rim. No spines. Avicularia adventitious. Ovicells small, partly immersed.

Type species: *Nellia oculata* Busk, 1852b.

Nellia tenuis Harmer
(Fig. 10c)

Nellia tenuis Harmer, 1926: 245, pl. 14, figs 16-17.
Nellia tenuis Hayward, 1988: 286, pl. 1, fig. a; Gordon, 1989a: 450, fig. 3.

DESCRIPTION

Colony delicate, inconspicuous, formed from internodes 1-4mm long, 0.25mm wide; dividing dichotomously at infrequent intervals, most often developing simply an undivided series of two or three internodes. Joints between internodes consisting of slender, cuticular tubes; each internode finely tapered proximally. Autozooids about 0.5×0.25mm, the narrow, oval opesia comprising about three-fifths of total autozooid length. A pair of avicularia at the distal end of each autozooid; rostra pointed, hooked, at right angles to long axis of internode.

DISTRIBUTION

Nellia tenuis is probably quite common in shallow reefal habitats. At Heron Island, it was present in samples 14 and 24, from the reef flat west of the cay, and the reef crest to the south. Harmer (1926) had fragmentary specimens from three localities in the Indo-Malaysian region, and listed a fourth from the South China Sea. Ryland (1984) illustrated specimens from Fiji. It was abundant on Mauritian reefs, as part of a bryozoan sward developed beneath coral boulders (Hayward, 1988).

Superfamily BUGULOIDEA Gray, 1848
Family BUGULIDAE Gray, 1848

Colony erect and branched, unjointed, unilaminar, attached by rhizoids. Zooids long, parallel-sided, with almost all of the frontal surface membranous; lateral walls lightly calcified; marginal spines usually present. Pedunculate 'bird's head' avicularia characteristically present. Ovicells independent and hyperstomial, with the ectooecium membranous.

Bugula Oken, 1815

Colony erect, growing from an upright ancestrula, branching; attached by rhizoids which issue from frontal, lateral and basal surfaces of the autozooids. The latter arranged in two or more series, alternating; boat-shaped, with the proximal end forked and the distal end of the next lowest zooid wedged into the fork, extending beyond it on the frontal side; with a row of uniporous, or one to two multiporous, septula. Seen from the front the zooids are usually truncate distally and slightly attenuate proximally. Basal and lateral walls lightly calcified, the membrane occupying most of the front; orifice closed by a sphincter and no operculum can be distinguished. One or more spines may be present, usually confined to the distal angles of the zooid. In most species, a pedunculate avicularium shaped like a bird's head present on the side of all or many zooids. Ovicell hyperstomial, with calcified endooecium and membranous ectooecium; typically globular, but sometimes reduced to a hemisphere or less, closed by the inner vesicle which sometimes forms the major part of the ovicell.

In biserial species the arrangement of zooids at a bifurcation usually conforms to one of three patterns, originally described by Harmer (1923) as types 3, 4 and 5. The bifurcations are best studied from the basal side in stained and cleared preparations, but can generally be observed in a piece of a clean specimen viewed by transmitted light. The pattern of consecutive bifurcations is laterally reversed, so that the bifurcations immediately above and below any given one are mirror images of it. For descriptive purposes the zooids involved in the bifurcation are distinguished by letters (Fig. 4). The first zooid from which two

zooids are budded is referred to as A, the one beside it (which also buds two) as B. The outer zooids above A and B are C and D respectively while the inner zooids are E and F. In bifurcations of type 3 the axil is formed by zooids E and F. In type 4 the axil is formed by F and G (G being immediately distal to E in the same series). Zooid E is thus excluded from the axil, and the proximal part of G connects with F. In type 5 the enclosing process has been further extended so that both E and F are completely surrounded, and the axil is formed by G and H (Fig. 4). It should be noted, however, that the connecting portion between G and H may be very slender. In a further development of the enclosing process, several zooids may be surrounded; the branch then becomes quadriserial below the bifurcations.

Type species: *Sertularia neritina* Linnaeus, 1758.

Bugula dentata (Lamouroux)
(Fig. 4)

Acamarchis dentata Lamouroux, 1816: 135, pl. 3, figs 3a,b.

Bugula dentata: Busk, 1852b: 46, pl. 35, figs 1-5; Harmer, 1926: 439 (cum syn.), pl. 30, figs, 5,6; pl. 32, figs 21-25; Ryland 1974: 343; 1984: 68, fig. 4; Winston, 1986: 6.

Bugula sp.: Doak, 1971, colour plate 31 and rear cover; Coleman, 1977: 80 (colour plate).

DESCRIPTION

Colony tufted, not on a stalk, with some tendency to spiralling of branches; to 10cm. Branches narrow, of uniform width, the zooids biserial. Bifurcations of type 5, i.e., with two zooids wholly enclosed, most obvious in basal view. Zooids 0.6×0.25mm (basal), in Heron Island material. Opesia occupying three-fifths or more of the frontal surface; the external margin of the zooid inrolling proximally, narrowing the opesia. Inner distal angle with one spine, outer with two, sometimes long, and jointed at the base; a third outer spine some way below the other two. The spines of equal size on both sides of the branch, or the outer ones (with reference to the proximal bifurcation) much larger. Avicularia of two kinds: ordinary marginal avicularia attached about two-thirds way down the zooid, a little above or just below the vortex of the opesia; giant avicularia present or not. Ordinary avicularia about 0.2mm in length, a little less than the width of the bearing zooid at the point of attachment; dorsal profile of rostrum straight, its tip abruptly hooked (rectangular). Giant avicularia, when present, most often replacing normal avicularia on the two outer zooids (C, D) at bifurcations; much longer than the width of the bearing zooid; its entire upper profile convex, the rostral tip sometimes with lateral cusps; the mandible clavate, with a weak terminal point (Harmer, 1926, pl. 32, figs 21,23, 25). Ovicells globose, attached somewhat obliquely over the inner distal angle (Harmer, 1926,

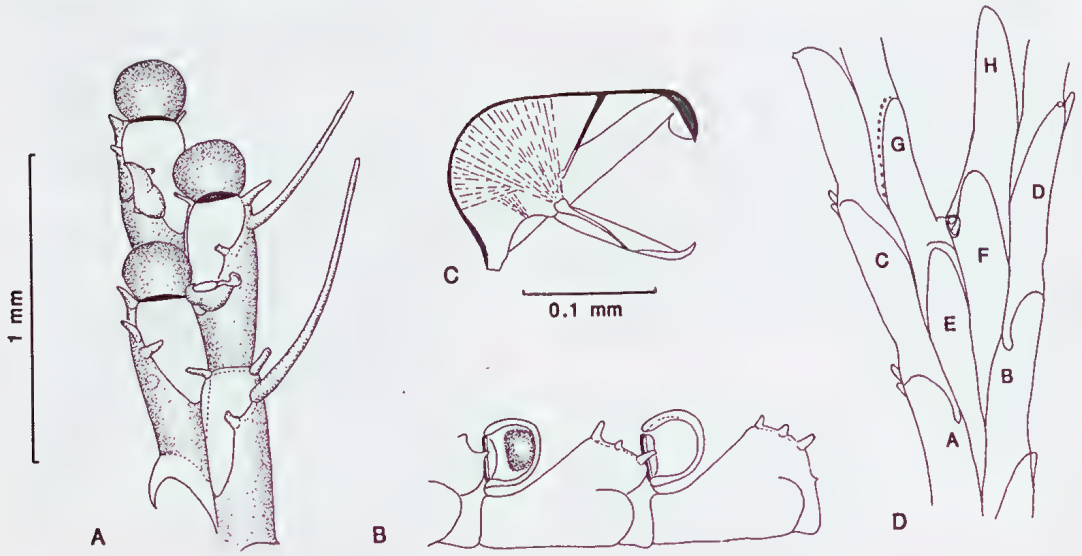

FIG. 4. *Bugula dentata*. A, Group of autozooids, with ovicells and avicularia. B, Autozooids in lateral view. C, Avicularium. D, Basal view of a dichotomy.

pl. 32, fig. 21) or wider than long, occupying the full width of the distal margin; surface calcification rippled; the closing membrane cuticularized.

REMARKS

The living colony is deep bottle green in colour, though acquiring a bluish sheen in flash photographs (Doak, 1971, pl. 31, & back cover; Coleman, 1977:80); on preservation the colour disappears leaving the colony of leaden appearance. The variability of this species was mentioned by Ryland (1974). In particular, the obliquely orientated ovicells, emphasized as diagnostic by Harmer (1926), seem to have been observed only in material from Indonesia. Giant avicularia have been recorded only from Singapore, the Banda Sea and Torres Strait. The normal, marginal avicularia are attached about two-thirds way down the outer wall of the zooid but, since the opesiae vary in length, the avicularian attachment may be either lateral or proximal relative to the opesia. The unusual and distinctively cuticularized ooecial closure, unremarked until 1974, characterizes all specimens from Madeira to New Zealand.

DISTRIBUTION

Widely distributed in the tropics and subtropics from Madeira and Cape Verde Is., to southern Africa, Indian Ocean (Amirante Island), Indonesia, Japan, Lifu, and northern New Zealand. In Australia, Coleman (1977) gives the depth range as 2-40 m; the habitat as rocky reefs, coral reefs and wharf piles; and its distribution to all States except N.T.

Bugula vectifera Harmer
(Fig. 5)

Bugula vectifera Harmer, 1926: 442, pl. 31, figs 1-6.

DESCRIPTION

Colony a loose spreading tuft, delicate, pale translucent straw-brown; to about 15mm in height; anchored proximally by rhizoids; the branches also attached to the substratum by intermittent rhizoids. Branches with zooids in two series, with type 4 bifurcations (Fig. 5D). Zooids weakly calcified; elongate, narrowed proximally, 0.55 (SD 0.03)×0.13 (SD 0.01)mm basally; opesia occupying about three-quarters of the frontal surface. No marginal spines. Avicularia attached on pedicels, proximal to the opesia,

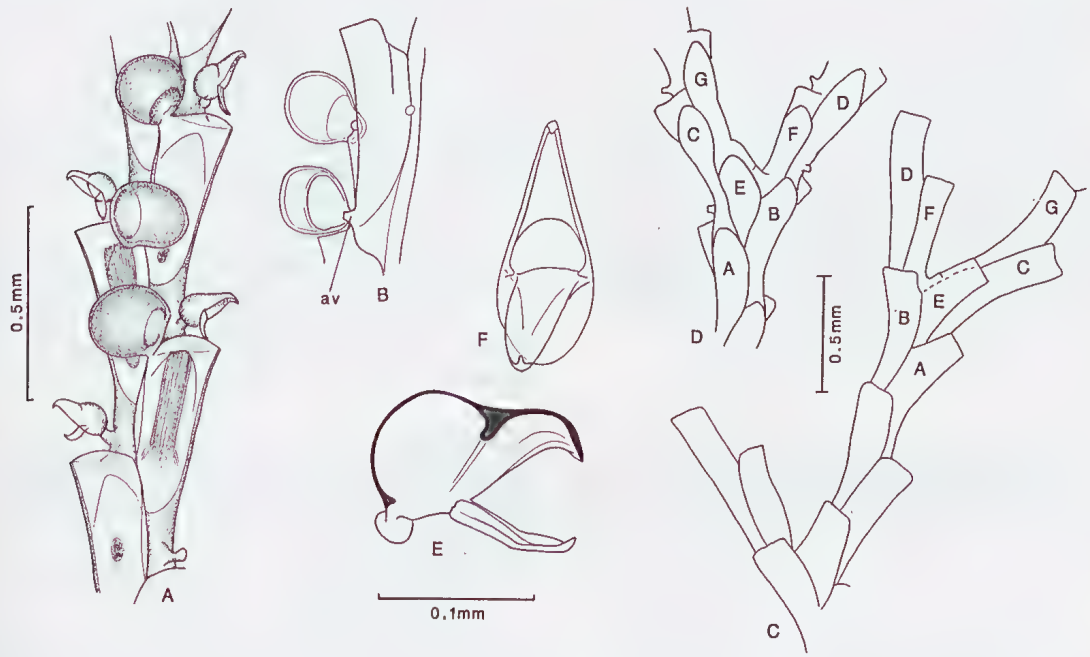

FIG. 5. *Bugula vectifera*. A, Group of autozooids, with ovicells and avicularia. B, Autozooids in lateral view, showing attachment of ovicells and avicularia. C, Part of a branch in basal view. D, A dichotomy in basal view. E, Avicularium. F, Palatal view of avicularium.

close to the distal margin of the preceding zooid; their length approximately equal to the terminal width of the preceding zooid; rostrum as long as the head, its tip sharply downcurved (Fig. 5E); width about the same as in *B. subglobosa* but, the rostrum being longer, lacking the swollen appearance of that species (Fig. 5F, cf. Fig. 6D). Ovicells prominent, a little longer than broad, narrowly attached to the inner distal angle of the bearing zooid (Fig. 5A,B), transversely orientated; the opening directed downwards and across the end of the bearing zooid, invisible from most viewpoints, close to the avicularium of the succeeding zooid. Embryos pale mahogany or pale purple-brown. Tentacle number 17-18, 'about 12' in Harmer's material.

DISCUSSION

Some differences are apparent between the Heron Island material and that described by Harmer. These probably relate mainly to the narrowness of the zooids in the Indonesian specimens (0.53 (SD 0.05) × 0.085 (SD 0.01)mm in British Museum specimen 1928.3.6.287, Borneo Bank), with 'their frontal surfaces sloping obliquely away from the median raised part of the branch'. In the Heron Island specimens this is slightly evident in the proximal part of the colony, but not elsewhere where the distal angles of the zooids tend to be raised well above the surface of the next distal zooid. Zooids tend to be uniserial proximally, though not to the extent described by Harmer in one of the Borneo Bank specimens; neither is there any longitudinal thickening here. Indeed, the habit of the colonies is semi-repent (*Scrupocellaria*-like) rather than arborescent, with a supporting stem. In other respects the agreement between the two groups of specimens is very close.

OCCURRENCE

Found, usually with *B. subglobosa*, among the under fauna of several boulders in the tract at Blue Pools, 27-31 Jul 1988. First record from Australia.

DISTRIBUTION

Great Barrier Reef, Java, Borneo Bank (Strait of Makassar), eastern Honshu, Japan (Harmer, 1926).

Bugula subglobosa Harmer
(Fig. 6)

Bugula subglobosa Harmer, 1926: 444, pl. 32, figs 15-18.

DESCRIPTION

Colony a loose spreading tuft, attached proximally by rhizoids, delicate, pale straw coloured, up to about 15mm; the branches also attached to the substratum by intermittent rhizoids. Branches with zooids in two series, with type 4 bifurcations (Fig. 6B). Zooids elongate, narrowing proximally, 0.59 (SD 0.04) × 0.13 (SD 0.01)mm basally; weakly calcified. Opesia occupying about three-quarters of the frontal surface. No marginal spines. Avicularia attached on pedicels, proximal to the opesia, almost under the distal edge of the preceding zooid; short (much shorter than the terminal width of the preceding zooid), very convex dorsally; the rostrum comprising less than half the total length, sharply downcurved (Fig. 6C); the head broad in relation to overall length, appearing swollen (hence *subglobosa*, Fig. 6D). Ovicells prominent, longer than broad, narrowly attached to the inner distal angle of the bearing zooid, transversely orientated (Fig. 6A); the opening directed downwards and across the end of the bearing zooid, concealed from most viewpoints, opposite the avicularium of the succeeding zooid. Embryos pale milky yellow. Tentacle number about 18.

The Siboga specimen (British Museum 1928.3.6.91) from North Celebes has larger zooids, 0.7 (SD 0.03) × 0.15 (SD 0.04)mm, but is of the same delicate colony form.

OCCURRENCE

Found, usually with *B. vectifera*, among the under fauna of several boulders in the tract at Blue Pools, 27-31 Jul 1988. First record from Australia.

DISTRIBUTION

Great Barrier Reef, Flores, Sumbawa, Timor, North Celebes and eastern Honshu, Japan (Harmer, 1926).

Family BEANIIDAE Canu & Bassler, 1927

Colony encrusting, loosely adherent, unilaminar; or erect, bilaminar, foliaceous; attached to substratum by rhizoids. Autozooids contiguous to widely disjunct, linked by long or short tubular extrusions of the mural septula.

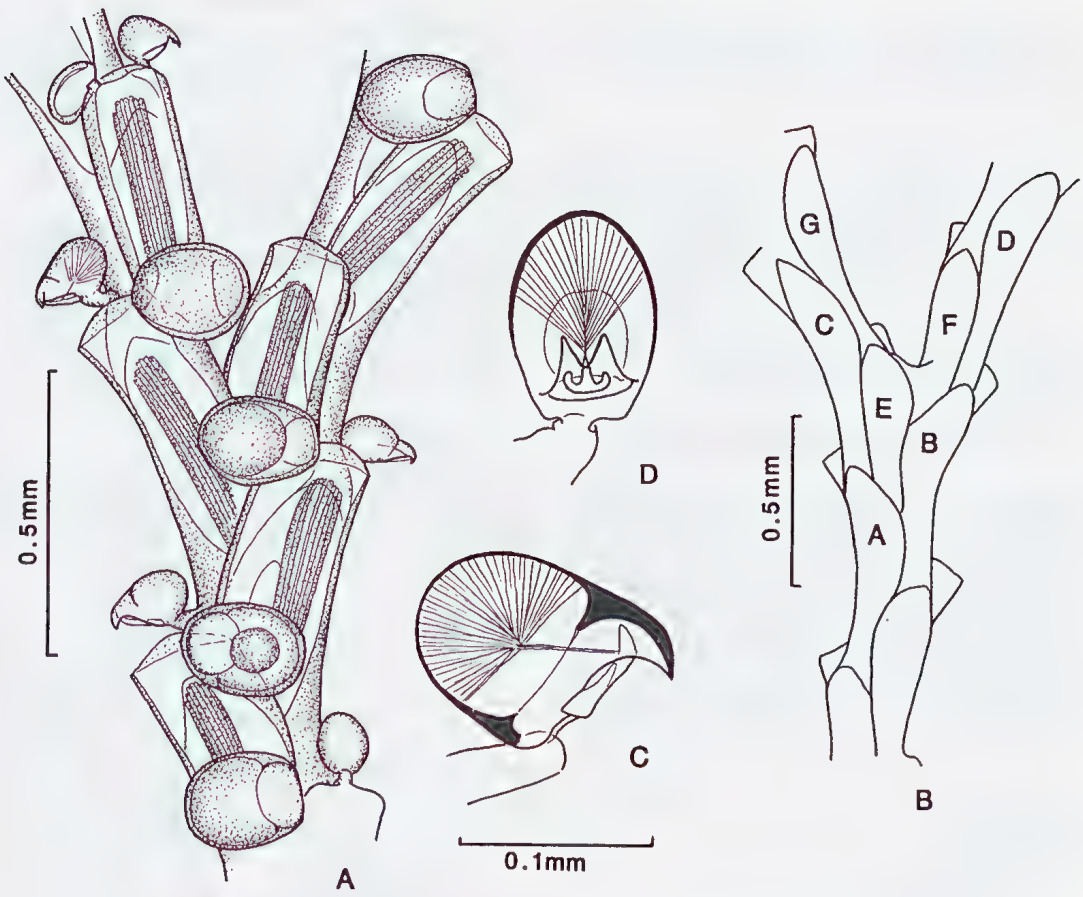

FIG. 6. *Bugula subglobosa*. A, Part of a branch, with autozooids bearing ovicells and avicularia. B, A dichotomy in basal view. C, Avicularium. D, Avicularium in distal view.

Frontal surface entirely membranous, with or without a border of marginal spines. Avicularia adventitious, pedunculate, of bird's head form. Ovicells present or absent.

Beania Johnston, 1840

Colony encrusting, unilaminar, ramifying or reticulate, attached to the substratum by rhizoids and generally loosely adherent. Autozooids closely packed, or widely spaced apart, but not contiguous, linked to each other by tubular extensions of mural pore chambers; recumbent, or erect, sometimes with an elongate, narrowly tubular, proximal portion. Frontal membrane occupying whole of broad distal portion of autozooid, bordered by thin spines in many species; distal spines or spinous processes present or absent. Avicularia present or absent; pedunculate, with a hooked rostrum. Ovicells reduced, vestigial or absent.

Type species: *Beania mirabilis* Johnston, 1840.

Beania magellanica (Busk)

Diachoris magellanica Busk, 1852b: 54, pl.67, figs 1-3.

Beania magellanica: Harmer, 1926: 412, pl. 28, figs 1-4, text- fig.1; Gordon, 1984: 46, pl. 11, fig. H.

DESCRIPTION

This species is distinguished from all other species of *Beania* by the six, regularly-arranged connecting tubes linking each autozooid with its neighbours, by a complete absence of spines, except for two to four tiny processes at the distal end of the autozooid, and by its greatly enlarged, paired avicularia. It is probably common in reef

habitats, but its filmy, transparent colonies are quite inconspicuous in the field, and only become readily apparent once specimens begin to dry.

DISTRIBUTION

Beania magellanica seems to be practically ubiquitous in tropical, subtropical and temperate seas. It has a circumpolar distribution in the Southern Ocean, though not extending into Antarctic waters, and in the western Pacific ranges northwards to Japan, and in the Atlantic region as far as the Mediterranean. It is certainly present in the eastern Pacific (Osburn, 1950) and probably occurs throughout the Indian Ocean.

Family CABEREIDAE Busk, 1852a

Colony erect, branching, jointed, attached to substratum by rhizoids; branches dividing dichotomously, unilaminar, with frontal and basal surfaces, autozooids in two, sometimes more, alternating longitudinal series. Autozooids well calcified, with moderately sized opesia; cryptocyst generally narrow, gymnocyst well developed. Spines present, or rarely, absent, one often modified as a flat plate, the scutum, overarching the frontal membrane. Avicularia adventitious, sessile, sometimes absent; vibracula generally present on basal surface. Ovicell hyperstomial, prominent.

Scrupocellaria van Beneden, 1845

Colony branching, erect and bushy, or repent and spreading; attached to the substratum by rhizoids. Branches biserial, with defined frontal and abfrontal faces, dividing dichotomously at regular intervals, each jointed at its base. Autozooids with well developed gymnocyst and oval frontal membrane; spines usually present at distal end of autozooid; a specially modified lateral spine, or scutum, present in many species, flattened and arching over the frontal membrane, sometimes hiding it completely. Heterozooids polymorphic: lateral avicularia typically present at outer distal angles of autozooids, often dimorphic; frontal avicularia often present on gymnocyst, also often dimorphic; vibracula typically present on abfrontal surfaces. Ovicell hyperstomial, globular, with or without pores, or larger fenestrae.

Type species: *Sertularia scruposa* Linnaeus, 1758.

Species of *Scrupocellaria* may be quite common in shallow reefal habitats, forming swards on the undersides of boulders, in association with other erect Cheilostomata, such as *Margaretta, Nellia* and *Vasignyella.* Three common tropical/subtropical species occur on the reef flats of Heron Island.

Scrupocellaria diadema Busk
(Fig. 7)

Scrupocellaria diadema Busk, 1852a: 370; 1852b: 24, pl. 28, figs 1-3.

Scrupocellaria diadema: Harmer, 1926: 375, pl. 25, figs 20-25; Ryland, 1984: 68, fig. 3; Hayward, 1988: 285, fig. 3C.

DESCRIPTION

This species forms stout, bushy, erect colonies. Autozooids 0.35–0.5mm long, with the opesia comprising about three-quarters total length; the

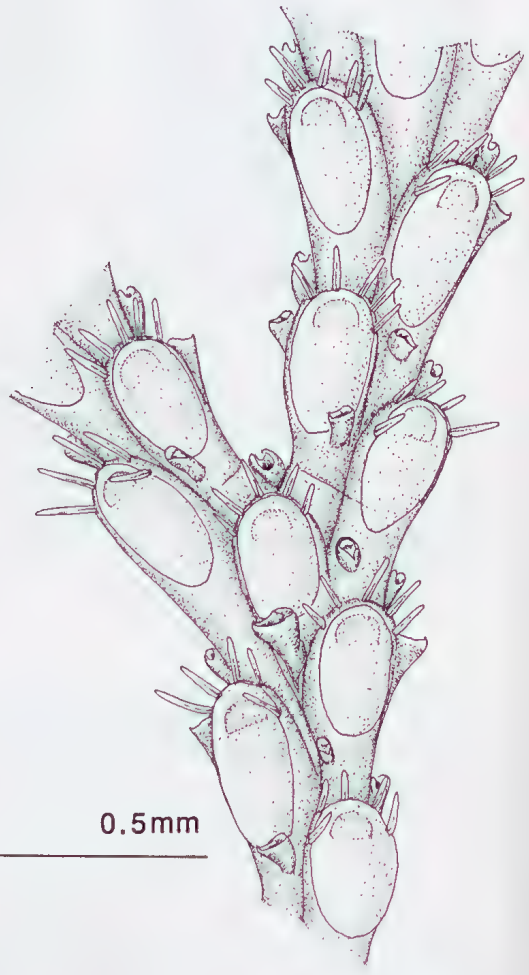

FIG. 7. *Scrupocellaria diadema.*

opesiae of the two series of autozooids overlapping along the branch. Each autozooid with two pairs of short, disto-lateral spines, and a single median distal spine; scutum narrowly oval, covering just the central area of the frontal membrane, but frequently absent. Disto-lateral avicularia small, monomorphic, a single, abfrontal vibraculum just visible distal to each; frontal avicularia shortly columnar, with the rostrum almost perpendicular to frontal plane, dimorphic, those borne by autozooids proximal to dichotomies greatly enlarged; a single vibraculum occurs in the axil of each dichotomy. Ovicell characteristic: wider than long, with conspicuous tubiform pores.

DISTRIBUTION

S. diadema was described from Moreton Bay, Queensland. It ranges northwards to Japan, throughout the Indo-Malaysian region, and westwards to India and Mauritius.

Scrupocellaria maderensis Busk
(Fig. 8)

Scrupocellaria maderensis Busk, 1860: 280; 1861: 77, pl. 32, fig. 1.
Scrupocellaria maderensis: Harmer, 1926: 372, pl. 25, figs 16-19; Gordon, 1984: 47, pl. 12, figs F,G; Ryland, 1984, fig. 2; Hayward, 1988: 283.

DESCRIPTION

Colony an erect, freely branching tuft, with the internodes between dichotomies often exceeding 2mm. Autozooids commonly about 0.35mm long; opesia small and round, comprising less than half total autozooid length, and those of the two autozooid series do not overlap along the branch. Up to four short spines on the outer distal corner of the autozooid, one or two on the inner; the scutum, invariably present, is rounded, with a straight distal edge, and almost completely hides the frontal membrane proximal to the operculum. Disto-lateral avicularia monomorphic, very large, with hooked rostrum, giving a serrated outline to the branch edge; frontal avicularia usually absent; vibraculum present on the abfrontal surface of each autozooid, and two in the axil of the dichotomy. Ovicell longer than wide, tilted towards axis of branch; flattened frontally, with a single fenestra.

DISTRIBUTION

Scrupocellaria maderensis is widely distributed in the warm temperate and tropical waters of the eastern Atlantic and Indo-West-Pacific regions. In the western Pacific it ranges from southern New Zealand to Japan.

Scrupocellaria spatulata (d'Orbigny)
(Fig. 9)

Cellularia spatulata d'Orbigny 1851: 50.
Scrupocellaria spatulata: Harmer, 1926: 382, pl. 26, figs 1-10; Winston & Heimberg, 1986: 7, figs 11-12; Hayward, 1988: 283.

DESCRIPTION

Colony forming delicate, spreading tufts up to 10mm high. Autozooids slender, 0.4-0.5mm long, the opesia comprising slightly less than half total frontal length; two series of opesiae just overlapping along the branch. Two or three spines on the outer distal corner of the autozooid, and usually two on the inner; non-ovicellate autozooids may have, in addition, one or two median distal spines; scutum narrowly oval, covering only a small central portion of the frontal membrane. Disto-lateral avicularia dimorphic: most usually tiny, with a laterally orientated, triangular mandible, occasionally

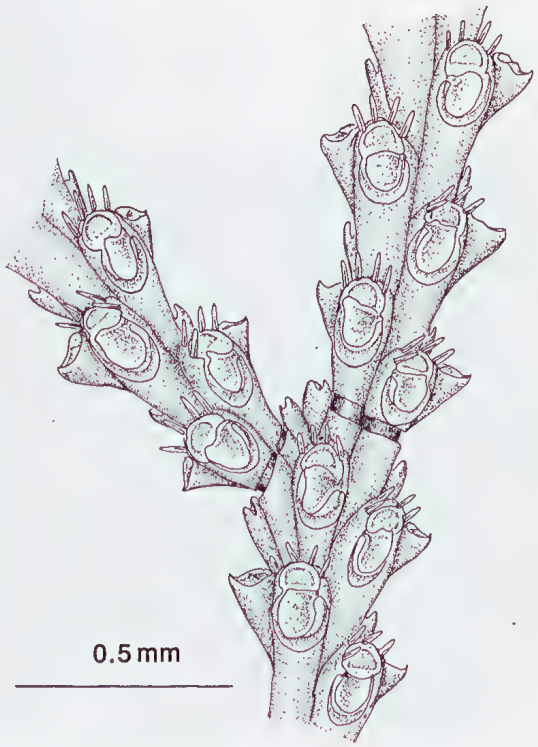

FIG. 8. *Scrupocellaria maderensis*.

FIG. 9. *Scrupocellaria spatulata.*

replaced by a grossly enlarged type with slender, digitate rostrum orientated parallel to the long axis of the branch; frontal avicularia sparse, monomorphic, columnar, situated close to the base of the scutum of the adjacent autozooid; a single vibraculum on the abfrontal surface of each autozooid, and one in the axil of each dichotomy. Ovicell as wide as long, globular, with small, regular perforations.

DISTRIBUTION

This species is distributed throughout the Indo-West-Pacific region, from Queensland to East Africa, and from Victoria northwards to the Philippines.

Superfamily MICROPOROIDEA Gray, 1848
Family MICROPORIDAE Gray, 1848

Colony encrusting or erect. Autozooids with membranous frontal wall underlain by an extensive cryptocyst; opesia reduced, often scarcely exceeding area of operculum; gymnocyst usually little developed. Spines present or absent. Avicularia present, adventitious, interzooidal or vicarious. Ovicells present or absent. Vertical walls with basal pore chambers or mural septula.

Micropora Gray, 1848

Colony encrusting. Autozooids typically flat, with lateral walls raised and thickened, and often developed as prominent umbones lateral to the opesia; frontal membrane entirely underlain by a thickly calcified, perforate cryptocyst, with paired opesiules situated close to its distal corners; opesia small, exactly coincident with orifice, with a thickened rim; no gymnocyst. Spines present or absent. Avicularia vicarious, smaller than autozooids; lacking in some species. Ovicells partly immersed, prominent, with small, scattered pores; closed by autozooid operculum. Vertical walls with large mural septula, which may extend to the basal wall.

Type species: *Flustra coriacea* Johnston, 1847.

Micropora angusta MacGillivray
(Fig. 10a)

Micropora coriacea var. *angusta* MacGillivray, 1887: 67.

Micropora sagittata d'Hondt, 1986: 712, pl. 6, figs 1,2.

DESCRIPTION

Colony loosely encrusting, forming flat, multilaminar sheets. Autozooids narrowly rectangular, 0.6-0.75 × 0.25-0.3mm; cryptocyst flat, finely granular, densely perforated, bounded by a thick, crenulate mural rim. Opesia raised above plane of cryptocyst, its lower lip almost perpendicular, thick, with a crenulate rim; more or less semicircular, with rounded corners. No oral spines. Opesiules indistinct. Avicularia relatively large; rostrum 0.16mm long, with broadly triangular mandible, proximo-laterally directed. Ovicell elongate oval, surface coarsely granular, with numerous tiny perforations; opesia of ovicellate autozooids longer than in non-ovicellate autozooids.

REMARKS

MacGillivray (1887) described the morphology of this species quite precisely although, regarding it simply as an interesting variant of *M. coriacea* Johnston, he unfortunately did not figure it or give a locality for his material. D'Hondt's material, which is unquestionably the same species as that from Heron Island, was from New Caledonia. P.L. Cook (in litt.) has re-examined MacGillivray's specimens of *M. coriacea* var. *angusta*, in the Victoria Museum, Melbourne, and reports that it is the same species as recorded here from Heron Island; specimen F45537A, Port

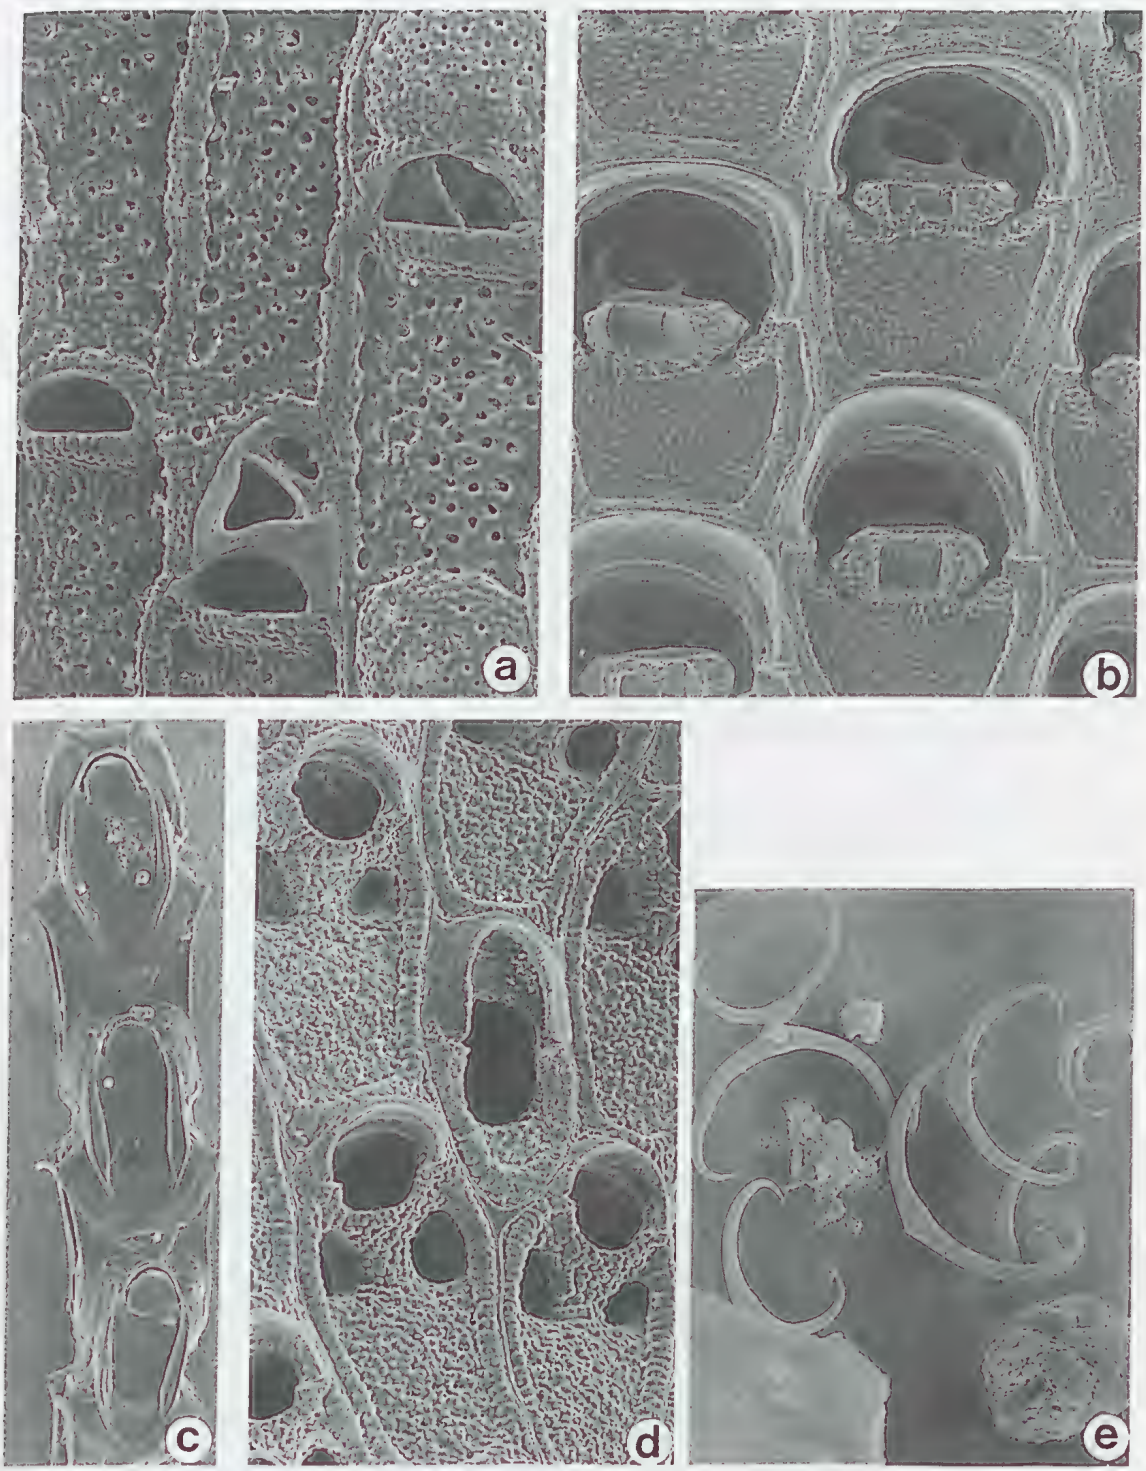

FIG. 10. a, *Micropora angusta*, ×110. b, *Steginoporella magnilabris*, ×50. c, *Nellia tenuis*, ×70. d,e *Thalamoporella stapifera*; d, autozooids and an avicularium, ×70; e, group of calipers, ×800.

Phillip Heads, is here designated as lectotype of *Micropora angusta* MacGillivray. The loosely encrusting, multilaminar colony form, and the finely punctate ovicell are unusual features for a species of *Micropora.*

Micropora variperforata Waters
(Fig. 2f)

Micropora variperforata Waters, 1887:51, pl.8, fig. 27.
Micropora variperforata: Gordon, 1986: 69, pl. 27, fig. B.

DESCRIPTION

Colony forming an irregular, spreading unilaminar sheet. Autozooids oval to hexagonal, 0.45-0.6×0.35-0.4mm; cryptocyst flat, nodular, with about 20-35 small, randomly distributed pores; opesiules recessed but distinct, proximolateral to opesia; an irregular series of comparatively large pores developed around the margins of the cryptocyst; mural rim crenulate, thickened, in later ontogeny continuous with a conspicuous proximal ridge of cryptocystal calcification. Opesia wider than long, 0.12-0.14 x 0.06-0.08mm; no oral spines. Avicularium scarcely larger than opesia; rostrum triangular, acute to frontal plane and laterally directed. Ovicell about as wide as long, the surface finely nodular, except for a smooth or faintly striated frontal band immediately above the aperture.

DISTRIBUTION

Several colonies occurred in sample 22, from the reef crest, northeast of the cay. The Heron Island specimens are strikingly similar to the Recent New Zealand material figured by Gordon (1986), so that *M. variperforata* is known from the western South Island of New Zealand as well as from New Zealand Tertiary deposits.

Family STEGINOPORELLIDAE Hincks, 1884

Colony encrusting; or erect, frondose or vinculariiform, attached by an encrusting base. Autozooids with well developed cryptocyst, which descends to basal wall in distal half of zooid, delimiting a tube for the exsertion of the polypide; gymnocyst reduced or lacking. Autozooids often dimorphic: unmodified *A* zooids represent majority; *B* zooids, perhaps primitive avicularia, are characterized by enlarged, toothed opercula. No ovicells. Vertical walls with multiporous mural septula.

Steginoporella Smitt 1873

Colony encrusting, or erect, frondose or narrow and branched. Autozooids typically dimorphic, both types containing polypides, distinguished principally by relative size of operculum. Frontal wall membranous, lacking a gymnocyst; underlain by a concave cryptocyst, which descends to the distal wall or to the basal wall in the distal half of the zooid, thus dividing its cavity into two chambers; withdrawn polypide located in proximal chamber, exserting via a tubular foramen ('polypide tube') in the distal part of the cryptocyst. Vertical walls of autozooids with large multiporous septula. No ovicells; embryos brooded within maternal autozooids. No spines. *B* zooids, characterized by enlarged and thickly sclerotized opercula, perhaps represent primitive vicarious avicularia.

Type species: *Membranipora magnilabris* Busk, 1854.

Steginoporella magnilabris (Busk)
(Fig. 10b)

Membranipora magnilabris Busk, 1854: 62, pl. 65, fig. 4.
Steganoporella magnilabris: Harmer, 1926: 277, pl. 17, figs 1-3, 7, 9, 12, text-fig. 10; Cook, 1964a: 53, pl. 1, fig. 4, text-fig. 2.
Steginoporella magnilabris: Winston, 1984: 10, figs 17,18.

DESCRIPTION

Colony forming extensive, flat, encrusting sheets, or occasionally erect, bilaminar or unilaminar plates; deep reddish-brown or horn-coloured. Autozooids rounded distally, straight proximally, commonly 0.9-1.0×0.6-0.7mm. Frontal membrane thick, opaque, bordered by a raised, crenulate mural rim; *A* zooids with distinctive semicircular operculum, as wide as zooid and about half as long, with a dark brown arched sclerite, and a submarginal series of small teeth on its inner face; *B* zooids, having proportionately much larger operculum, armed with stout, conspicuous, marginal teeth on its inner face, varying in frequency, from 0.2-30% in different geographical populations (Cook, 1964a). Cryptocyst occupying about half total length of autozooid, depressed, finely nodular, with numerous fine perforations; descending abruptly to basal wall of autozooid, with rounded polypide tube situated centrally in vertical distal part of cryptocyst and not visible in frontal view. Upper

distal edge of cryptocyst produced as a concave, or deeply cupped, process immediately above polypide tube. Distal half of autozooid with a raised rim supporting the operculum, below which is a broad oral shelf.

DISTRIBUTION

S. magnilabris occurs in shallow tropical waters, from the Caribbean, West Africa, East Africa and the Indian Ocean, Malaysia, Indonesia and the Philippines, and northwards to southern Japan.

Family THALAMOPORELLIDAE Levinsen, 1909

Colony encrusting or erect. Autozooids with frontal membrane entirely underlain by a granular, concave cryptocyst; opesia usually coincident with operculum; single or paired opesiules present, large. No gymnocyst. Avicularia vicarious. Ovicell large, bivalved; or lacking. Vertical walls with multiporous mural septula.

Thalamoporella Hincks, 1887

Colony encrusting or erect. Autozooids with membranous frontal wall underlain by extensive cryptocyst; no gymnocystal calcification. Cryptocyst concave or depressed, with a pair of large opesiules bounded by basally deflected cryptocyst, which may extend to the basal wall; opesia small, usually almost coincident with operculum. No spines. Avicularia vicarious. Ovicell bulbous; bivalved, with a longitudinal median suture, borne by a modified maternal zooid. Vertical walls with multiporous septula. Calcareous spicules, of unknown significance, present in cavity of autozooid.

Type species: *Flustra rozieri* Audouin, 1826.

Thalamoporella granulata Levinsen (Fig. 11a,b)

Thalamoporella granulata Levinsen, 1909: 789 (part), pl. 6a, figs 1a-f.
Thalamoporella granulata: Harmer, 1926: 297.

DESCRIPTION

Colony forming a flat, encrusting sheet. Autozooids rectangular to polygonal, bounded by low, crenulate, mural rims; 0.6-0.7×0.3-0.4mm. Cryptocyst with finely beaded surface, flat or slightly convex proximally, concave distally; opesiules irregularly oval, of unequal size, bounded proximally and laterally by descending cryptocyst which reaches to the basal wall of the autozooid; opesia with semicircular distal rim, its proximal edge shallowly concave. Avicularium as long as autozooid; rostrum constituting half total length, narrowly spatulate, curved laterally to left or right, the autozooid embraced by the curve consequently with an asymmetrically placed opesia. Brooding zooid shorter than autozooid, with proportionately broader opesia; capped by a thin-walled, bivalved ovicell, with triangular aperture closed by a modified operculum. Spicules of two types: widely opened compasses, of two sizes, and small, closed calipers.

DISTRIBUTION

The type locality for this species is Torres Strait; Harmer (1926) redescribed the material on which Levinsen (1909) founded *T. granulata*, but the species does not seem to have been reported subsequently from elsewhere. It appears common at Heron Island; large colonies were present in three of the samples reported on here.

Thalamoporella stapifera Levinsen (Fig. 10d,e)

Thalamoporella granulata var. *stapifera* Levinsen, 1909: 188, pl. 6, figs 5a-e.
Thalamoporella stapifera: Harmer, 1926: 297, pl. 19, figs 17,20,25; Soule & Soule, 1970: 10, figs 4C-G; Winston & Heimberg, 1986: 8, figs 13-16.

DESCRIPTION

Colony forming a broad, flat, encrusting sheet. Autozooids elongate, rectangular to irregularly hexagonal, bounded by thick, crenulate mural rims; 0.6-0.8×0.25-0.5mm. Cryptocyst more or less flat, slightly concave proximal to opesia; opesiules irregularly oval, of equal or unequal size, cryptocyst descending to basal wall, to form complete tube; opesia with semicircular distal rim, its proximal edge deeply concave. Avicularium shorter than autozooid; rostrum constituting less than half total length, symmetrical, distally rounded. Brooding zooid shorter than autozooid, with proportionately broader opesia, and especially pronounced opesiular tubes; ovicell thin-walled, bulbous, with triangular aperture closed by a modified operculum. Spicules of two types: widely open compasses, and large, wishbone-shaped calipers.

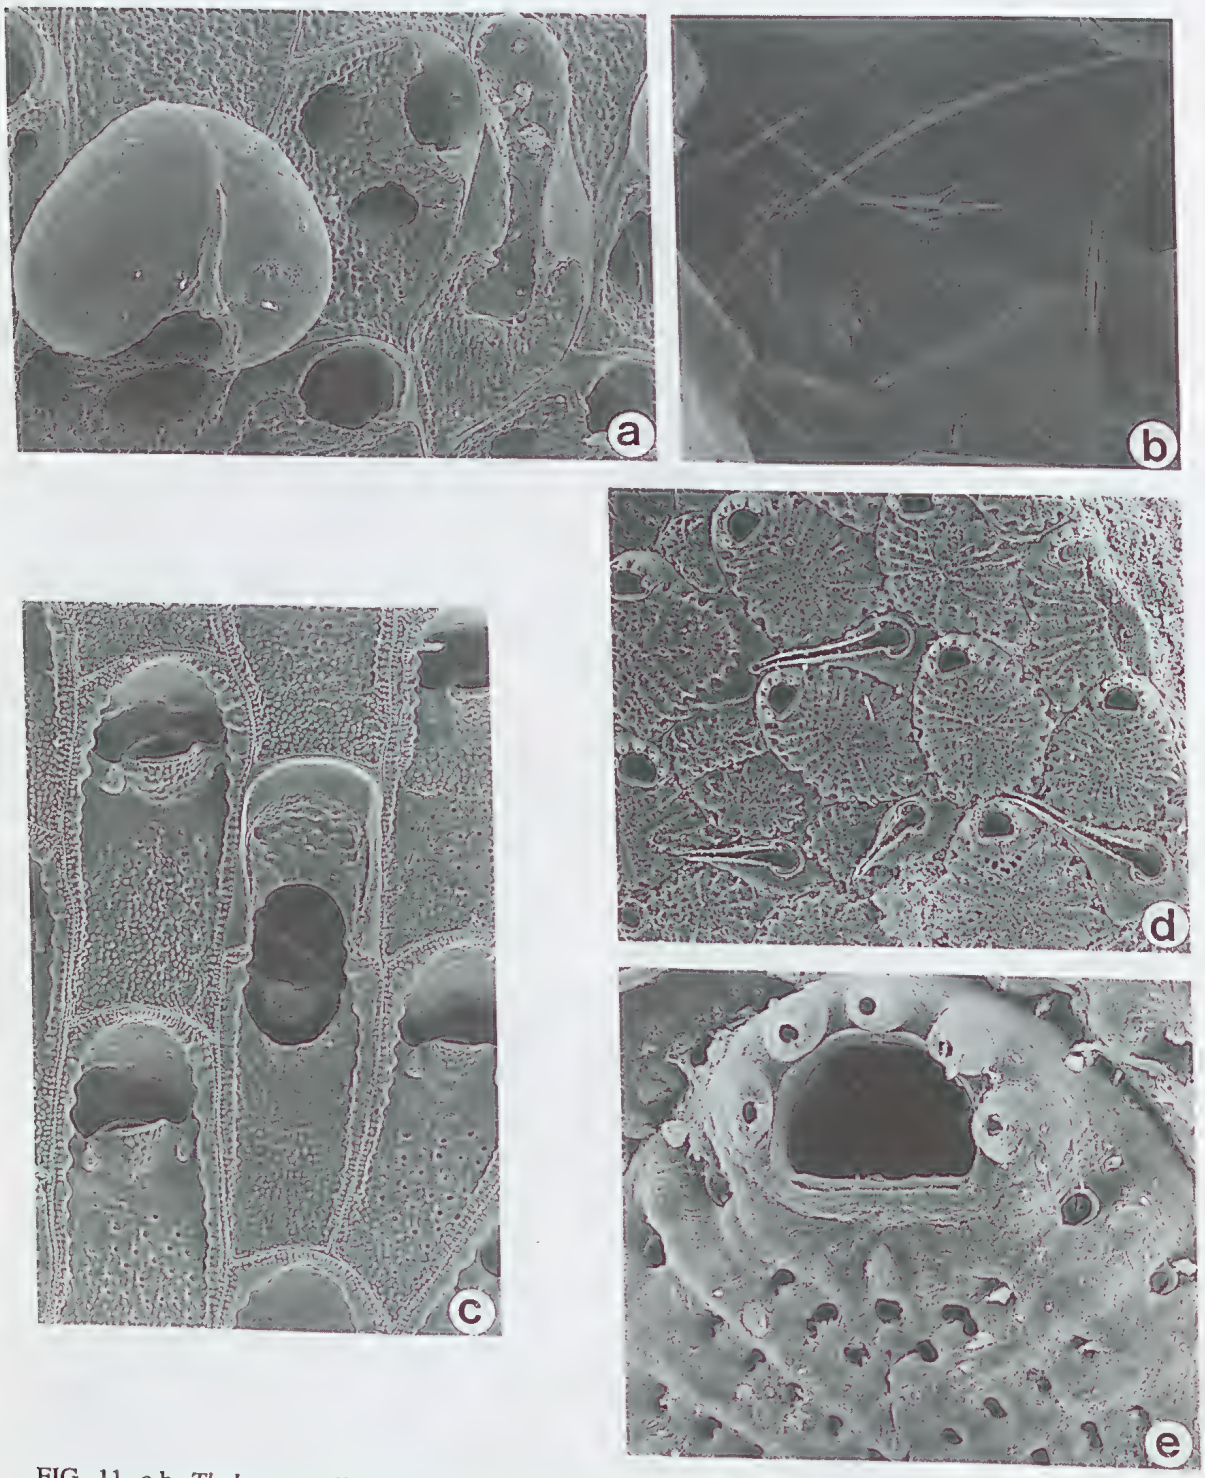

FIG. 11. a,b, *Thalamoporella granulata*; a, autozooids, an ovicell and an avicularium, ×70; b, group of compasses, ×250. c, *Labioporella bursaria*, ×60. d,e, *Puellina egretta*; d, ×65; e, ×400.

DISTRIBUTION

This species has been reported from Hawaii, Timor, Lombok and Mauritius, and is perhaps widely distributed through the Indo-West-Pacific realm. It has not been previously recorded from Australia. It was present in two of the Heron Island samples, numbers 24 and 26.

Labioporella Harmer, 1926

Colony encrusting or erect. Autozooids with membranous frontal wall underlain by extensive, porous cryptocyst; opesia constituting one-third or less of total length; no gymnocyst. Distal edge of cryptocyst deflected to meet basal wall, dividing cavity of cystid into two parts, forming a prominent tube through which the polypide passes on eversion. No spines. Avicularia vicarious, with extensive palatal cryptocyst; cystid divided by transverse septum, rostrum with proximo-lateral condyles but no crossbar. No ovicells. Vertical walls with multiporous septula.

Type species: *Labiopora crenulata* Levinsen, 1909.

Labioporella bursaria (MacGillivray) (Fig. 11c)

Amphiblestrum bursarium MacGillivray, 1887; 66, pl. 2, fig. 2.

Labioporella bursaria: Harmer, 1926: 285, pl. 21, figs 12, 15.

DESCRIPTION

Colony forming flat, unilaminar, encrusting sheets. Autozooids elongate, rectangular, separated by distinct sutures; 0.6-0.85×c. 0.35mm. Mural rim raised and crenulate in distal half of autozooid, smoothly rounded along middle portion of distal terminal wall for reception of operculum. Cryptocyst occupying three-quarters of autozooid length, finely granular, with a group of about 30 small pores in its middle region; flat, dipping sharply adjacent to polypide tube, which is markedly convex frontally, with a transversely oval aperture. Avicularia as large as autozooids; cryptocyst finely granular, imperforate, with an oval foramen through which a transverse, medially-thickened septum is visible, dividing the cystid cavity in half; rostrum slightly less than half length of avicularium, smoothly rounded, semi-elliptical, with thickened, proximo-lateral condyles.

DISTRIBUTION

Described by Harmer (1926) from Queensland and the Celebes, *L. bursaria* is also known from Victoria and South Australia. At Heron Island it occurred in two samples, from the reef flat and the reef crest south of the cay.

Suborder ASCOPHORINA Levinsen, 1909
Superfamily CRIBRILINOIDEA Hincks, 1879
Family CRIBRILINIDAE Hincks, 1879

Colony encrusting, sheet-like; or erect, attached by an encrusting base. Frontal surface of autozooids consisting of a shield of fused, flattened spines (costae) overarching the frontal membrane; costae hollow, often with one or more uncalcified spots (pelmatidia) and with intercostal spaces between the points of fusion permitting the passage of water to the space between the shield and the membrane. Distal oral spines present or absent. Avicularia adventitious or vicarious, or lacking. Ovicell hyperstomial. Vertical walls with basal pore chambers or mural septula.

Puellina Jullien, 1886

Colony encrusting, unilaminar. Autozooids with reduced proximal gymnocyst, and costate frontal shield covering whole of frontal membrane. Frontal shield consisting of radiating series of costae, each fused at intervals along lateral margins, with small intercostal pores between points of fusion; each costa with one or more uncalcified frontal pores (pelmatidia). Operculum D-shaped, closely fitting a calcified secondary orifice, proximal edge of which (apertural bar) is formed by the first pair of costae. Short, slender spines present around distal and lateral borders of orifice. A pair of slender, non-calcified papillae present, proximo-lateral to orifice, each protruding through a proximal intercostal pore. Avicularia interzooidal, with well-developed gymnocystal cystid. Ovicell hyperstomial, imperforate, closed by autozooid operculum. Basal pore chambers present. Ancestrula tatiform.

Type species: *Lepralia gattyae* Landsborough, 1852.

Species of *Puellina* are frequently characterized by the small size of both autozooids and colony. They are abundant in all temperate and tropical seas, apparently favouring biogenic carbonate substrata. They are all confusingly similar and many more species may exist than has been

previously recognized. Bishop & Household (1987) reviewed species of *Puellina* in British coastal waters, and redescribed and figured *P. innominata* (Couch), which, together with *P. radiata* (Moll), has been reported from almost all the world's seas. All records of these, and other, species of *Puellina* (formerly *Cribrilaria*) need to be examined in the light of Bishop & Household's (1987) work. The three species here described from Heron Island have probably been reported previously from Queensland and adjacent areas as *P. innominata* or *P. radiata*. Features important in identifying species of *Puellina* are: size and shape of orifice, number of spines, form of the suborificial lacuna, and morphology of the avicularium.

Puellina decipiens sp. nov.
(Fig. 12d,e)

TYPE MATERIAL
HOLOTYPE: GH5225, Heron Island, Stn 22, 15 Apr 1972.

ETYMOLOGY
Latin *decipio, -ere*, to beguile or cheat.

DESCRIPTION
Autozooids broadly oval, flat, separated by shallow grooves. Gymnocyst limited to a narrow, proximal band; frontal shield consisting of about 16 fused costae, each with a pronounced tubercle basally (i.e., at periphery) bearing the single pelmatidium. A single, large, transversely oval lacuna immediately proximal to the apertural bar. Secondary orifice wider than long, with five, evenly spaced disto-lateral spines, four persisting in ovicelled autozooids. Avicularia infrequent; cystid small, inconspicuous, rostrum elongate triangular. Ovicell slightly wider than long, with indistinct longitudinal carina.

Measurements (means and standard deviations of 20 values, mm): autozooid length 0.29±0.02; width 0.21±0.02; orifice length 0.05±0.002; width 0.06±0.003; avicularium length 0.10± 0.01 (n = 14).

REMARKS
The short avicularium is very similar to that of the European *P. innominata* (Couch), but *P. decipiens* differs from that, and other, species of *Puellina* in its very large subapertural lacuna and flat, non-umbonate frontal shield.

Puellina egretta sp. nov.
(Fig. 11d,e)

Cribrilaria aff. *radiata*: Ristedt, 1985: 20, fig. 3e-h .

TYPE MATERIAL
HOLOTYPE: GH5226, Heron Island, Stn 12, 12 Apr 1972.

ETYMOLOGY
French *aigrette*, a heron.

DESCRIPTION
Autozooids broadly oval to irregular, flat, separated by deep grooves. Gymnocyst minimally developed, inconspicuous; frontal shield formed from about 19 fused costae, each broadened but scarcely tuberculate proximally, pelmatidia indistinct. Apertural bar with a small median thickening, proximal to which is a small, round lacuna, clearly distinct from the first series of intercostal pores. Secondary orifice wider than long; five closely spaced oral spines present. Avicularia frequent; cystid well developed, with broad, smooth gymnocyst; rostrum slender, elongate, directed disto-medially along the border of the adjoining autozooid. Ovicell not found.

Measurements (means and standard deviations of 20 values, mm): autozooid length 0.34±0.03; width 0.27±0.03; orifice length 0.05±0.003; width 0.07±0.005; avicularium rostrum length 0.24±0.05.

REMARKS
This species develops rather larger colonies than the other two described here, and is thus more immediately obvious. The broad, flat autozooids and numerous elongate avicularia are especially distinctive.

DISTRIBUTION
Ristedt (1985) figured specimens of a *Puellina* from the Seychelles and the Philippine Islands which are clearly referable to *P. egretta*.

Puellina vulgaris sp. nov.
(Fig. 12b,c)

TYPE MATERIAL
HOLOTYPE: GH5227, Heron Island, Stn 23, 16 Apr 1972.

ETYMOLOGY
Latin *vulgaris*, commonplace or ordinary.

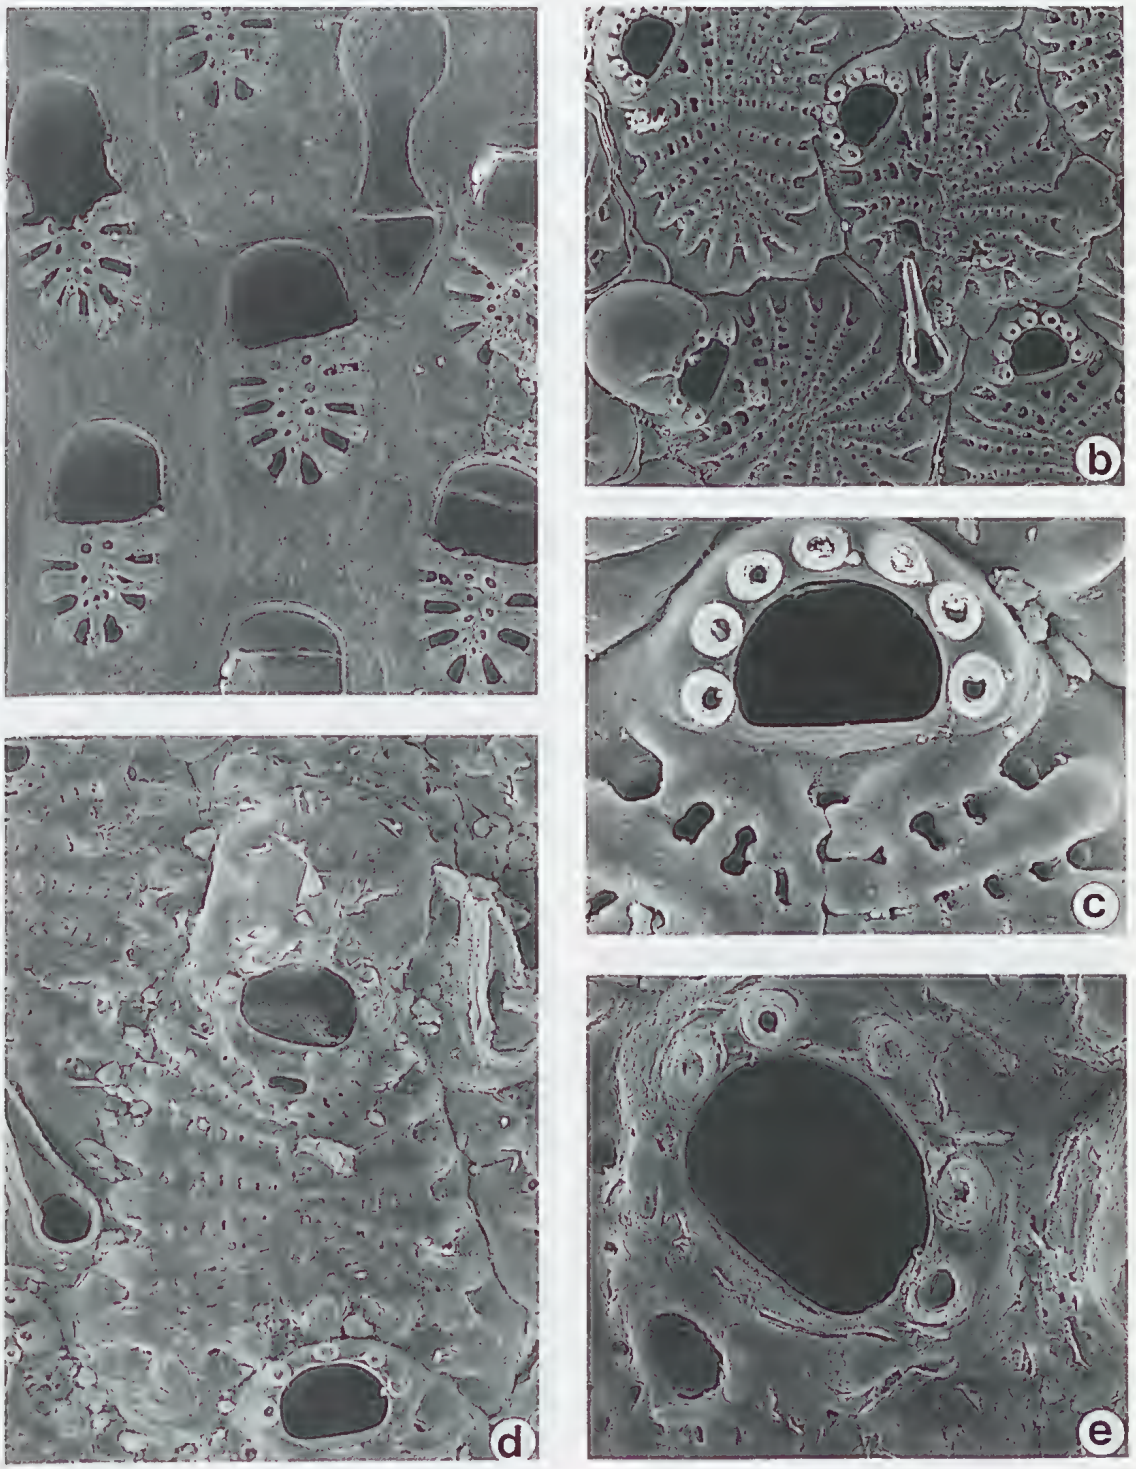

FIG. 12. a, *Figularia fissa*, ×75. b,c, *Puellina vulgaris*; b, ×130; c, ×450. d,e, *Puellina decipiens*; d, ×220; e, ×500.

DESCRIPTION

Colony forming small unilaminar patches. Autozooids oval, convex, separated by deep grooves. Gymnocyst clearly visible as a smooth border around the autozooid; frontal shield formed from 15-16 costae, each broadened proximally but not tuberculate; pelmatidia indistinct; intercostal pores relatively large, particularly in distal half of shield. A single, moderately sized subapertural lacuna present. Secondary orifice wider than long, with seven closely spaced spines, four persisting in ovicelled autozooids. Avicularia infrequent; cystid small, indistinct; rostrum narrowly triangular, relatively short, directed distally or disto-laterally. Ovicell spherical, as wide as long, with a small frontal umbo. Measurements (means and standard deviation of 20 values, mm): autozooid length 0.27±0.02; width 0.21±0.02; orifice length 0.04±0.003; width 0.05±0.005; avicularium rostrum length 0.12±0.02 (n = 5).

REMARKS

The seven oral spines, conspicuous subapertural lacuna, and rather small avicularium together distinguish this species from other tropical species of *Puellina.*

Figularia Jullien,1886

Colony encrusting. Autozooids with well-developed gymnocyst and, often extensive, costate frontal shield; costae fused medially and along their length, with a few irregular pores between the points of fusion, and with one or more pseudopores on each. Aperture rounded-quadrangular; operculum pivoting on lateral condyles, frequently compound, with a transverse line of flexure level with the condyles. Oral spines present or absent. Avicularia vicarious or interzooidal, generally sparse. Ovicell hyperstomial, prominent, closed by autozooidal operculum; typically with a longitudinal, median suture, and one or more large pores, or fenestrae, on each side. Vertical walls with uniporous or multiporous septula. Ancestrula tatiform.

Type species: *Lepralia figularis* Johnston, 1847.

Figularia fissa (Hincks) (Fig. 12a)

Cribrilina figularis var. *fissa* Hincks, 1880a: 196, pl. 26, fig. 8.

Figularia fissa: Harmer, 1926: 478, pl. 34, figs 19-23.

DESCRIPTION

Colony forming extensive, unilaminar sheets; brownish-coloured, with the opercula of the autozooids conspicuously dark mahogany. Autozooids elongate, convex, with costate frontal shield comprising about one-third total length; 0.55-0.8 × c.0.35mm. Costae flat, 8-10 in total; widely spaced, with elongate gaps between, each with a single, distal, pseudopore. Avicularia rare, about as long as autozooid, with a striking, spoon-shaped rostrum. Ovicell wider than long, the ectooecium on each side of the median suture with an elongate, curved, frontal fenestra.

REMARKS

This distinctive species is immediately recognized by its costate frontal shield, which has relatively few, widely spaced costae, and by its characteristic avicularia. *F. fissa* is evidently quite common at Heron Island, and was present in four of the samples described here.

DISTRIBUTION

F. fissa does not seem to have been recorded previously from Australia; it is known to occur in the Indo-Malayan region, from Singapore to New Guinea, and perhaps has a limited distribution in the western Pacific.

Superfamily CATENICELLOIDEA Busk, 1852a
Family SAVIGNYELLIDAE Levinsen, 1909

Colony erect, consisting of branching, uniserial chains of autozooids; jointed, each internode formed from a single clavate autozooid. Frontal wall of autozooids a porous gymnocyst, with or without mural septula; orifice with or without a sinus, its proximal rim sometimes formed from a pair of fused costae; oral spines present or absent. Avicularia adventitious, adjacent to orifice, or lacking. Ovicell present or absent.

Vasignyella Gordon, 1989a

Colony erect to repent, attached by rhizoids. Autozooids elongate, clavate, in branching uniserial chains. Frontal wall largely gymnocystal, with scattered pores; proximal side of orifice bordered by a pair of small, fused costae. No spines. Avicularia paired, lateral to orifice. Ovicell unknown. Large uniporous septula in lateral walls of autozooid.

Type species: *Catenaria otophora* Kirkpatrick, 1890b.

Vasignyella otophora (Kirkpatrick) (Fig. 14a)

Catenaria otophora Kirkpatrick, 1890b: 17, pl. 5, figs 1a-c.
Savignyella otophora: Harmer, 1957: 763, pl. 51, figs 19-21.
Vasignyella otophora: Gordon, 1989a: 453, figs 13-15.

DESCRIPTION

Colony erect or repent, attached to the substratum by delicate, chitinous rhizoids; composed of uniserial chains of slender, clavate autozooids, branching at irregular intervals. Autozooids very lightly calcified, clavate or fusiform, broadest distally, tapered proximally; 1.0-1.3×0.25mm. Primary orifice terminal, about as wide as long, the proximal edge shallowly concave between indistinct condyles; proximal border of orifice formed by a pair of short, fused costae. Frontal wall evenly perforated by large, round pores; a row of about five large, uniporous septula in each lateral wall. Avicularia lateral to orifice, paired; the rostrum triangular, distally directed, projecting conspicuously. Each autozooid buds another from its disto-basal surface, and one or more additional autozooids may be budded from the lateral septula; the proximal part of each autozooid, immediately above its point of origin, is uncalcified, and appears as a brown, cuticular node.

DISTRIBUTION

V. otophora is probably widely distributed throughout the Indo-West-Pacific realm, but is particularly inconspicuous and has been reported on very few occasions. Most records are centred on the Indo-Malayan region, but it has also been recorded as far west as the Sudanese Red Sea (Dumont, 1981) and, to the east, from Samoa (Gordon, 1989a).

Superfamily HIPPOTHOOIDEA Busk, 1859
Family HIPPOTHOIDAE Busk, 1859

Colony encrusting or erect. Various zooid polymorphs occur, including female zooids and dwarf zooeciules. Autozooids with gymnocystal frontal wall; imperforate, or with small punctae and/or tubercles. Primary orifice rounded or sinuate; condyles present; oral spines generally lacking. Avicularia interzooidal or vicarious, or absent. Ovicell hyperstomial, closed by zooidal operculum; or absent. Vertical walls with basal pore chambers and small mural septula.

Hippothoa Lamouroux, 1821

Colony encrusting, consisting of branching, uniserial chains of polymorphic zooids. Autozooids clavate, with a slender, stolon- like proximal portion; ovicellate female zooids often smaller than autozooids, ovicell with frontal umbo or apical perforation, closed by zooidal operculum; zooeciules minute, cylindrical, with simple orifice, of unknown function. Frontal wall imperforate, smooth, or ridged. Primary orifice with sinus and distinct condyles; no oral spines. No avicularia. Tubular pore chambers in lateral walls. Ancestrula kenozooidal or tatiform.

Type species: *Hippothoa divaricata* Lamouroux, 1821.

Hippothoa calciophilia Gordon (Fig. 13a,b)

Hippothoa calciophilia Gordon, 1984: 108, text-fig. 10; pl. 42, figs A-C.

DESCRIPTION

Colony diffuse, spreading widely over the substratum; zooid chains branching in a cruciform manner, each zooid producing one distal and paired lateral buds. Distal, clavate portion of autozooid about 0.3×0.15mm; filiform proximal portion 0.02mm wide, 1-1.5×length of distal portion. Primary orifice slightly longer than wide, commonly 0.06×0.05mm, with a deep, broad, U-shaped sinus, and small, rounded condyles. Frontal wall steeply convex, often with fine, transverse corrugations, and a longitudinal ridge. Female zooids most usually laterally budded from autozooids, the distal portion of similar size to autozooids, the filiform proximal portion usually shorter; ovicell with semicircular aperture, and a single, small, apical perforation. Zooeciules sporadic, budded from either or both of the two basal pore chambers on each side of an autozooid; 0.05-0.1mm long, with minute distal orifice.

REMARKS

H. calciophilia has only recently been distinguished from other species of *Hippothoa* (Gordon, 1984). It is probably widely distributed throughout the Great Barrier Reef province, but its small size and cryptic habits render it very inconspicuous.

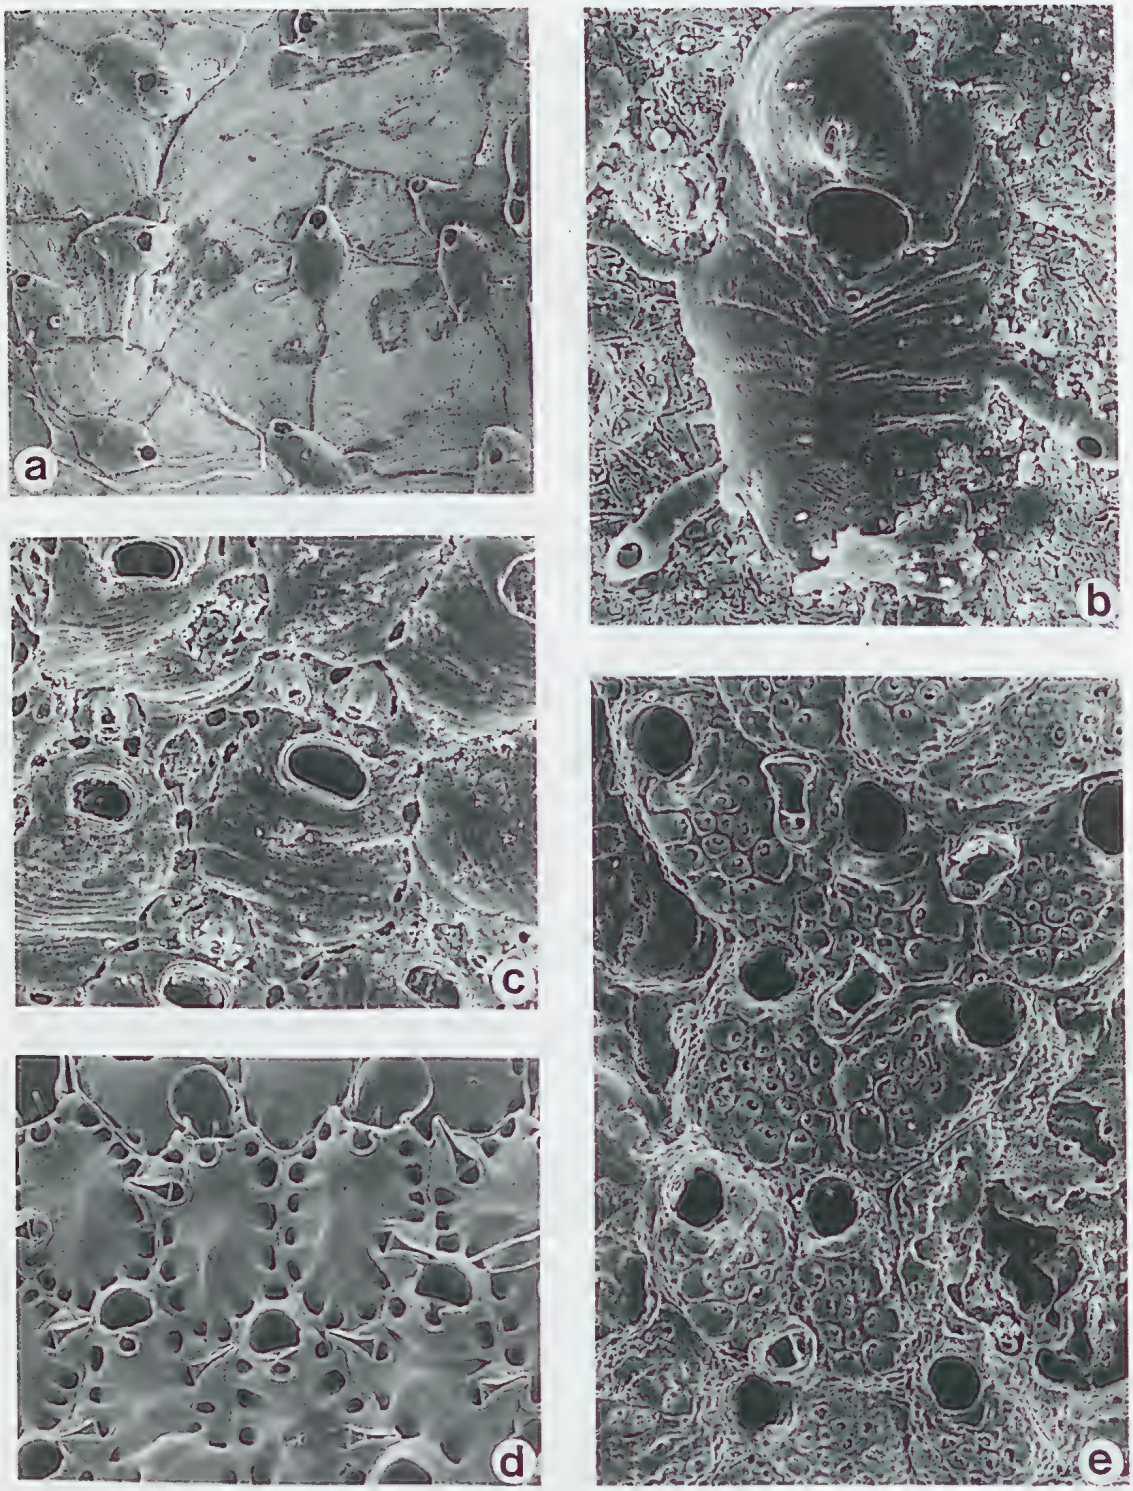

FIG. 13. a,b, *Hippothoa calciophilia*; a, part of a colony, ×50; b, a female zooid, with zooeciules, ×215. c, *Chorizopora brongniartii*, ×85. d, *Exochella conjuncta*, ×70. e, *Tremogasterina spathulata*, ×65.

Family CHORIZOPORIDAE Vigneaux, 1949

Colony encrusting, unilaminar. Frontal wall of autozooids imperforate, or with minute punctae. Primary orifice semicircular, without a sinus. Avicularia interzooidal. Ovicell hyperstomial, imperforate. Small kenozooids present. Vertical walls with tubular basal pore chambers.

Chorizopora Hincks, 1879

Colony encrusting, forming thin unilaminar sheets. Autozooids slightly disjunct, linked by tubular extensions of the basal pore chambers. Frontal wall gymnocystal, thinly calcified, imperforate. Primary orifice semicircular or D-shaped; oral spines present or absent. Avicularia vicarious, smaller than autozooids; small kenozooids with rounded membranous frontal fenestrae interspersed among autozooids. Ovicell hyperstomial, imperforate, closed by autozooid operculum.

Type species: *Flustra brongniartii* Audouin, 1826.

Chorizopora brongniartii (Audouin)
(Fig. 13c)

Flustra brongniartii Audouin, 1826: 240; Savigny pl. 10, fig. 6.
Chorizopora brongniartii: Hayward & Ryland, 1979: 240, fig. 103; Gordon, 1984: 113, pl. 44, fig. C; Hayward, 1988: 327.

REMARKS

The thin, hyaline colonies of *C. brongniartii* are inconspicuous on the carbonate substrata it appears to favour and are easily overlooked in wet material. At least three other species of *Chorizopora* are known from New Zealand (Gordon, 1984), but *C. brongniartii* is readily recognized by the smooth or transversely wrinkled, but non-spinous, frontal walls of its autozooids.

DISTRIBUTION

C. brongniartii is widely distributed in all temperate and tropical shelf seas.

Superfamily ARACHNOPUSIOIDEA Jullien, 1888
Family EXECHONELLIDAE Harmer, 1957

Colony encrusting. Autozooids with perforated, umbonuloid frontal wall. Orifice with well marked peristome; lacking spines. Avicularia adventitious and/or vicarious or interzooidal. Ovicells present or absent.

Tremogasterina Canu, 1911

Colony encrusting or erect, multilaminar. Autozooids with umbonuloid frontal wall, perforated by few, large, frontal foramina, and with small marginal pores. Calcified orifice rim with lateral condyles; no oral spines. Avicularia interzooidal and/or vicarious. Ovicells prominent, hyperstomial, imperforate; not closed by autozooid operculum. Autozooids linked by large, multiporous septula. Ancestrula tatiform.

Type species: *Tremogasterina problematica* Canu, 1911.

Tremogasterina has a worldwide distribution, in shallow coastal waters, between the 30° north and south parallels. The genus was studied in detail by Cook (1977).

Tremogasterina spathulata (Canu & Bassler)
(Fig. 13e)

Hiantopora spathulata Canu & Bassler, 1929: 116, pl. 11, figs 13, 14.
Arachnopusia spathulata: Harmer, 1957: 657, pl. 68, figs 22, 23, 25, 31.
Tremogasterina spathulata: Cook, 1977: 136, pl. 5, fig. A; text- figs 1B, 5A.

DESCRIPTION

Colony forming small, unilaminar patches, generally inconspicuous. Autozooids oval, convex, separated by deep grooves; 0.5-0.6×0.3-0.4mm. Orifice longer than wide, narrowest proximally; proximal edge more or less straight, thickened, and frequently with a short, suboral mucro. Four or five delicate, distal spines present. Frontal wall with a variable number (2-20) of irregular foramina, each with a broad, thick rim, the sutures between giving a tessellated effect; marginal pores inconspicuous. Avicularia sporadic, developed on disto-lateral borders of autozooids, 0.2mm long, typically distally directed; rostrum spatulate, with straight distal edge, upcurved. Ovicell wider than long.

DISTRIBUTION

Widely distributed in the Indo-West-Pacific region, from the Red Sea to the Philippines. *T. spathulata* is essentially a shallow water species, and its small colonies occur on coral rubble and other hard substrata; on Mauritian reefs it is especially common on the inner reef flat (Hayward,

1988). At Heron Island it was present in half of the samples studied to date.

Superfamily UMBONULOIDEA Canu, 1904
Family EXOCHELLIDAE Bassler, 1935

Colony encrusting or erect. Autozooids with umbonuloid frontal shield bordered by conspicuous marginal pores. Orifice with well developed peristome, incorporating one or more denticles on its inner, proximal edge; oral spines present. Avicularia adventitious. Ovicell present. Vertical walls with basal pore chambers or mural septula.

Exochella Jullien,1888

Colony encrusting, unilaminar. Frontal wall of autozooids umbonuloid, imperforate other than for a single series of large, marginal pores. Orifice obscured in early ontogeny by a complex peristome, its lobed proximal edge corresponding with ridges on its inner face which delimit one or two narrow channels; at the lip of the peristome, these channels may close distally to form one or two distinct spiramina. Oral spines typically present. Avicularia adventitious, budded from marginal pores (frontal septula) proximo-lateral to orifice; one, two, or more per autozooid, usually with acuminate rostrum. Ovicell spherical, imperforate, sometimes partly immersed, not closed by autozooid operculum. Basal or mural pore chambers present.

Type species: *Mucronella tricuspis* Hincks, 1881c.

Exochella is distributed almost exclusively in the southern hemisphere. There are several Antarctic species, and a number of others from cold temperate or subantarctic waters of South America, the Southern Indian Ocean and New Zealand (Hayward, 1991). *E. conjuncta* Brown is the only species known to range into tropical waters.

Exochella conjuncta Brown
(Fig. 13d)

Exochella conjuncta Brown, 1952: 294, figs 220-223.
Exochella conjuncta: Gordon, 1989b:30, pl.14, fig. A.

DESCRIPTION

Colony forming small, rounded patches. Autozooids oval to hexagonal, convex, separated by thickened ridges which become indistinct in later ontogeny; small, 0.35-0.4 by about 0.25mm. Frontal wall with few, large, marginal pores; thickening steadily, becoming vitreous and smooth, with the boundaries of each autozooid marked only by the pronounced, rounded, marginal pores. Peristome with paired inner ridges, delimiting a single median channel, opening externally as an oval spiramen. Two short, distal, oral spines present in newly budded autozooids, obscured by development of peristome. One or two avicularia per autozooid, 0.13mm long, with slender, laterally-directed rostrum. Ovicell spherical, smooth, largely immersed and hidden in later ontogeny.

DISTRIBUTION

E. conjuncta was first described from Pliocene deposits of New Zealand (Brown, 1952), and subsequently shown to have a Recent distribution extending from the South Island of New Zealand to New South Wales (Gordon, 1989b). Its presence at Heron Island marks a considerable extension in its known range.

Family CELLEPORARIIDAE Harmer, 1957

Colony encrusting, multilaminar, massive or nodular; often erect, developing stout, irregular branched or lobed forms; or pisiform, encrusting erect substrata; or discoidal and unattached. Autozooids recumbent to erect, typically without regular orientation; frontal wall umbonuloid, with marginal pores. Orifice without a sinus, with or without one or more proximal denticles; oral spines present or absent. Avicularia adventitious, associated with orifice, and vicarious; typically polymorphic. Ovicells present.

Celleporaria Lamouroux, 1821

Colony encrusting, or erect and irregularly branched, or massive; multilaminar, developed by frontal budding of successive autozooid generations. Autozooids recumbent at growing margins, elsewhere suberect, with varying orientation. Frontal wall umbonuloid, with indistinct marginal pores. Oral spines typically present. Avicularia adventitious and vicarious, frequently polymorphic. Ovicell hyperstomial, small and spherical, imperforate.

Type species: *Cellepora cristata* Lamarck, 1816.

This genus is widely distributed in tropical and subtropical seas, with many species reported from shallow reef habitats. Colonies are often large, and conspicuously pigmented. Unfor-

tunately, identification is often difficult. The taxonomy of *Celleporaria* is confused, at least partly because many species have still to be named, and a majority of described species are poorly known and have never been adequately illustrated.

Celleporaria tridenticulata (Busk)
(Fig. 14b,c)

Cellepora tridenticulata Busk, 1881: 343,344,347, pl. 26, fig. 9; 1884: 198, pl. 29, fig. 3; pl. 35, fig. 17.
Celleporaria tridenticulata: Harmer, 1957: 670, pl. 42, figs 5-10; Gordon, 1984: 115, pl. 45, figs C-E.

DESCRIPTION

The aperture of *C. tridenticulata* bears three conspicuous denticles on its concave proximal border, which may be pointed, truncate, bifid, or even trifid. It has two (rarely three or four) slender, distal oral spines, and a median, proximal, suboral avicularium on a short umbonate cystid, with the oval rostrum acute to the orifice plane and facing laterally. Vicarious avicularia vary from 0.3 to 0.5mm long, with a slender rostrum, slightly spatulate distally, with a finely serrate edge, and a stout crossbar, which lacks a columella.

DISTRIBUTION

Described originally from Torres Strait, this species has been recorded from throughout the Great Barrier Reef province, from New South Wales, Victoria and New Zealand. It is distributed through the Indo-Malaysian Archipelago, westwards to India, Sri Lanka and Mauritius. Canu & Bassler's (1930) record from the Galapagos Islands should perhaps be re-examined.

REMARKS

C. vagans (q.v.) also bears three, thin, pointed denticles on the proximal border of the orifice. It is distinguished from *C. tridenticulata* by its lack of oral spines; by its deeply notched peristome; and by its vicarious avicularium, which is more slender than that of *C. tridenticulata*, with a smooth edge to the rostrum and a distinct columella.

Celleporaria aperta ((Hincks)
(Fig. 14d,e)

Schizoporella aperta Hincks, 1882: 126, pl. 5, fig. 3.
Celleporaria aperta: Harmer, 1957: 673 (in part); Winston & Heimberg, 1986: 32, figs 79-84.

DESCRIPTION

Colony multilaminar and nodular, but rather small, rarely occupying more than a few cm^2 of substratum. Recumbent autozooids commonly 0.5×0.3mm, with convex, nodular frontal wall; marginal pores few, small and indistinct. Primary orifice wider than long, about 0.1×0.15mm, the proximal border slightly concave, with a shallow, irregularly U-shaped sinus medially; condyles small, pointed, inconspicuous; typically with two, widely spaced, disto-lateral spines, and occasionally with a third, distally situated. Suboral avicularium characteristic: proximal to sinus, small, with oval rostrum, finely denticulate distally, 0.05mm long; perpendicular to plane of orifice and facing laterally. Vicarious avicularia sporadic, rostrum commonly 0.2-0.3mm long, parallel-sided, and rounded distally, or rather lanceolate with a tapered distal tip; crossbar stout, flattened. Ovicell shallow, imperforate, with finely nodular calcification.

REMARKS

Winston & Heimberg (1986) re-examined some of the material studied by Harmer (1957), and considered that he had confused several species of *Celleporaria* in his account of *C. aperta*.

DISTRIBUTION

C. aperta seems to be widely distributed in the western Pacific, from the South China Sea to Queensland, and throughout the East Indies, ranging to Sri Lanka and East Africa. Its reported occurrence from West Africa, Cape Verde Islands (Cook, 1968b, 1985) and the Caribbean should be regarded with caution until specimens from those regions have been examined by SEM.

Celleporaria desperabilis sp. nov.
(Fig. 15e,f)

TYPE MATERIAL

HOLOTYPE: GH5228, Heron Island, Stn 14, 12 Apr 1972.
PARATYPE: GH5229, as for holotype.

ETYMOLOGY

Latin *despero, desperabilis*, hopeless.

DESCRIPTION

Colony forming a multilaminar, encrusting

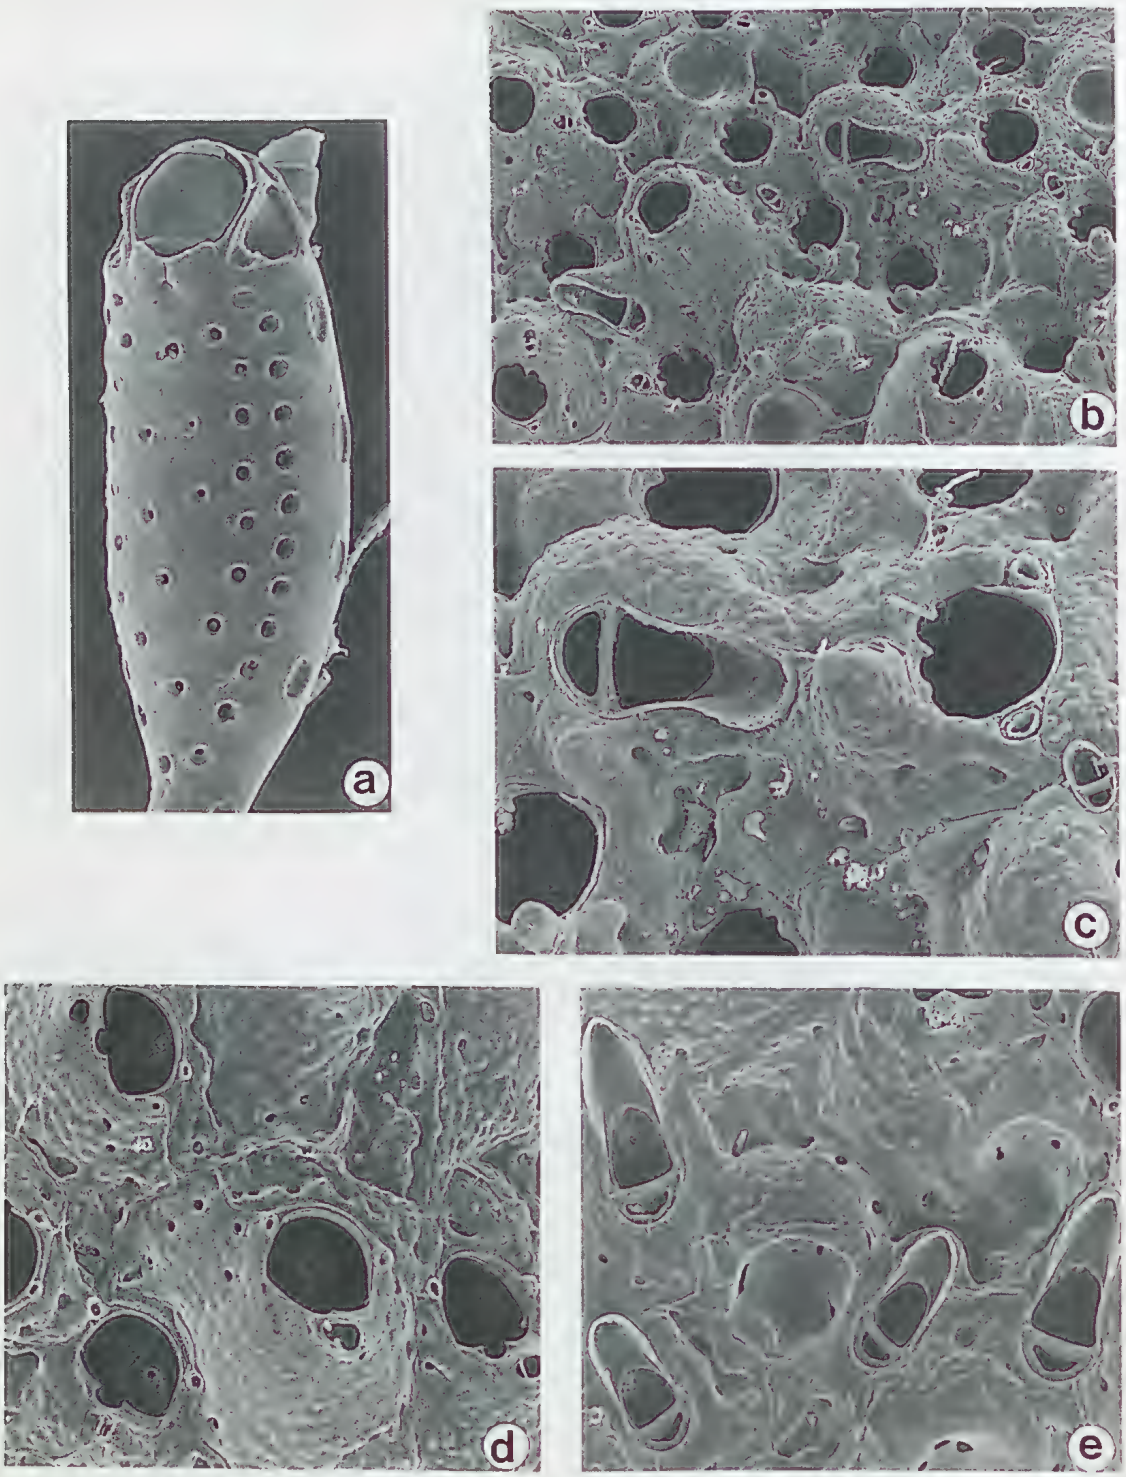

FIG. 14. a, *Vasignyella otophora*, ×120. b, c, *Celleporaria tridenticulata*; b, ×50; c, detail to show primary orifice and a vicarious avicularia, ×120. d,e, *Celleporaria aperta*; d, ×85; e, vicarious avicularia, ×95.

sheet. Autozooids 0.6-0.7×0.4-0.5mm; frontal wall convex, finely nodular or wrinkled, with few, relatively large, marginal pores. Primary orifice wider than long, about 0.12×0.17mm, the proximal border gently concave, bearing three denticles within its edge: lateral denticles stout, pointed; median denticle variable, quadrate, or anvil-shaped, its free edge often notched or bifid, sometimes completely divided to give two separate, slender denticles. No oral spines. Peristome developing early in ontogeny, enclosing and obscuring proximal and lateral borders of orifice; a single median suboral avicularium, columnar, the rostrum perpendicular to plane of orifice, elongate triangular, about 0.15mm long, with finely toothed distal edge; crossbar slender, with a conspicuous columella; apically, the avicularium is produced as a tapered umbo. Adjacent to the proximal end of the avicularium, the peristome is deeply notched. Tiny adventitious avicularia, with oval rostrum, often frequent along margins of autozooids. Vicarious avicularia rare, apparently absent from many colonies; small, rostrum 0.15-0.25mm long, parallel-sided, deeply cupped distally. Ovicell a simple hemisphere, widely open frontally, lightly calcified, but thickening slightly in later ontogeny.

REMARKS

This species is distinguished from *C. tridenticulata* by its large, columnar suboral avicularium, deep peristome, and lack of oral spines. *C. vagans* (q.v.) has three thin, pointed denticles within the proximal edge of the orifice; its suboral avicularium is proportionately much smaller than that of *C. desperabilis*, and the ovicell larger, with a granular surface, and an asymmetrical aperture which may bear a small avicularium on its rim.

Celleporaria fusca (Busk)
(Fig. 15a-d)

Cellepora fusca Busk, 1854: 88, pl. 119, fig. 2; pl. 120, fig. 6.
Celleporaria fusca: Harmer, 1957: 680, pl. 43, figs 1-7.

DESCRIPTION

Colony forming massive, nodulated, multilaminar sheets, often exceeding 25cm^2; less frequently, developing erect, irregularly branching growths; deep purplish-brown in colour. Aperture about as wide as long, more or less D-shaped, the proximal border slightly concave, and arched frontally. No oral spines. Peristomial thickening most pronounced proximally, incorporating a single medio-proximal avicularium, vertically orientated with respect to the aperture, its cystid produced apically as a stout, pointed umbo; rostrum facing laterally, small and oval (0.05mm long), or longer (0.15-0.30mm), with a strongly denticulate distal edge. Vicarious avicularia generally infrequent, but characteristic: rostrum slender, lanceolate, rounded distally and often with a slight lateral curve; 0.2-0.6mm long. Ovicell spherical, imperforate, its orifice rim with an asymmetrical thickening which may include a small adventitious avicularium. Immediately below the avicularium the peristome rim bears a narrow notch, on the other side of which the rim is slightly thickened.

REMARKS

Winston & Heimberg (1986) indicated that Harmer's (1957) account of *C. fusca* was founded on a number of similar, deeply pigmented species. Harmer's figures, however, appear to represent true *C. fusca*. The type specimen (BMNH reg. no. 1854.11.15.180) is labelled 'pl. 119. Cape Capricorn' in Busk's hand, although the published type locality was given as Bass' Strait. A second Busk collection specimen (BMNH 1899.7.1.4867A) is labelled 'Bass' Strait'; both this and the type specimen are labelled 'R', for HMS Rattlesnake. A Hincks collection specimen from Bass' Strait (BMNH 1899.5.1.1316), Torres Strait specimen figured by Harmer (1957)(BMNH 1963.9.8.11), and a Siboga specimen from Makassar (BMNH 1963.9.8.14 part) have all been compared with the two Busk collection specimens, and with the present series from Heron Island, and it is clear that they all represent a single species. On the basis of these specimens, *C. fusca* can be said to range along the entire east coast of Australia, from Bass Strait to Torres Strait, and into the Indo-Malaysian Archipelago. In view of Winston & Heimberg's (1986) account, the synonymy constructed by Harmer should be viewed with caution, until records from the Indian Ocean can be re-examined.

Celleporaria pigmentaria (Waters)
(Fig. 16d,e)

Holoporella pigmentaria Waters, 1909: 163, pl. 15, figs 16-19; pl. 16, figs 9-16; pl. 17, figs 22, 23.
Celleporaria pigmentaria: Harmer, 1957: 684, pl. 43, fig. 8; text- fig. 58.

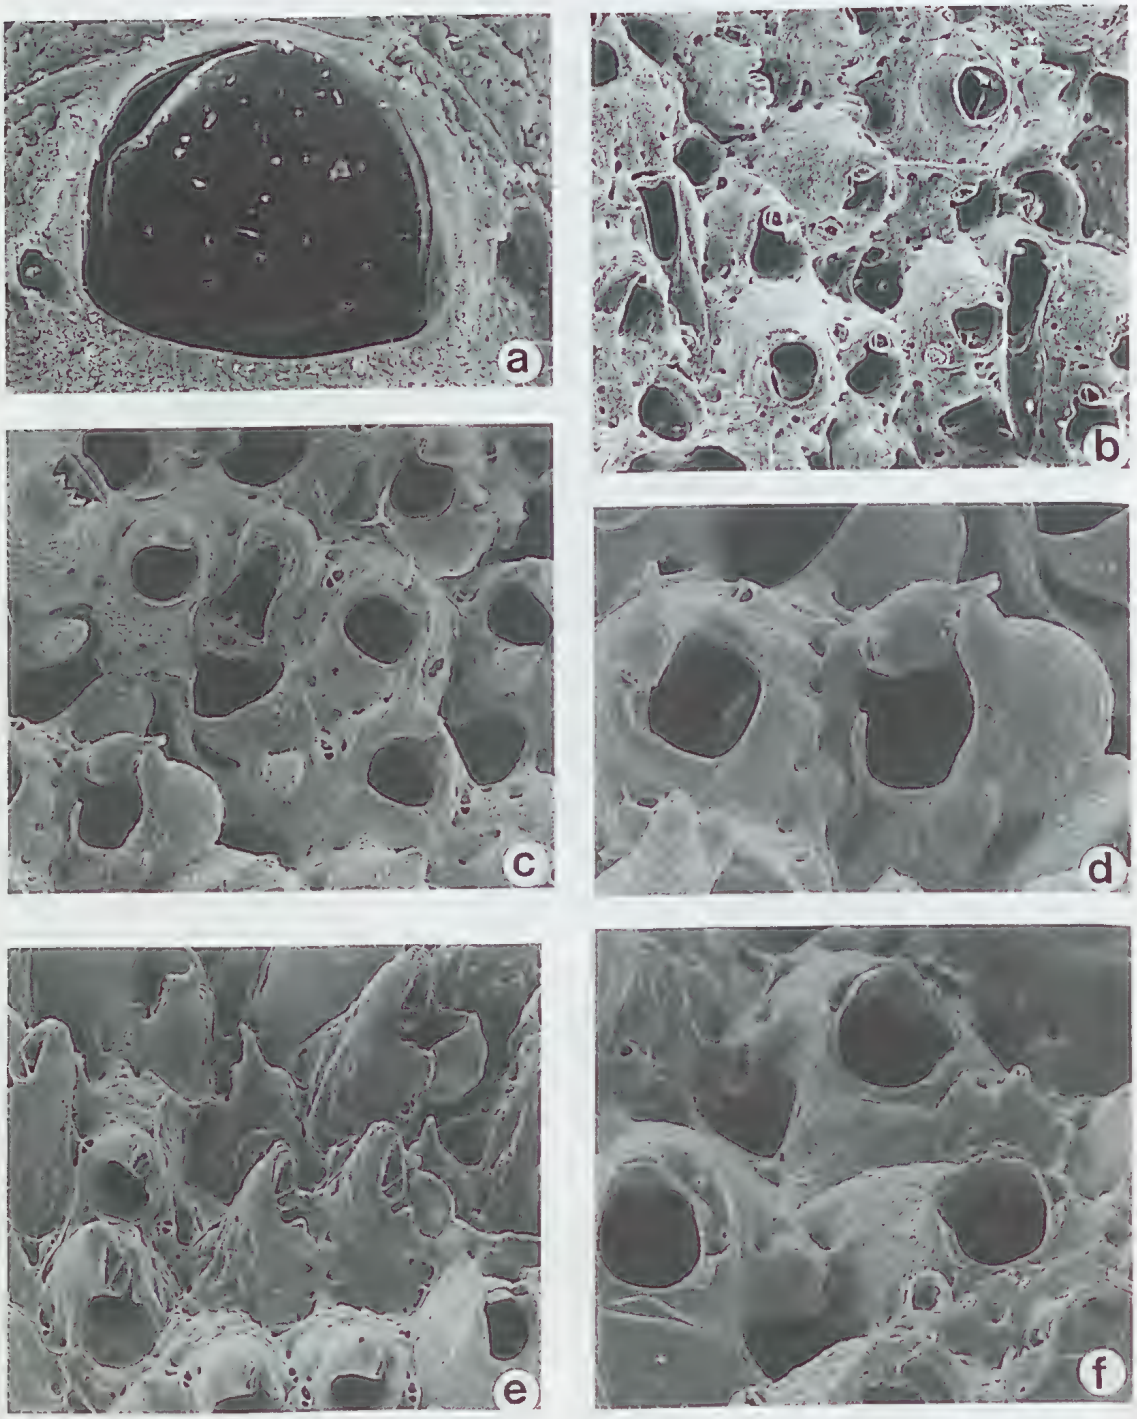

FIG. 15. a-d, *Celleporaria fusca*; a, primary orifice, ×290; b, part of colony, with elongate vicarious avicularia, ×45; c, part of colony, with spatulate vicarious avicularia, ×70; d, detail to show ovicell, ×120. e,f, *Celleporaria desperabilis*; e, ×55; f, ×100.

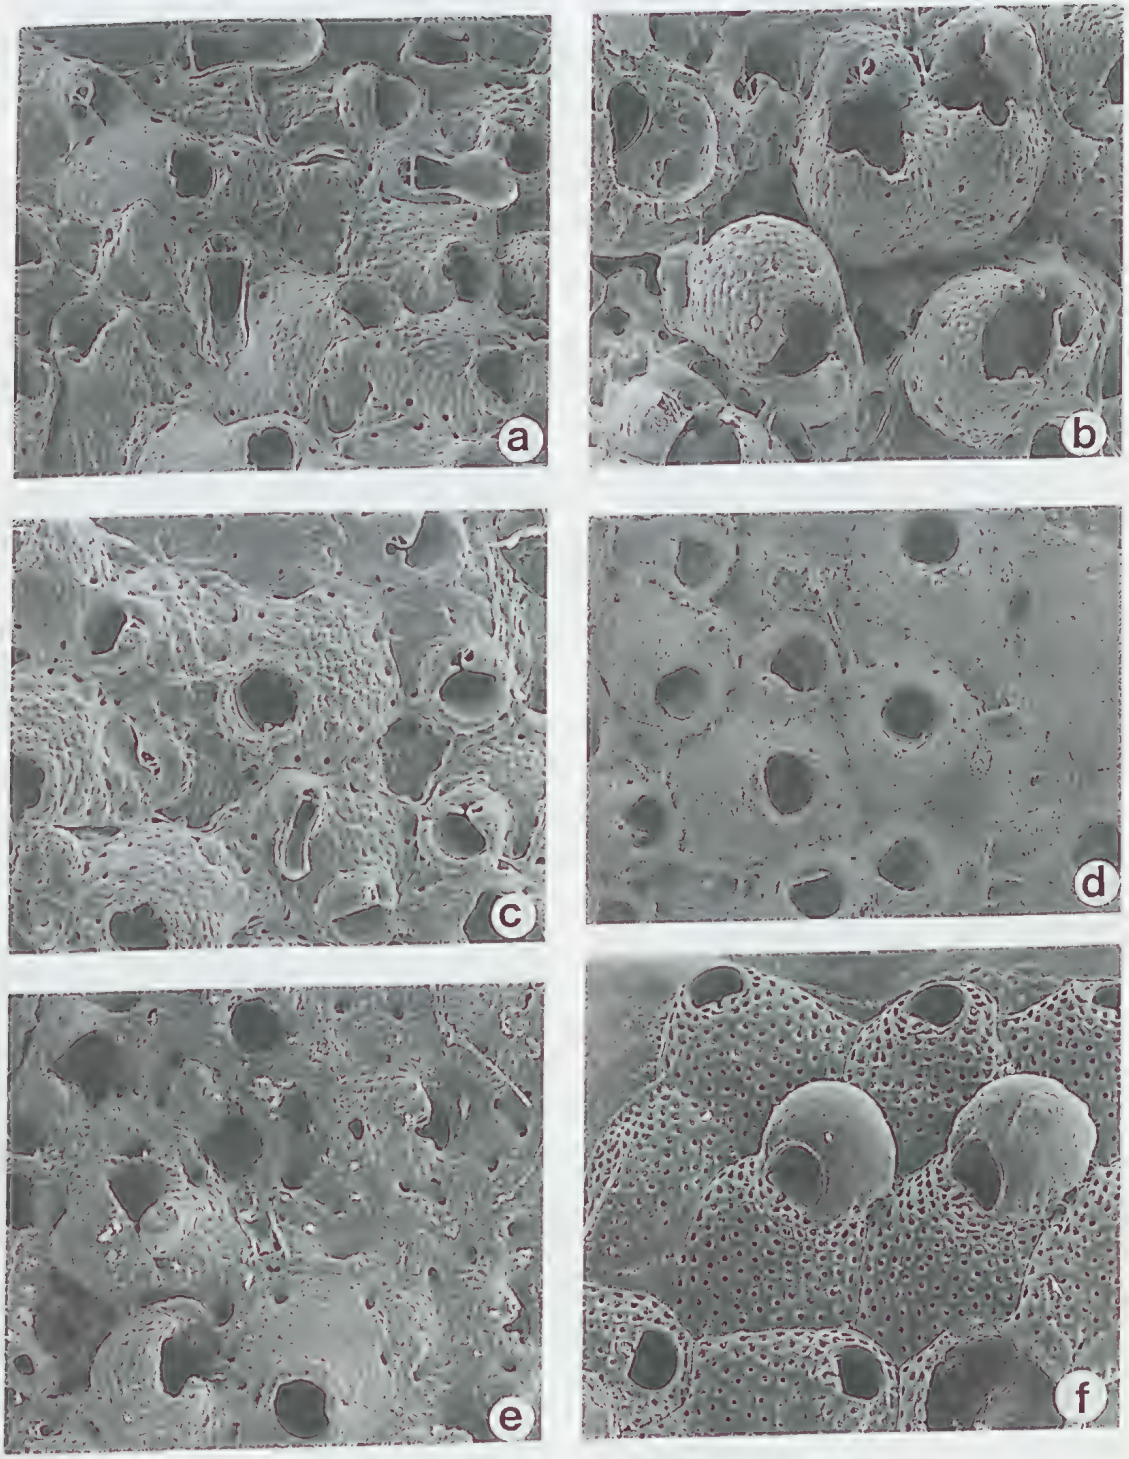

FIG. 16. a-c, *Celleporaria vagans*; a, ×45; b, ×50; c, ×45. d,e, *Celleporaria pigmentaria*; d, ×45; e, ×60. f, *Arthropoma cecilii*, ×50.

DESCRIPTION

Colony multilaminar, nodular, occasionally developing stout, erect, branching forms, deep brown to black. Autozooids oval, strongly convex, thickly calcified; commonly 0.5-0.6×0.4-0.5mm. Frontal wall coarsely nodular, with small, indistinct marginal pores. Aperture orbicular, slightly wider than long, its rim thickened but not especially prominent; a very small avicularium present mid-proximally, vertically orientated, with oval rostrum 0.05mm long; adjacent to the avicularium the peristomial rim clearly notched. No oral spines. Vicarious avicularia rare, usually absent; rostrum narrowly scaphoid, 0.25mm long, with incomplete crossbar. Peristomial avicularium occasionally giving rise to a stout, spiked mucro, which may be particularly accentuated among the oldest autozooids. Ovicell hemispherical, thickly calcified, inconspicuous.

REMARKS

This species was originally described from the Red Sea (Waters, 1909), and reported from a single Indonesian locality by Harmer (1957). The present material has been compared with the specimens from Ghardaqa and Sumbawa listed by Harmer, and with a specimen collected previously from Heron Island by L. Vail, and all seem to represent a single species.

Celleporaria vagans (Busk)
(Fig. 16a-c)

Cellepora vagans Busk, 1881: 343; 1884: 198, pl. 29, fig. 10; pl. 35, fig. 11.
Celleporaria vagans: Harmer, 1957: 671, pl. 42, fig. 4; text-fig. 55.

DESCRIPTION

Colony forming a multilaminar, encrusting sheet. Autozooids 0.6-0.8×c.0.4mm; frontal wall convex, nodular and rugose, bordered by small but distinct marginal pores. Primary orifice wider than long, commonly 0.17×0.12mm; proximal edge shallowly concave, with three thin, pointed denticles evenly spaced just within its rim. No oral spines. Peristome deep, developing in early ontogeny, enveloping lateral and proximal borders of orifice; a single median suboral avicularium, small, columnar, its apex produced as a short, pointed umbo; rostrum 0.1-0.2mm long, oval, orientated vertically to orifice plane and directed laterally. Peristome rim deeply notched adjacent to the proximal end of the avicularium; in later ontogeny a process extending from the peristome rim eventually fuses with the opposite rim, below the avicularium, to delimit a rounded spiramen. Vicarious avicularia infrequent, variable in length, but reaching 0.6mm; elongate, narrowest medially, spatulate and slightly cupped distally. Ovicell more than a hemisphere, overarching the primary orifice, surface finely granular, with a few indistinct perforations; its aperture irregularly triangular, the rim often peaked medially, and bearing a small avicularium in later ontogeny.

DISTRIBUTION

C. vagans is known from Hawaii, Torres Strait, Indonesia, and the eastern Indian Ocean, but from relatively few specimens. Busk's (1881, 1884) material from Crozet Island perhaps represents a different species, and requires re-examination.

Superfamily SCHIZOPORELLOIDEA Jullien, 1883
Family HIPPOPODINIDAE Levinsen, 1909

Colony encrusting. Autozooids with cryptocystidean frontal wall, evenly perforated. Orifice more or less bell-shaped: arched distally, shallowly concave proximally, with prominent lateral condyles. No oral spines. Avicularia adventitious, typically associated with orifice. Ovicell partly or wholly immersed, perforated, closed by autozooid operculum.

Hippopodina Levinsen, 1909

Colony encrusting. Frontal wall of autozooid with cryptocystidean development, perforated by numerous, closely spaced, small pores. Primary orifice bell-shaped; proximal border shallowly concave between distinct lateral condyles; no oral spines. Avicularia adventitious. Ovicell partially immersed in next autozooid, finely perforate, closed by autozooidal operculum. Vertical walls of autozooids with numerous, small, uniporous septula.

Type species: *Lepralia feegeensis* Busk, 1884.

Hippopodina feegeensis (Busk)
(Fig. 17a)

Lepralia feegeensis Busk, 1884: 144, pl. 22, figs 9, 9a, 9b.
Hippopodina feegeensis: Harmer, 1957: 974, pl. 67, figs 7-9; Winston & Heimberg, 1986: 16, figs 28-30.

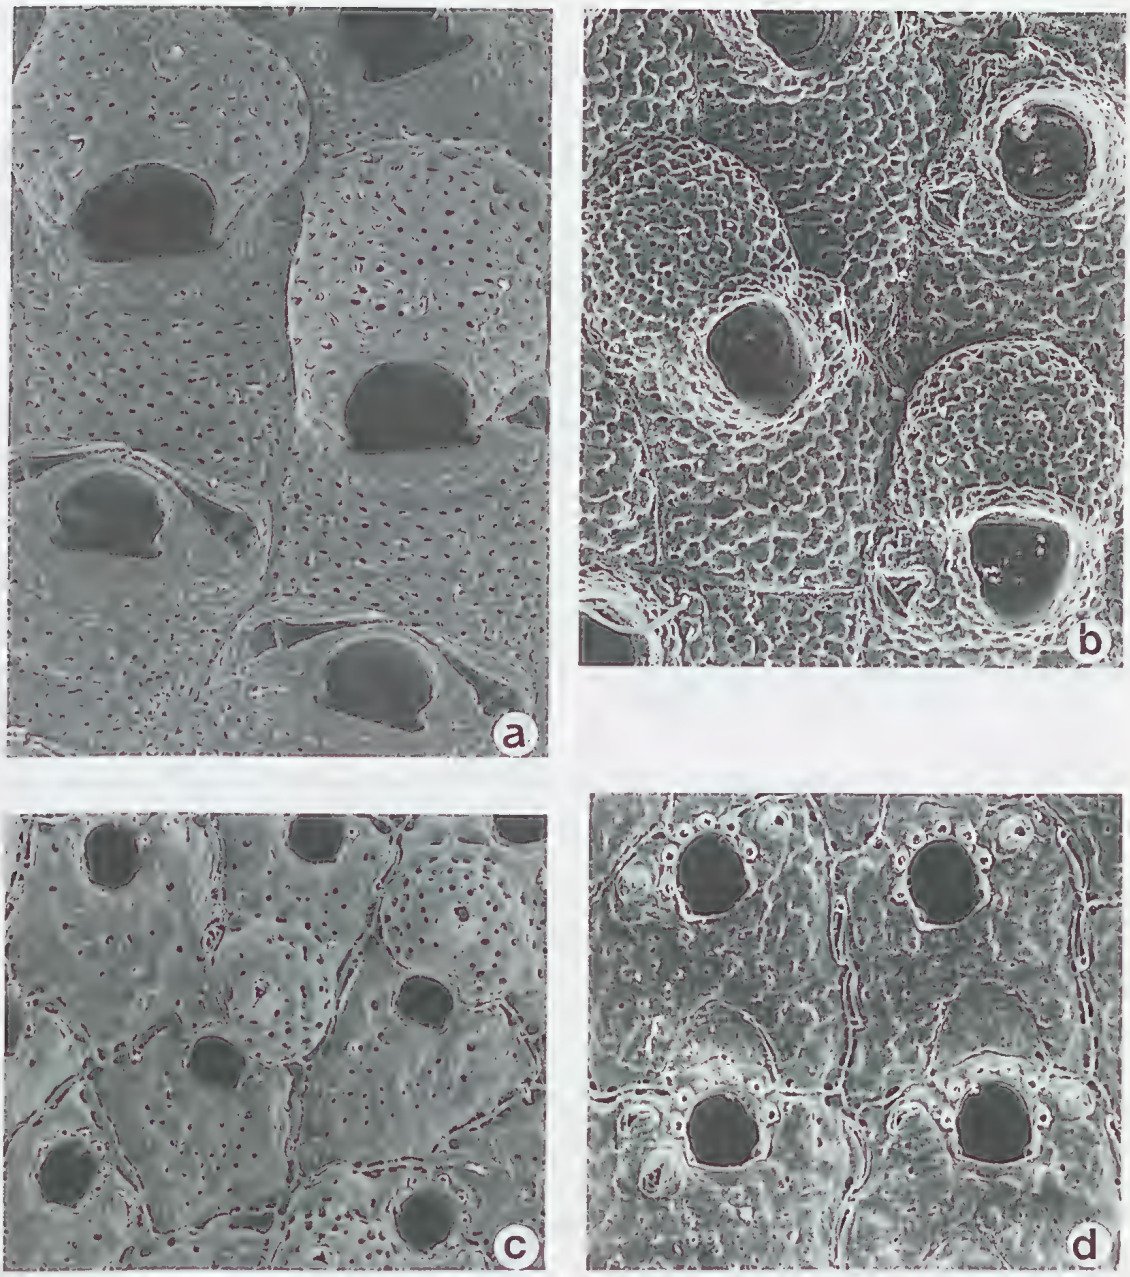

FIG. 17. a, *Hippopodina feegeensis*, ×55. b, *Cosciniopsis lonchaea*, ×50. c, d, *Thornelya perarmata*; c, ×60; d, ×85.

DESCRIPTION

Colonies forming thin, very extensive, light yellowish-brown, unilaminar sheets, glistening when dried. Autozooids oval to hexagonal, convex, separated by distinct grooves, lightly calcified; commonly 0.75-0.9×0.5-0.6mm. Primary orifice longer than wide, bell-shaped, with sharp, down-curved condyles. Frontal wall pearly or nodular, with numerous, densely-spaced, small pores, giving a speckled appearance at low magnification. Avicularia single or paired, disto-lateral to orifice; slender, acuminate rostrum directed medially, close to the distal border of the orifice.

Ovicell elongate oval, very prominent, densely perforated, with arched aperture.

REMARKS

H. feegeensis has a pan-tropical distribution in shallow waters. It forms broad flat sheets, often exceeding 100cm^2, on all kinds of hard substrata, and may be the most abundant bryozoan occurring on coral rubble in reef flat habitats. It is also often the primary colonising species on artificial substrata. It was common in 11 of the samples from Heron Island reported here.

Cosciniopsis Canu & Bassler, 1927

Colony encrusting, often strikingly pigmented. Autozooids large, robust, with thickly calcified, tuberculate frontal wall, pierced by numerous small pores. Primary orifice elongate-oval or bell- shaped, the proximal border broadly concave, between distinct lateral condyles. No oral spines. A well developed peristome typically present. Adventitious avicularia developed lateral to orifice, single or paired; lacking in some species. Ovicell hyperstomial, globular, with tuberculate calcification pierced by numerous small pores; closed by autozooid operculum.

Type species: *Cosciniopsis coelatus* Canu & Bassler, 1927.

Cosciniopsis lonchaea (Busk)
(Fig. 17b)

Lepralia lonchaea Busk, 1884: 146, text-fig. 43.
Cosciniopsis lonchaea: Harmer, 1957: 1083, pl. 72, figs 16, 17, 19, 20.

DESCRIPTION

Colony forming small, unilaminar patches. Autozooids oval to hexagonal, strongly convex, separated by deep grooves; 0.7-1.0×c.0.6mm. Primary orifice elongate-oval, the proximal edge with thickened, concave rim; condyles small and rounded; enveloped distally and laterally by a thin, raised peristome. Frontal calcification strikingly tuberculate, the tiny pores just visible between the tubercles. Most autozooids with a single, lateral-oral, avicularium; its blister-like cystid closely applied to the peristome, the acuminate rostrum acute to frontal plane, directed disto-medially towards the orifice. In some autozooids the lateral-oral avicularium is paired, one each side of the orifice; in others an identical avicularium occurs on the distal edge of the peristome, with the rostrum perpendicular to the frontal plane, directed towards the orifice of the autozooid. Ovicell slightly wider than long, globular, with tuberculate calcification and fine perforation identical to that of the autozooid.

DISTRIBUTION

Described originally from New Guinea, *C. lonchaea* has been reported from Torres Strait and South China Sea by Kirkpatrick (1890a,b) and from Indonesia by Harmer (1957). Waters (1909) recorded it from Sudan, while Harmer's (1957) synonymy of *Lepralia vestita* Hincks extends its range to Tahiti and Hawaii.

Thornelya Harmer, 1957

Colony encrusting, unilaminar. Primary orifice of autozooid bell-shaped, with broad, concave proximal border; condyles distinct; oral spines present. Frontal wall with large marginal pores, and small, scattered frontal pores. Adventitious avicularia present, often numerous, one to four per autozooid, most usually associated with the orifice or the ovicell, generally rather small. Ovicell recumbent on next autozooid, prominent, irregularly rounded, surface densely perforated, sutured, often bearing avicularia; closed by autozooid operculum.

Type species: *Lepralia ceylonica* Thornely, 1905.

Thornelya perarmata Harmer, 1957
(Fig. 17c,d)

Thornelya perarmata Harmer, 1957: 1105, pl. 73, figs 6-8.

DESCRIPTION

Colony forming very small, unilaminar patches. Autozooids irregularly rectangular to hexagonal, rather flat, separated by thickened sutures; 0.4-0.5×0.3-0.35mm. Primary orifice 0.12mm long, with six spines in a distal arc; condyles rounded, distinct. Frontal wall smoothly calcified, nodular; with 10-30 small pores centrally, and a single series of larger, elongate oval marginal pores. Avicularium single or paired, lateral to orifice; rostrum triangular, 0.1mm long, acute to frontal plane, directed towards orifice; one or two, occasionally more, avicularia developing in later ontogeny on distal edge of orifice, with rostrum directed towards it; additional avicularia developed along lateral margins of autozooids. Ovicell about as wide as long, prominent, with densely punctured, nodular surface; a single avicularium present on frontal surface, with rostrum proximally directed.

DISTRIBUTION

This species was described by Harmer (1957) from 141m off Waigeo Island, northwest New Guinea. It has not been recorded previously from the Great Barrier Reef, or from reef flat habitats. It seems to be common at Heron Island, and occurred in seven of the samples studied.

Family HIPPOPORINIDAE Brown, 1952

Colony encrusting; or erect with an encrusting base. Autozooids with regularly perforated frontal wall. Primary orifice shallowly concave proximally, or distinctly sinuate, with conspicuous condyles; no oral spines. Avicularia adventitious. Ovicell typically large, inflated, often sutured; in some genera brooding autozooids with large, dimorphic orifice.

Calyptotheca Harmer, 1957

Colony encrusting; sheet-like; or erect, bilaminate, plate-like. Frontal wall of autozooids densely perforated. Primary orifice sinuate, or with evenly concave proximal edge; dimorphic, typically larger and broader in brooding autozooids. Avicularia typically small, adventitious, lateral oral or sutural; rarely, vicarious; or absent. Ovicell large and conspicuous, perforated, closed by autozooid operculum.

Type species: *Schizoporella nivea* var. *wasinensis* Waters, 1913.

Calyptotheca tenuata Harmer
(Fig. 18b,c)

Calyptotheca tenuata Harmer, 1957: 1016, pl. 68, figs 16, 17.

DESCRIPTION

Colony developing extensive, multilaminar sheets. Autozooids oval to hexagonal or irregularly polygonal, convex, separated by thin, raised sutures; commonly 0.6-0.7×0.5mm. Primary orifice slightly wider than long, proximal border shallowly concave between knob-like proximo-lateral condyles; with a low, nodular peristome developing in later ontogeny. Frontal wall thick, densely and evenly perforated by regular, round pores, with nodular calcification between. Ovicell partly immersed in distally succeeding autozooid, wider than long, rather flattened frontally, with a coarsely nodular surface perforated by irregular pores. Avicularia sparse, developed on lateral margin of autozooid, proximal to orifice, directed medially and reaching midpoint of frontal wall; rostrum slender, acuminate, 0.35mm long.

DISTRIBUTION

C. tenuata was known only from Indonesia, the Loyalty Islands and Sri Lanka; Heron Island provides the first Australian record.

Calyptotheca thornelyae Dumont
(Fig. 18a)

Lepralia subimmersa: Thornely, 1905: 122.

[not] *Lepralia subimmersa* MacGillivray, 1879: 23, pl. 35, fig. 5.

Calyptotheca thornelyae Dumont, 1981: 625.

DESCRIPTION

Colony forming extensive, unilaminar or multilaminar, light reddish-brown sheets. Autozooids rectangular, hexagonal or irregularly polygonal, convex, separated by distinct sutures; 0.5-0.75×0.3-0.5mm. Primary orifice wider than long, proximal border shallowly and evenly concave between low, rounded, proximo-lateral condyles. Frontal wall thick, finely nodular, evenly perforated by numerous, small, round pores; a low, crenulate, peristomial rim characteristically present proximal to the orifice. Ovicell prominent, domed, occupying most of the frontal wall of the distally succeeding autozooid; calcification and perforation identical to that of autozooid frontal wall; orifice of brooding zooid shorter than that of autozooid, with more shallowly concave proximal edge. Adventitious avicularia sporadic, infrequent; 0.1mm long, with slender, acuminate rostrum; single or paired, most usually situated proximo-lateral to orifice, medially directed, occasionally budded along the lateral margins of autozooids in later ontogeny.

REMARKS

Thornely's (1905) two specimens of '*Lepralia subimmersa*' from Sri Lanka appear to be the only known material of this species, prior to its collection from Heron Island; one of the specimens was designated lectotype of *Calyptotheca thornelyae* by Dumont (1981). Both specimens have been compared with the Heron Island material, and there is no doubt that the two sets are conspecific. *Calyptotheca subimmersa* (MacGillivray) is presently known only from the southern coasts of Australia.

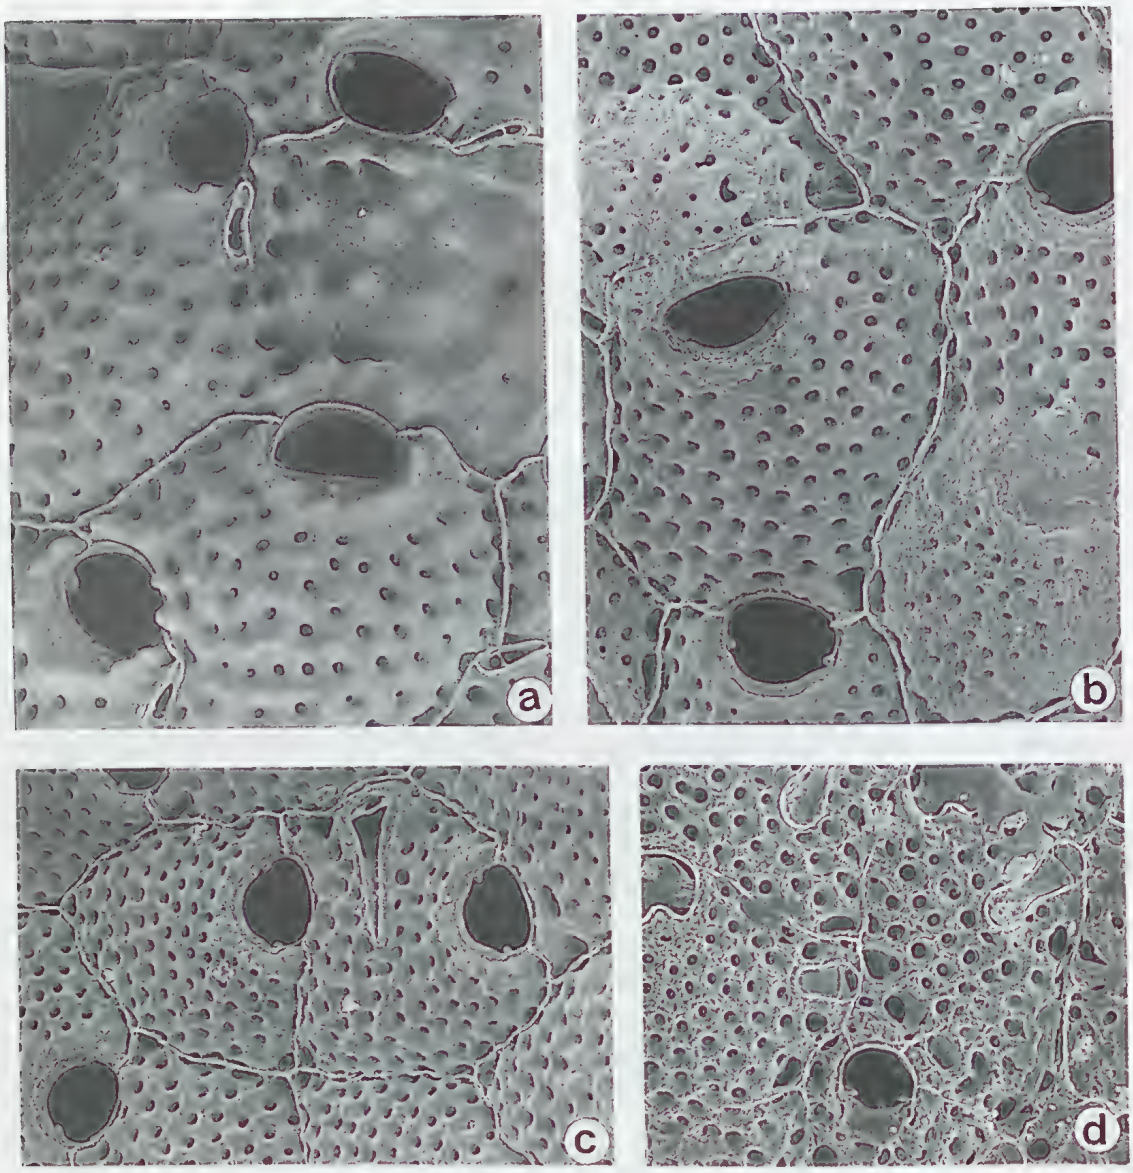

FIG. 18. a, *Calyptotheca thornelyae*, ×90. b,c, *Calyptotheca tenuata*; b, ×70; c, ×60; d, *Emballotheca pacifica*, ×70.

Emballotheca Levinsen, 1909

Colony encrusting. Autozooids with evenly perforated frontal wall. Primary orifice shallowly concave proximally, or distinctly sinuate; with well-marked condyles; dimorphic, larger and broader in brooding autozooids. No oral spines. Avicularia adventitious; or absent. Ovicells large, inflated, sutured; regularly porous.

Type species: *Eschara quadrata* MacGillivray, 1880.

Emballotheca pacifica Harmer
(Fig. 18d)

Emballotheca pacifica Harmer, 1957: 1088, pl. 67, figs 3-5.

DESCRIPTION

Colony an encrusting, multilaminar sheet. Autozooids rectangular to irregularly polygonal, convex, separated by distinct sutures. Primary orifice wider than long, its proximal border with

a rounded-triangular median process; with large, downcurved lateral condyles. Frontal wall thick, coarsely granular, perforated by large, irregular pores, which tend to fuse in later ontogenetic thickening. Ovicell prominent, obscuring much of distally succeeding autozooid, as wide as long, surface granular and coarsely perforated, and typically crossed by sutures; the orifice of ovicelled autozooids is broader than that of ordinary autozooids, with a shallowly concave proximal edge. Avicularia situated proximo-lateral to orifice, directed proximo-medially; of variable length, up to 0.3mm long; the smallest with a semielliptical mandible, the largest distinctly spoon-shaped.

DISTRIBUTION

Previously from isolated localities in the western Pacific, from the South China Sea to Torres Strait.

Robertsonidra Osburn, 1952

Colony encrusting. Autozooids with tuberculate frontal wall, bordered by conspicuous marginal pores. Primary orifice with proximal sinus, frequently with a pronounced lateral suboral umbo; spines present or absent. Avicularia adventitious. Ovicell hyperstomial, closed by autozooid operculum; surface tuberculate, with minute perforations. Vertical walls with very small uniporous septula; basal walls typically raised above the substratum on stout, projecting processes.

Type species: *Schizoporella oligopus* Robertson, 1908.

Robertsonidra argentea (Hincks)
(Fig. 19b)

Schizoporella argentea Hincks, 1881b: 158, pl. 9, figs 6, 6a.

Rhamphostomella argentea: Harmer, 1957: 1102 [part-tim].

[not] *Robertsonidra argentea*: Powell, 1967: 169.

Colony a small, yellowish-white patch; unilaminar. Autozooids oval to broadly hexagonal, convex, separated by distinct sutures; 0.6-0.75×0.4-0.5mm. Primary orifice about as long as wide; proximal edge deeply, symmetrically concave, lacking condyles; two or three, thin, evanescent spines present in early ontogeny; frequently a short, asymmetrically-placed suboral umbo. Frontal wall regularly tuberculate, with a single row of round marginal pores. Avicularia dimorphic, one or both types present on a single autozooid, some autozooids without either; lateral-suboral, acute to frontal plane, laterally directed, with short, hooked rostrum, or normal to frontal plane, proximo-laterally directed, with elongate triangular rostrum. Ovicell spherical, regularly tuberculate, with minute perforations.

OCCURRENCE

A single specimen collected from Heron Island, Stn 23, encrusting coral rock, constitutes the first Australian record.

REMARKS

Harmer's (1957) account of *R. argentea* was based on several different species, and there is no indication that he examined either the type specimen (BMNH reg.no. 1899.5.1.970, loc. 'Africa') or material of the genus type, *Schizoporella oligopus* Robertson, which he placed in the synonymy of *R. argentea*. Two of the Siboga specimens listed by Harmer (1957:1101) have been compared with the type specimen of *R. argentea* and found to represent two different, undescribed, species of *Robertsonidra*. Specimen 399D (Stn 164, BMNH reg.no. 1975.7.24.22) has a pear- shaped orifice with three distal oral spines and a disto- laterally orientated, lateral suboral avicularium, with an elongate triangular rostrum; the autozooids are only loosely coherent. Specimen 108F (Stn 144, BMNH reg.no. 1975.2.24.14) has a transversely oval orifice with a distinct U-shaped sinus, lacks spines, and has a distally-directed, lateral-suboral avicularium with a short, broadly triangular rostrum. Powell's (1967) figure of '*R. argentea*' from the southern Red Sea depicts yet another species of *Robertsonidra*, *R. oligopus*, which is known from the Galapagos Islands and Southern California is almost certainly distinct from *R. argentea*, and from any of the other species discussed here. The type locality of *R. argentea* is unknown, although its habitat, 'on coral', suggests it lies somewhere on the East African coast.

Robertsonidra novella sp. nov.
(Fig. 19a)

TYPE MATERIAL

HOLOTYPE: GH5230, Heron Island, Stn 22, 15 Apr 1972.

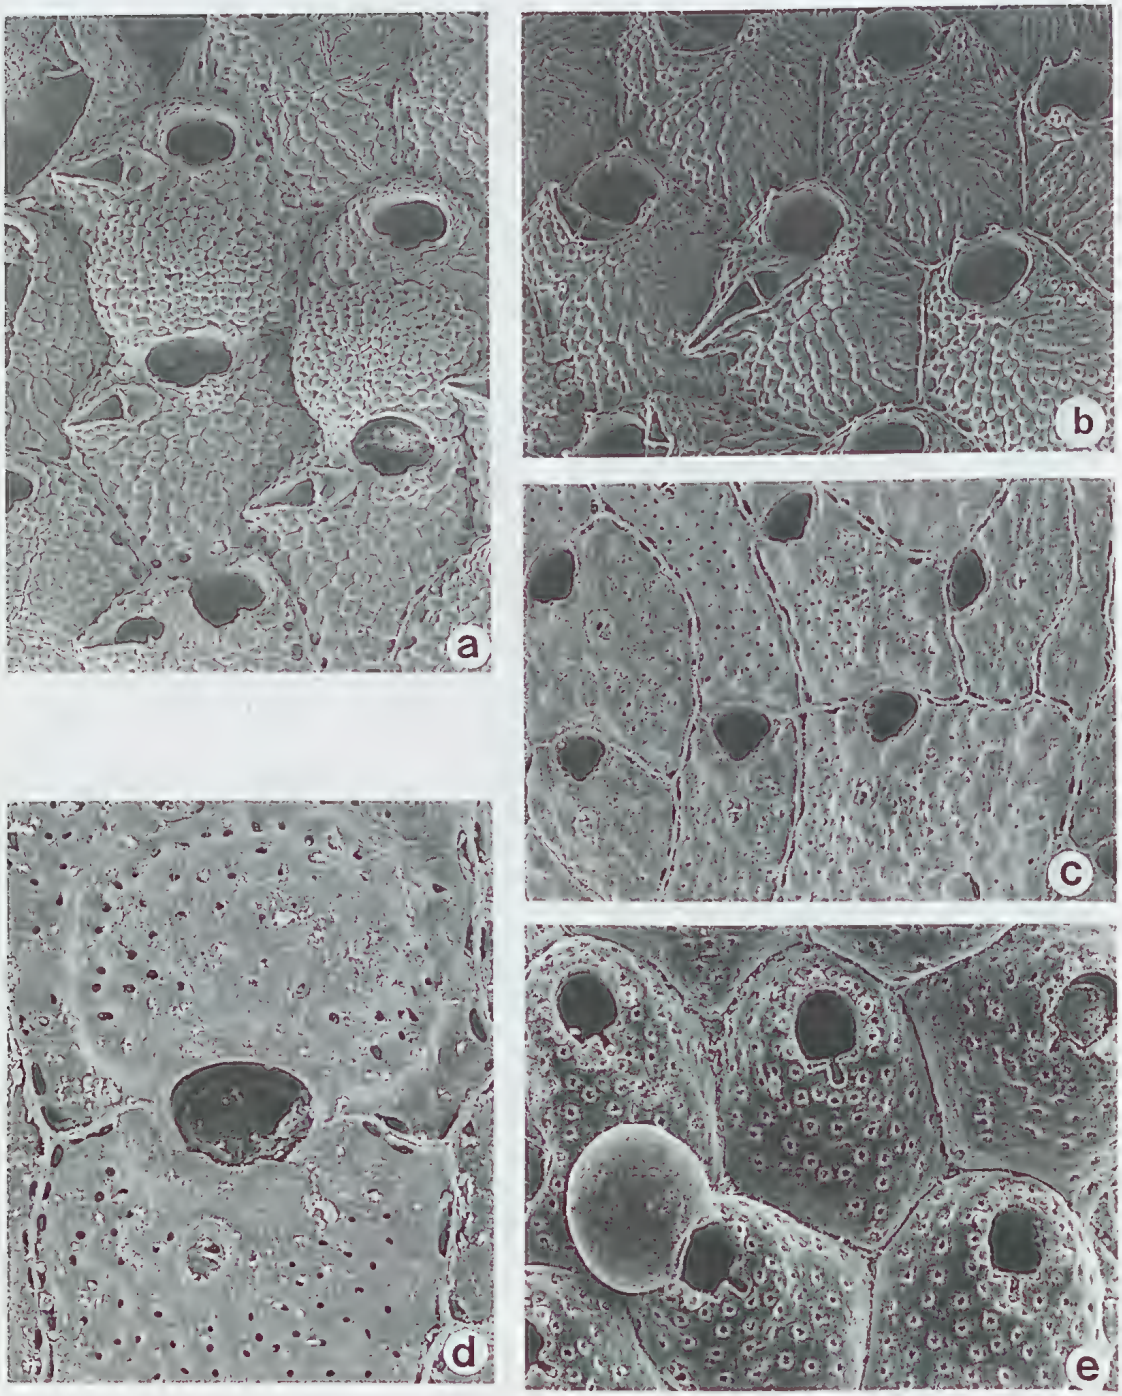

FIG. 19. a, *Robertsonidra novella*, ×60. b, *Robertsonidra argentea*, ×60. c,d, *Schizomavella inclusa*; c, ×70; d, ×140. e, *Phonicosia circinata*, ×70.

ETYMOLOGY
Latin *novella*, diminutive of *novus*, new.

DESCRIPTION
Colony forming small, silvery, unilaminar patches. Autozooids oval to hexagonal, strongly convex, separated by distinct grooves; 0.5-0.6×0.35-0.4mm. Primary orifice transversely oval, proximal border with a short, U-shaped sinus flanked by small condyles; one or two short, evanescent spines present distally, their bases persisting especially in ovicelled autozooids; a short umbo situated lateral to the sinus in many autozooids. Frontal wall regularly tuberculate, glistening under low magnification, with a single series of round marginal pores. Avicularia sporadic, lateral suboral; rostrum elongate triangular, directed proximo-laterally. In some autozooids a second, shorter avicularium occurs lateral to the sinus, with the rostrum acute to frontal plane and laterally directed. Ovicell slightly wider than long, globular, the surface tuberculate, with minute perforations between the tubercles.

REMARKS
This species is distinguished from *R. argentea* by its oval orifice, which has a distinct proximal sinus bounded by small condyles. It was present in three of the Heron Island samples.

Family SCHIZOPORELLIDAE Jullien, 1883

Colony encrusting or erect. Autozooids with cryptocystidean frontal wall; evenly perforated or with marginal pores only. Primary orifice typically with distinct proximal sinus and conspicuous condyles; oral spines present or absent. Avicularia adventitious and/or vicarious or interzooidal; or absent. Ovicells present. Vertical walls with basal pore chambers or mural septula.

Schizomavella Canu & Bassler, 1917

Colony encrusting. Frontal wall of autozooid with regularly distributed perforations. Primary orifice with distinct sinus and well-marked condyles; oral spines present or absent. Avicularia adventitious, typically suboral, but also lateral-oral, or frontal; dimorphic in some species. Ovicell hyperstomial, variably perforate, closed by autozooidal operculum. Vertical walls with small septula.

Type species: *Lepralia auriculata* Hassall, 1842.

Schizomavella inclusa (Thornely)
(Fig. 19c,d)

Schizoporella inclusa Thornely, 1906: 450.
Schizomavella inclusa: Harmer, 1957: 1028, pl. 66, figs 4, 6, 7; Winston & Heimberg, 1986: 18, figs 43, 44.

DESCRIPTION
Colony forming thin, flat encrustations. Autozooids irregularly rectangular, flat, separated by distinct sutures; 0.35-0.5×0.25-0.35mm. Primary orifice as wide as long, broadest distally and appearing pear-shaped, with a deep, U-shaped proximal sinus below short, distinct condyles. No oral spines. Frontal wall thick and vitreous, irregularly nodular, with numerous, small, round pores; marginal pores larger and more distinct. Avicularium suboral, proximally directed, 0.05mm long, with oval or bluntly triangular rostrum. A dimorphic avicularium, with enlarged, spatulate mandible was described by Harmer (1957). Ovicell wider than long, partially immersed; with numerous small pores, most densely distributed around edges.

DISTRIBUTION
S. inclusa has been described from scattered localities, from Madagascar, Mauritius and Sri Lanka, to Indonesia, New Guinea and New Britain. Harmer (1957) recorded a specimen from the Red Sea, but it has not been recorded previously, with certainty, from Australian seas.

Arthropoma Levinsen, 1909

Colony encrusting. Autozooid with evenly perforated frontal wall. Primary orifice with narrow medio-proximal sinus; operculum articulated. No oral spines. Avicularia absent. Ovicell prominent, imperforate, closed by autozooid operculum. Vertical walls with large, multiporous septula. Ancestrula identical to later autozooids.

Type species: *Flustra cecilii* Audouin, 1826.

Arthropoma cecilii (Audouin)
(Fig. 16f)

Flustra cecilii Audouin, 1826: 239; Savigny pl. 8, fig. 3.
Arthropoma cecilii: Harmer, 1957: 1001, pl. 72, fig. 23; text- fig.108; Gordon, 1984: 85, pl. 30, fig. A.

DESCRIPTION

Colony forming small, glistening, white patches; usually unilaminar. Autozooids lightly calcified, strongly convex, with densely perforated frontal wall; commonly 0.5-0.7× 0.5mm. Primary orifice slightly wider than long, D-shaped, with a very narrow, medio-proximal sinus. No avicularia, although Harmer (1957) reports a polymorph with an operculum twice the size of that of ordinary autozooids. Ovicell prominent, convex, smoothly calcified, opaque white.

DISTRIBUTION

A. cecilii is widespread and common in all shallow, tropical, subtropical and warm temperate seas. It has been reported previously from reef habitats in the Caribbean, the Indian Ocean, the East Indies and the GBR.

Phonicosia Jullien, 1888

Colony encrusting. Autozooid frontal wall with conspicuous marginal pores, and sometimes with additional pores proximo-lateral to orifice, but with central area usually imperforate. Primary orifice with proximal sinus; operculum articulated; distal oral spines present. Adventitious avicularia occur sporadically. Ovicell prominent; ectooecium membranous; entooecium calcified; imperforate, except for small basal pores around periphery; not closed by autozooid operculum. Basal pore chambers present.

Type species: *Phonicosia jousseaumei* Jullien, 1888 [= *Lepralia circinata* MacGillivray, 1869].

Phonicosia circinata (MacGillivray) (Fig. 19e)

Lepralia circinata MacGillivray, 1869: 134.
Arthropoma circinatum: Harmer, 1957: 1003, pl. 72, figs 29-30; Hayward & Cook, 1983: 69, fig. 17c.
Phonicosia circinata: Gordon, 1984: 87, pl. 30, figs E,F; 1989: 46.

DESCRIPTION

This distinctive species is readily recognized by its D-shaped orifice, with slit-like sinus and broad, denticulate condyles, surrounded by eight or nine spines.

DISTRIBUTION

P. circinata has a wide geographical distribution, ranging throughout the western Pacific Ocean, from Japan to New Zealand, eastwards to South Africa, Tristan da Cunha, the Patagonian Shelf and Tierra del Fuego; also at Marion Island and Kerguelen.

REMARKS

In some populations a large adventitious avicularium occurs proximal to the sinus, and the density and distribution of frontal wall pores also varies greatly. However, these variations may be observed over a relatively small geographic distance, and perhaps even within single populations.

Escharina Milne-Edwards,1836

Colony encrusting or erect. Frontal wall of autozooids with distinct marginal pores, and evenly scattered, minute perforations. Primary orifice with well marked sinus; oral spines present. Avicularia adventitious or interzooidal. Ovicell hyperstomial, imperforate, closed by autozooid operculum. Small basal pore chambers present.

Type species: *Eschara vulgaris* Moll, 1803.

Escharina pesanseris (Smitt)

Hippothoa pesanseris Smitt, 1873: 43, pl. 7, figs 159, 160 .
Escharina pesanseris: Harmer, 1957: 998, pl. 67, figs 12-14,18,19; Gordon, 1984: 84, pl. 29, figs A, B.

DESCRIPTION

Colony encrusting, forming small rounded patches; rather inconspicuous. Autozooids oval, convex; about 0.8×0.5mm; frontal wall finely granular, fine perforations revealed only by high magnification. Primary orifice longer than wide, with a narrow, slit-like sinus between broad condyles; with eight or nine stout distal oral spines, and a low proximal peristomial rim. Avicularia paired, lateral to orifice, with distinctive, duck's foot-shaped mandibles distally directed. Ovicell relatively small, wider than long, with a transverse frontal ridge; six spines only in ovicelled autozooids.

DISTRIBUTION

E. pesanseris has a circumtropical distribution in shallow water, and occurs commonly in reef habitats.

Stylopoma Canu & Bassler, 1920

Colony encrusting, multilaminar, developing

extensive nodular growths. Frontal wall of autozooids evenly perforated by small pores, with a marginal series of larger pores. Primary orifice with well developed condyles and deep proximal sinus; no oral spines. Avicularia adventitious, small, and vicarious, large. Ovicell globular, prominent, perforated; overhanging and eventually occluding orifice of brooding autozooid. Vertical walls with numerous, small, recessed septula.

Type species: *Eschara spongites* Pallas, 1766.

The genus *Stylopoma* has a pantropical distribution in shallow, coastal waters, and most species described seem to be commonly found in reef habitats. Most are brightly pigmented.

Stylopoma duboisii (Audouin)
(Fig. 20a,b)

Flustra?duboisii Audouin, 1826: 239; 1828: 66; Savigny pl. 8, figs 41, 42 .
Stylopoma duboisii: Harmer, 1957: 1033, pl. 74, figs 1-7; Winston & Heimberg, 1986: 20, figs 45-57.

DESCRIPTION

Autozooids irregularly polygonal, rather flat, separated by distinct sutures; 0.5-0.6×0.35-0.45mm. Primary orifice wider than long, D-shaped, the straight proximal border with a slit-like median sinus; condyles low and broad, occupying whole of proximal border on each side of sinus, distal edges finely toothed. Frontal wall densely perforated by small round pores, and with a single series of larger marginal pores; becoming coarsely nodular in later ontogeny. Typically, a single, small avicularium proximo-lateral to orifice, acute to frontal plane, disto-laterally directed; 0.05mm long, with short, triangular mandible. Additional avicularia may be budded in later ontogeny, especially in brooding autozooids, and most usually in proximity to the orifice. Vicarious avicularia infrequent, as large as autozooids, with broadly spatulate mandible. Ovicells globular, prominent, 0.5mm diameter, occupying the frontal surface of several adjacent autozooids; densely porous, with the aperture overhanging and obscuring the orifice of the maternal autozooid.

DISTRIBUTION

This species is common in shallow waters throughout Malaysia and Indonesia, and on the coasts of New Guinea and Queensland. It ranges westwards to Sri Lanka and the Red Sea, and was reported from West Africa by Cook (1968b). Seven of the Heron Island samples contained large colonies of *S. duboisii*.

Stylopoma thornelyae Livingstone
(Fig. 20c)

Schizoporella viridis var. *thornelyi* Livingstone, 1926: 84, pl. 8, figs 8, 9.

DESCRIPTION

Autozooids rectangular to polygonal, convex, separated by distinct sutures; 0.6-0.8×0.35-0.5mm. Primary orifice about as wide as long, proximal border with a broad V-shaped sinus occupying about half its width; condyles rectangular, distinct. Frontal wall densely perforated by small, evenly distributed pores, each in a shallow pit. A single, small adventitious avicularium present on many autozooids, lateral to sinus; rostrum 0.08mm long, acute to frontal plane, distally directed, supporting a short, triangular mandible. Vicarious avicularia sporadic, slightly smaller than autozooids, with waisted, spatulate rostrum.

DISTRIBUTION

This species is known with certainty only from the Great Barrier Reef, although part of the Indonesian material described by Harmer (1957) as *S. parviporosum* Canu & Bassler may represent *S. thornelyae*.

Stylopoma viride (Thornely)
(Fig. 20d)

Schizoporella viridis Thornely, 1905: 116, fig. 3.
Stylopoma viride: Harmer, 1957: 1036, pl. 74, figs 8-13; Winston & Heimberg, 1986: 21, figs 48-50.

DESCRIPTION

Autozooids rectangular, diamond-shaped or polygonal, convex, separated by distinct sutures; 0.8-1.2×0.5-0.6mm. Primary orifice orbicular, with a deep V-shaped sinus occupying two-thirds of the proximal width; condyles small, knob-like. Frontal wall densely perforated by small, round pores, the marginal series slightly larger and more distinct; calcification thick, forming raised, nodular ridges between the pores. Majority of autozooids with characteristic disto-lateral adventitious avicularium; rostrum slender, pointed, 0.35mm long, extending disto-medially above the orifice. A smaller suboral avicularium present in many autozooids, adjacent to sinus, with varying orientation. Vicarious avicularia identical to

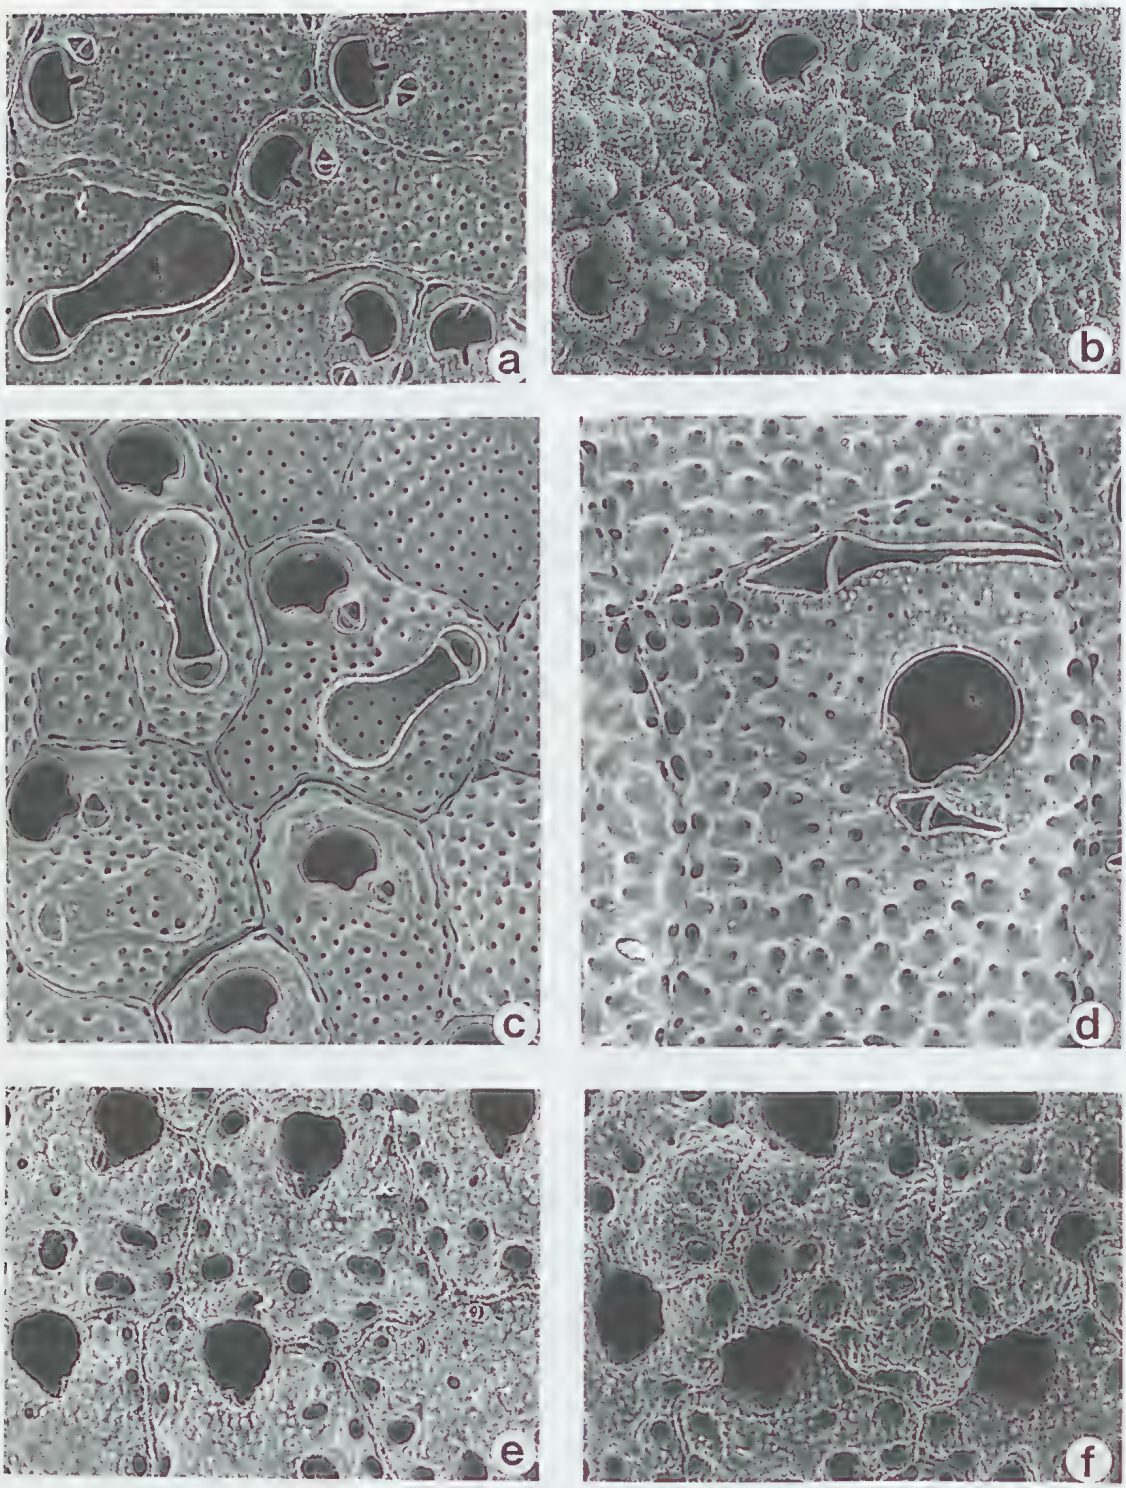

FIG. 20. a,b, *Stylopoma duboisii*; a, ×80; b, ×70. c, *Stylopoma thornelyae*, ×80. d, *Stylopoma viride*, ×80. e,f, *Cigclisula areolata*; e, autozooids, ×50; f, two ovicelled zooids, ×50.

disto-lateral adventitious avicularia; rare. Ovicell globose, as large as an autozooid, with identical calcification and perforation, and with an independent, frontally situated aperture.

REMARKS

The massive, multilaminar colonies of *S. viride* have a characteristic green coloration, muted in living colonies by a thick, greyish-brown frontal cuticle. The pigment is contained within the calcification and persists after the death of the colony.

DISTRIBUTION

This species is known from the Red Sea, Sri Lanka and other localities in the Indian Ocean; it has been widely reported from Malaysia, Indonesia, New Guinea and the Philippines, and is distributed on north and northeast coasts of Australia, and along the Great Barrier Reef.

Family STOMACHETOSELLIDAE Canu & Bassler, 1917

Colony encrusting, forming a thick, multilaminar sheet; or erect, as folded, bilaminar plates attached by an encrusting base. Autozooids thickly calcified; frontal wall with marginal and frontal pores. Primary orifice sinuate or bell-shaped, encircled by a deep, thick peristome. Avicularia adventitious and/or vicarious; or absent. Ovicells present, typically with few, large, frontal lacunae.

Cigclisula Canu & Bassler, 1927

Colony encrusting or erect, unilaminar or multilaminar, often nodular or massive. Frontal wall of autozooid with marginal perforations (sometimes in double or triple series), with stout interareolar ridges developing in later ontogeny; central area of frontal wall imperforate. Primary orifice more or less bell-shaped, the proximal border shallowly concave between distinct condyles. No oral spines. A thickened peristomial rim developing in later ontogeny, characteristically incorporating a proximal suboral avicularium, eccentrically placed and laterally directed. Additional small, adventitious avicularia may be present elsewhere on autozooid; in some species large, vicarious avicularia also occur. Ovicell characteristic: prominent, grossly inflated, sutured, with a few, large, frontal lacunae.

Type species: *Escharoides occlusa* Busk, 1884.

Cigclisula areolata (Kirkpatrick) (Fig. 20e,f)

Lepralia occlusa var. *areolata* Kirkpatrick, 1890a: 618, pl. 16, figs 7, 7a.
Porella areolata: Livingstone, 1926: 91, pl. 8, fig. 4.
Cigclisula areolata: Hastings, 1932: 434.

DESCRIPTION

Colony forming thick, extensive multilaminar sheets. Autozooids oval to hexagonal, strongly convex, thickly calcified, separated by distinct sutures; commonly 0.6-0.7 × 0.4-0.5mm. Primary orifice as wide as long, bell-shaped, with concave proximal border; condyles small, rounded. Frontal calcification coarsely granular, becoming distinctly nodular in later ontogeny, with a double or triple series of marginal pores, but the central area of the frontal wall imperforate. As the frontal wall thickens, stout ridges develop peripherally, eventually forming a series of large, deep areolae, each of which may enclose two or more of the original pores. Orifice encircled by a thick, peristomial rim; a single, small avicularium proximo-medially; its rostrum perpendicular to frontal plane and facing laterally, immersed in peristomial calcification, but with tip of rostrum hooked and distinct. Large vicarious avicularia occur sporadically. Ovicell wider than long, almost as large as autozooid, globular and prominent, with the aperture overhanging the autozooid orifice; bordered by large areolae, and with four to eight large lacunae frontally.

DISTRIBUTION

This species is known only from Torres Strait and the Great Barrier Reef. At Heron Island large colonies were present in two samples from reef crest locations.

Family SMITTINIDAE Levinsen, 1909

Colony encrusting or erect. Autozooids with cryptocystidean frontal wall, evenly perforated or with marginal perforations only. Primary orifice with or without a median proximal denticle (lyrula) and proximo-lateral condyles; oral spines present or absent. Avicularia adventitious, or absent. Ovicell prominent, perforate or imperforate.

Smittoidea Osburn, 1952

Frontal wall of autozooids with marginal pores only. Avicularium situated medially on the frontal wall, immediately proximal to the orifice,

often partly enveloped by the peristome; typically proximally directed. Ovicell prominent, evenly perforated. Vertical walls with mural septula.

Type species: *Smittoidea prolifica* Osburn, 1952.

Smittoidea pacifica Soule & Soule (Fig. 24e,f)

Smittoidea pacifica Soule & Soule, 1973: 380, figs I, F-H.

DESCRIPTION

Colony a small, silvery-white, unilaminar patch. Autozooids oval to hexagonal, flat or slightly convex, separated by indistinct sutures; 0.4-0.5×0.2-0.3mm. Primary orifice wider than long; lyrula anvil-shaped, broad and deep, occupying entire width of orifice; condyles short and blunt, indistinct. No oral spines. Peristome completely encircling orifice, its edge thickened and slightly lobed in later ontogeny; with a conspicuous U-shaped notch medio-proximally, the inner edges of which may be thickened to define a descending groove. Frontal wall coarsely nodular, bordered by large and conspicuous marginal pores. A single suboral avicularium on each autozooid, directed proximally or proximo-laterally; rostrum elongate, finely tapered, rounded at tip, its edges sometimes finely denticulate; crossbar thickened, the proximal opesia circular. Ovicell slightly wider than long, frontal surface with numerous small pores; developing a coarsely nodular ooecial cover, which extends to the distal edge of the peristome, leaving only the central frontal area of the ovicell exposed.

REMARKS

Soule & Soule (1973) founded this species on specimens collected from Hawaii. They included Osburn's (1952) record of *S. reticulata* (J. Macgillivray) from the Galapagos Islands in the synonymy of *S. pacifica*, while noting that one zooid in Osburn's specimen bore six oral spines. The Heron Island specimens here described have been compared with Hawaiian paratype material of *S. pacifica*, which they match exactly.

S. reticulata is distributed in the eastern Atlantic region from the Mediterranean to the Barents Sea, and almost certainly does not occur in the Pacific. Osburn's Galapagos material does not belong to *S. reticulata*, and is possibly not *S. pacifica* either.

Parasmittina Osburn, 1952

Colony encrusting, unilaminar or multilaminar. Frontal wall of autozooid with marginal pores only. Primary orifice with medio-proximal lyrula and paired lateral condyles; oral spines usually present; typically with a well developed peristome. Avicularia adventitious and interzooidal, frequently polymorphic, often numerous; characteristically, one or more occur lateral to the orifice. Ovicell hyperstomial, prominent, with frontal pores; not closed by autozooid operculum. Small basal pore chambers present.

Type species: *Lepralia jeffreysi* Norman, 1876.

Species of *Parasmittina* are common, and often abundant, in shallow reef habitats. Species diversity is usually high (e.g., Soule & Soule, 1973; Hayward, 1988) and it is probable that many tropical species remain to be recognized.

Parasmittina hastingsae Soule & Soule (Fig. 21a-c)

Parasmittina hastingsae Soule & Soule, 1973: 417, figs 9C,D.

Parasmittina hastingsae: Winston & Heimberg, 1986: 26, figs 59-63.

DESCRIPTION

Colony forming broad, yellowish, multilaminar sheets. Autozooids oval, hexagonal or irregular, convex, separated by distinct sutures; commonly 0.35-0.5×c.0.25mm. Primary orifice slightly wider than long, rounded; lyrula occupying about half proximal orifice width, with convex edge and bluntly pointed corners; condyles acute, distinct. Two or three (rarely four) short, distal oral spines present in early ontogeny; peristome developed as paired lateral folds, with a deep, medio-proximal sinus between; erect and slightly flared, enclosing distal border of orifice in later ontogeny. Frontal wall of autozooid finely nodular, with a single series of round marginal pores. As calcification thickens in later ontogeny, the boundaries between individual autozooids become increasingly obscure, and the marginal pores much more irregular in outline. Avicularia of three main types, all becoming more frequent in later ontogeny: most characteristically a short, oval type, proximo-lateral to orifice, proximally directed; less frequently, a larger type with rostrum elongate, tapered, rounded distally and serrated along its edge, directed proximally; finally, a large interzooidal type with rostrum tapered, rounded and slightly flared distally, its

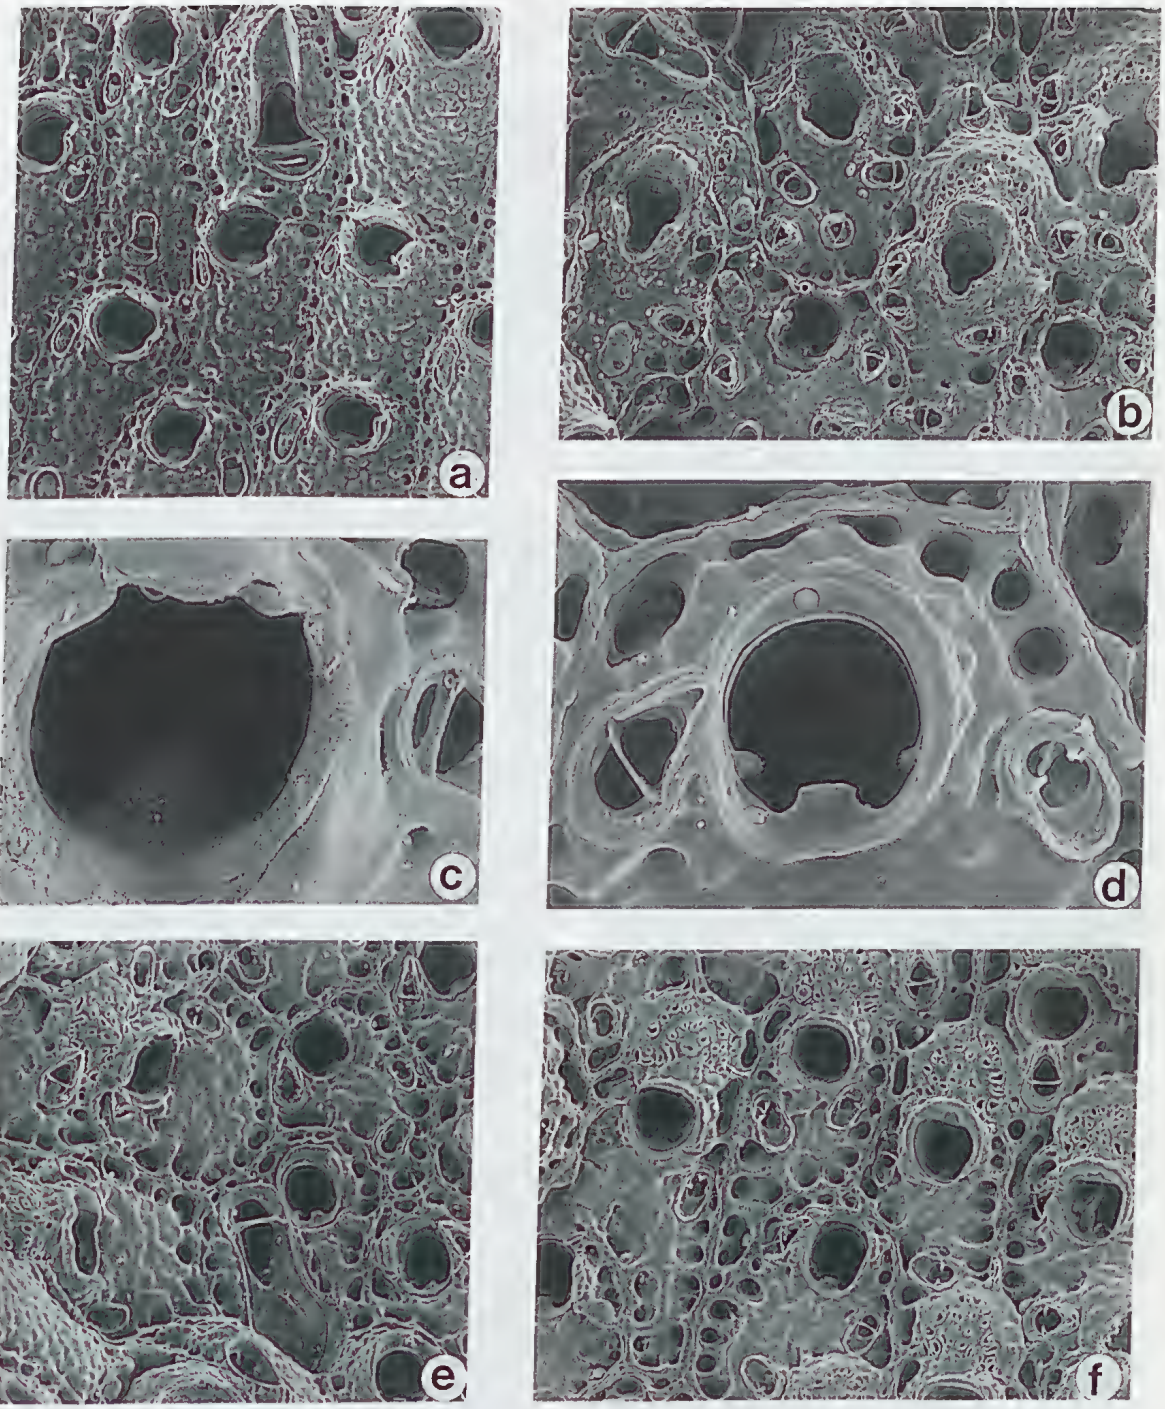

FIG. 21. a-c, *Parasmittina hastingsae*; a, autozooids and a giant avicularium, ×60; b, part of the Hawaiian paratype material, ×55; c, primary orifice, ×250. d-f, *Parasmittina galerita*; d, primary orifice, ×220; e, autozooids and a giant avicularium, ×60; f, ovicelled autozooids, ×55.

edge serrated, distally directed. Ovicell more or less spherical, with 20-30 thickly rimmed, relatively large, frontal pores; the peristome extending onto its frontal surface, forming a complete tube, distal portion of which becoming immersed below an encroaching ooecial cover.

REMARKS

This species was especially abundant in the Heron Island collections. It is distinguished from other species of the genus by the combination of small, oval avicularia (proximally directed when lateral to orifice), and large avicularia with tapered, serrated rostra, which are proximally directed when lateral to the autozooid orifice, but distally directed when interzooidal. *P. hastingsae* was described from Hawaii by Soule & Soule (1973) and subsequently reported from Komodo, Indonesia, by Winston & Heimberg (1986).

Parasmittina galerita sp. nov.
(Fig. 21d-f)

Smittina parsevalii: Harmer, 1957: 941 [part], pl. 65, fig. 5 [only].

TYPE MATERIAL

HOLOTYPE: GH5231, Heron Island, Stn 16, 13 Apr 1972.

ETYMOLOGY

Latin *galerum*, a helmet.

DESCRIPTION

Colony a multilaminar sheet. Autozooids small, rectangular to irregularly polygonal, convex, separated by thickened sutures. Primary orifice about as wide as long; lyrula short, occupying about half total width of orifice; its edge slightly curved; condyles small, rounded, downcurved, with finely denticulate edges; a single, inconspicuous, mid-distal oral spine present in early ontogeny. Peristome widely open proximally, at first consisting simply of paired, subtriangular lateral lappets, extending to enclose the distal border of the orifice in later ontogeny. Frontal wall coarsely nodular, bordered by large, and conspicuous marginal pores. Avicularia frequent, polymorphic: each autozooid typically with two, lateral suboral avicularia, the first short, 0.1mm long, oval or shoe-shaped, proximally directed, the second longer, 0.15mm, with acute triangular rostrum directed disto-medially onto the peristome rim; giant avicularia sporadic, as long as autozooids, the rostrum narrow, spatulate distally, with smooth rim. Ovicell relatively small, wider than long, with about 20 small pores frontally; developing a nodular, peripheral ooecial cover, and a distinct frontal lip where the peristome traverses it.

Measurements (means and standard deviations of 20 values, mm): autozooid length 0.51±0.06; width 0.33±0.04; orifice length 0.10±0.007; width 0.10±0.005.

REMARKS

The specimens assigned to *Cellepora parsevalii* Audouin by Harmer (1957) encompass at least two species. The Red Sea specimen listed by him (Ghardaqa, 4D) is quite distinct from that from Makassar Strait (38I, Siboga Stn 77), which is the same species as that described here from Heron Island. *P. parsevaliformis* Soule & Soule also has just a single mid-distal oral spine, and a similar array of avicularia, with a short oval type proximally directed, and an acute triangular type directed disto-medially onto the peristome. However, *P. parsevaliformis* differs from *P. galerita* in its longer orifice, narrower sinus, with distinctly cusped corners, and in its ovicell, which is smooth frontally, with a peripheral band of relatively large pores.

Parasmittina latiavicularia (Kirkpatrick)
(Fig. 22a-c)

Smittia latiavicularia Kirkpatrick, 1888: 80, pl. 10, fig. 3.

Parasmittina latiavicularia: Hayward, 1988: 301, fig. 5a.

Parasmittina leviavicularia Soule & Soule, 1973: 409, figs 7E-G.

DESCRIPTION

Colony a small, irregular, multilaminar patch. Autozooids oval to hexagonal, convex, separated by distinct sutures; 0.45-0.7×0.35-0.45mm. Primary orifice longer than wide, distinctly oval, the distal border with a few indistinct denticulations medially; lyrula occupying about half width of proximal edge, slender, with curved edges and cusped corners; condyles oval, prominent, downcurved, with finely denticulate edges. One or two slender, distinct oral spines present in early ontogeny. Peristome consisting almost entirely of paired lateral lappets; widely open proximally. Frontal wall nodular, bordered by a single or double series of large pores. Avicularia numerous: characteristically, single or paired lateral oral, with acute triangular rostrum disto-medially directed, ascending the peristomial lappet; either or both replaced by a short, oval or shoe-shaped avicularium, with proximally directed rostrum; in some autozooids the triangular avicularium may be medio-proximally situated, with the rostrum distally directed, along the edge of the peristome; in older parts of the

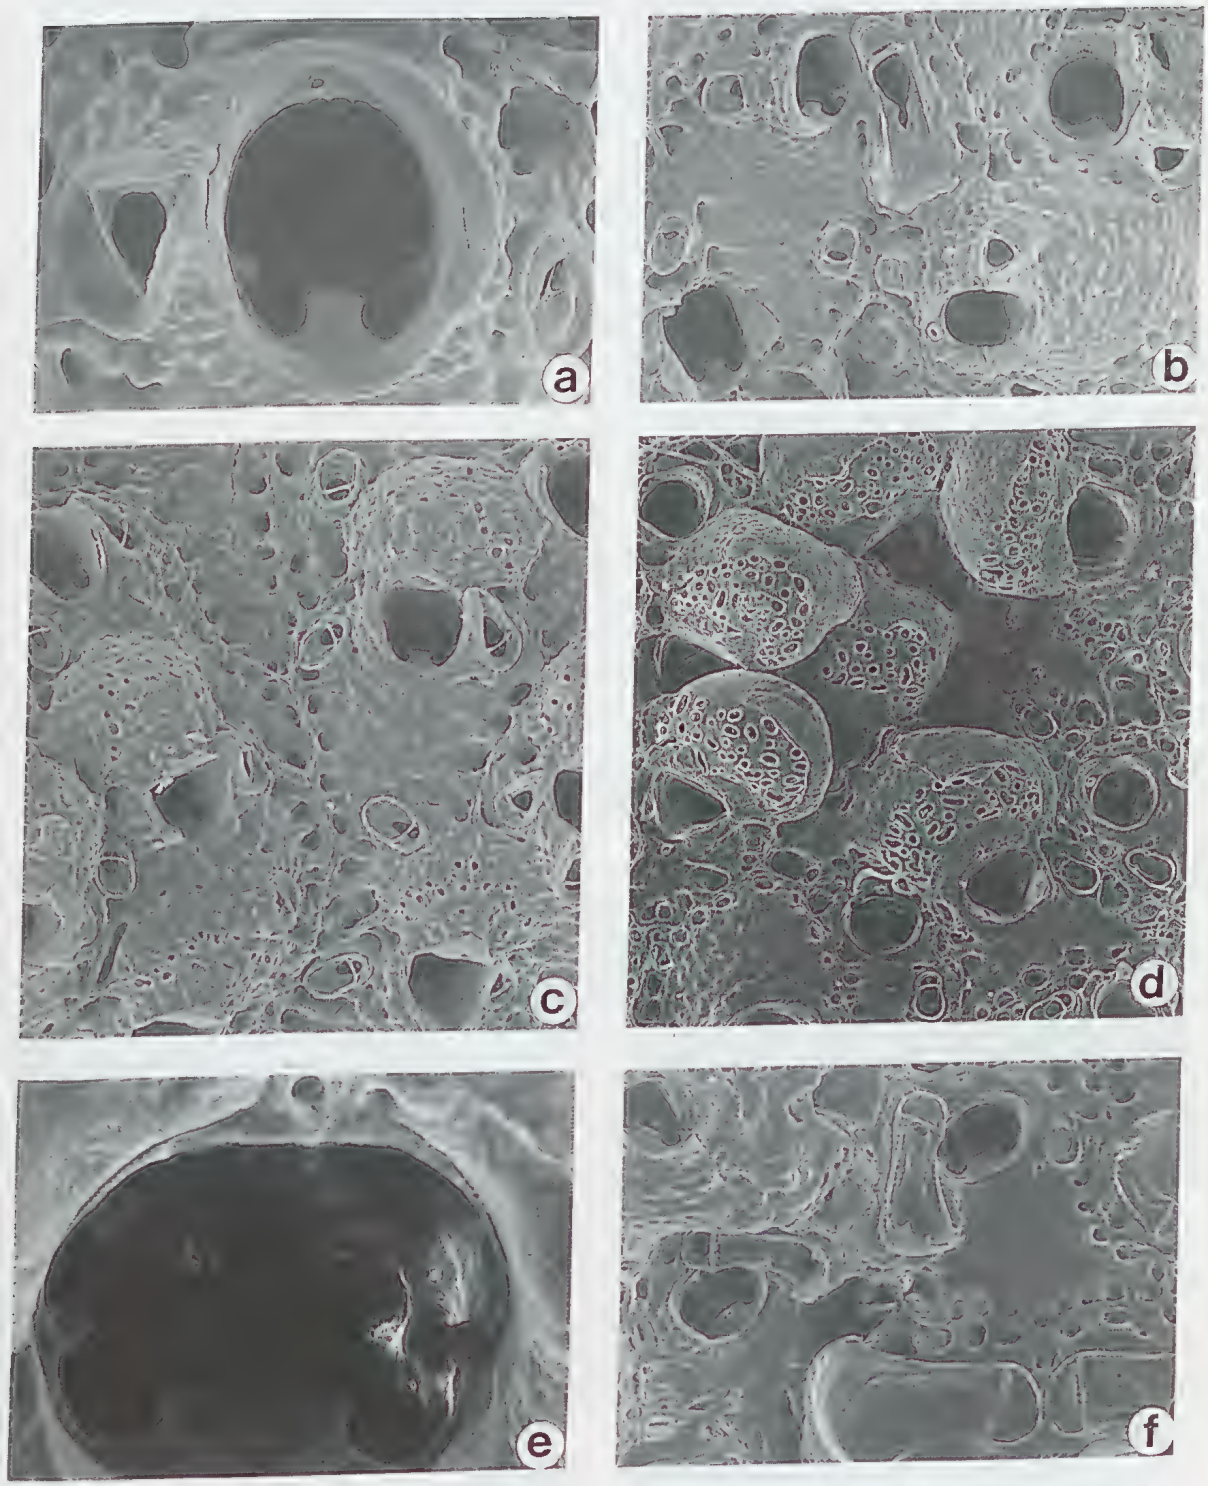

FIG. 22. a-c, *Parasmittina latiavicularia*; a, primary orifice, ×240; b, autozooids and a giant avicularium, ×90; c, ovicelled autozooids, ×80. d-f, *Parasmittina onychorrhyncha*; d, ovicelled autozooids, ×60; e, primary orifice, ×400; f, autozooids and giant avicularia, ×90.

colony the small oval avicularia may proliferate along the margins of the autozooids. Giant avicularia rare, occasionally replacing the lateral suboral avicularium, rostrum shorter than autozooid, broadened or rather angular distally, with an irregularly cusped rim. Ovicell spherical, prominent, with about 20 small frontal pores; becoming coarsely nodular, developing a distinct frontal lip above the secondary orifice, and often with a well developed umbo.

DISTRIBUTION

This rather inconspicuous species has been previously reported only from Mauritius and Hawaii. It was present in two of the Heron Island samples.

Parasmittina onychorrhyncha sp. nov.
(Fig. 22d-f)

TYPE MATERIAL

HOLOTYPE: GH5232, Heron Island, Stn 25, 18 Apr 1972.

ETYMOLOGY

Greek *Onychos*, a claw, and *rhynchos*, a snout.

DESCRIPTION

Colony an irregular, multilaminar sheet. Autozooids rectangular, hexagonal or oval at growing edges, but often irregularly polygonal in frontally budded laminae; convex, separated by distinct sutures. Primary orifice wider than long; lyrula short and broad, with straight edge, occupying about half proximal border; condyles thin, pointed, downcurved; typically with a single, slender, mid-distal oral spine. Peristome widely open proximally, consisting largely of paired, subtriangular lateral lappets. Frontal wall distinctly nodular, bordered by conspicuous marginal pores. Avicularia sporadic, frequent on some parts of colony, rare elsewhere, polymorphic: most often short, shoe-shaped, about 0.1mm long, proximo-lateral to orifice and proximally directed; less often, about 0.2mm long, distal or disto-lateral to orifice, narrowly spatulate or bluntly triangular, directed proximo-laterally; occasionally gigantic, occupying half frontal area of autozooid, the rostrum broadly spatulate, deeply cupped, with a coarsely toothed distal rim. Ovicell globose, prominent, closely perforated frontally by numerous small, irregular pores; developing a granular ooecial cover, often slightly raised and frilled where it borders the perforate frontal region of the ovicell.

Measurements (means and standard deviations of 20 values, mm): autozooid length 0.59±0.05; width 0.33±0.05; orifice length 0.10±0.007; width 0.12±0.006.

REMARKS

P. delicatula (Busk, 1884), described from Hawaii, and *P. fistulata* (Harmer, 1957), from Indonesia, are very similar species which can be separated principally by the morphology of the primary orifice and the occurrence of particular types of avicularia. These features also serve to distinguish both species from *P. onychorrhyncha*.

Parasmittina serrula Soule & Soule
(Fig. 23e,f, 24a)

Parasmittina serrula Soule & Soule, 1973: 386, figs 3D-F.

Parasmittina serrula: Gordon, 1984: 96, pl. 35, figs B, C.

DESCRIPTION

Colony forming small, glistening white patches, rarely more than 5mm in diameter. Autozooids oval to hexagonal, small, convex, separated by deep grooves; 0.3-0.5×c.0.25mm. Primary orifice wider than long, with denticulate distal border; lyrula occupying about half width of proximal border, with slightly curved edge and cusped corners; condyles downcurved, rounded, with very finely denticulate edges. Two to four long, stout distal oral spines; obliterated in brooding autozooids but persisting into late ontogeny in others. Peristome most prominent laterally and proximally, with a well-marked medio-proximal notch, often flanked on each side by a stout, erect process. Frontal wall finely nodular, bordered by large and distinct marginal pores. Lateral suboral avicularia typically paired, equally-sized; the rostrum slender, parallel-sided, rounded at tip, with very fine serrations along its distal edges; characteristically inclined so that the rostrum lies on its side. Giant avicularia occasional, as long as autozooid, with the rostrum slightly flared distally and very coarsely serrated. Ovicell spherical, smooth, with 15-20 regularly dispersed pores; peristome encroaches onto frontal surface of ovicell in later ontogeny, but an ooecial cover does not seem to develop.

DISTRIBUTION

Soule & Soule (1973) found this to be the commonest species of *Parasmittina* on Hawaiian reefs. It was subsequently described and figured

from the Kermadec Islands by Gordon (1984) and from Belize by Winston (1984). It occurred in three of the Heron Island samples but has not previously been reported from Australia.

Parasmittina turbula sp. nov.
(Fig. 23a-d)

TYPE MATERIAL
HOLOTYPE: GH5233, Heron Island, Stn 25, 18 Apr 1972.

ETYMOLOGY
Latin *turba*, disorder.

DESCRIPTION
Colony encrusting, multilaminar, developing an irregular, mamillate form, the later generations of autozooids lacking regular orientation. Autozooids oval to irregular, convex, separated by distinct sutures; frontal wall irregularly nodular, bordered by large marginal pores, with thickened struts between; 0.5×0.3mm. Primary orifice about as wide as long (0.12mm); lyrula occupying about one-third of proximal width, short, rectangular, with a gently curved edge; condyles oval, downcurved, with finely crenulate edges. A single disto-medial spine present; peristome complete, initially with a delicately flared lip, a deep distal embayment accommodating the spine, and a shallow mid-proximal notch flanked by thickened internal ridges. With ontogenetic thickening the peristome becomes deeper, the distal spine is obliterated and the proximal notch accentuated. Avicularia polymorphic, numerous; one or two lateral to the peristome in newly budded autozooids, usually narrow, parallel-sided, from 0.2-0.3mm long, proximally directed, occasionally shorter, triangular and disto-medially directed; additional avicularia develop in later ontogeny, typically clustered around the peristome, and directed towards the orifice; gigantic avicularia present in a few autozooids, laterally situated and proximally directed, with flared, slightly spatulate mandible. Ovicell spherical, with numerous fine perforations, rapidly enveloped by secondary calcification; with a number of small avicularia developing on its frontal surface, directed towards the autozooidal orifice.

REMARKS
The slender, parallel-sided avicularia recall those of *P. areolata* Soule & Soule. *P. turbula* is distinguished from that species by its single, distal oral spine, the morphology of the lyrula and condyles, and by the clusters of medially directed avicularia developed around the peristome in later ontogeny.

Pleurocodonellina Soule & Soule, 1973

Colony encrusting. Autozooid frontal wall with marginal pores only. Primary orifice with strongly developed condyles; proximal border concave, developed as a broad or shallow sinus. Peristome developing in early ontogeny, completely surrounding orifice, its inner edge often thickened medio-proximally and forming a secondary sinus. Distal oral spines present. Avicularia adventitious, dimorphic, typically situated proximo-lateral to orifice. Ovicell with small, scattered pores. Vertical walls with small uniporous septula.

Type species: *Pleurocodonellina lahainae* Soule & Soule, 1973.

Pleurocodonellina signata (Waters)
(Fig. 24b)

Smittia signata Waters, 1889: 17, pl. 3, figs 4-6.
Smittina signata: Harmer, 1957: 928, pl. 63, figs 27-29.
Parasmittina signata: Winston & Heimberg, 1986: 21, figs 51-54.

DESCRIPTION
Colony forming extensive, pinkish brown, unilaminar sheets. Autozooids commonly 0.5×0.3mm, with a finely nodular frontal wall, bordered by a single series of large and conspicuous areolae. Primary orifice wider than long, with broad, flat condyles delimiting a narrow, rounded, proximal sinus; one to three distal oral spines present in early ontogeny. Peristome thin, erect, completely surrounding orifice and obliterating spine bases. Most autozooids with a single avicularium proximo-lateral to orifice; rostrum slender, elongate triangular, proximally directed. Ovicell recumbent on succeeding autozooid, wider than long; frontal surface slightly flattened, with small distal pores.

REMARKS
Cheetham & Sandberg (1964) tentatively assigned this species to *Rimulostoma* Vigneaux, while noting that the published accounts of both the genus (Vigneaux, 1949) and its Miocene type species (Duvergier, 1921) were inadequate for detailed morphological comparisons. Soule & Soule (1973) suggested that *Smittia signata* Waters might be placed in their genus

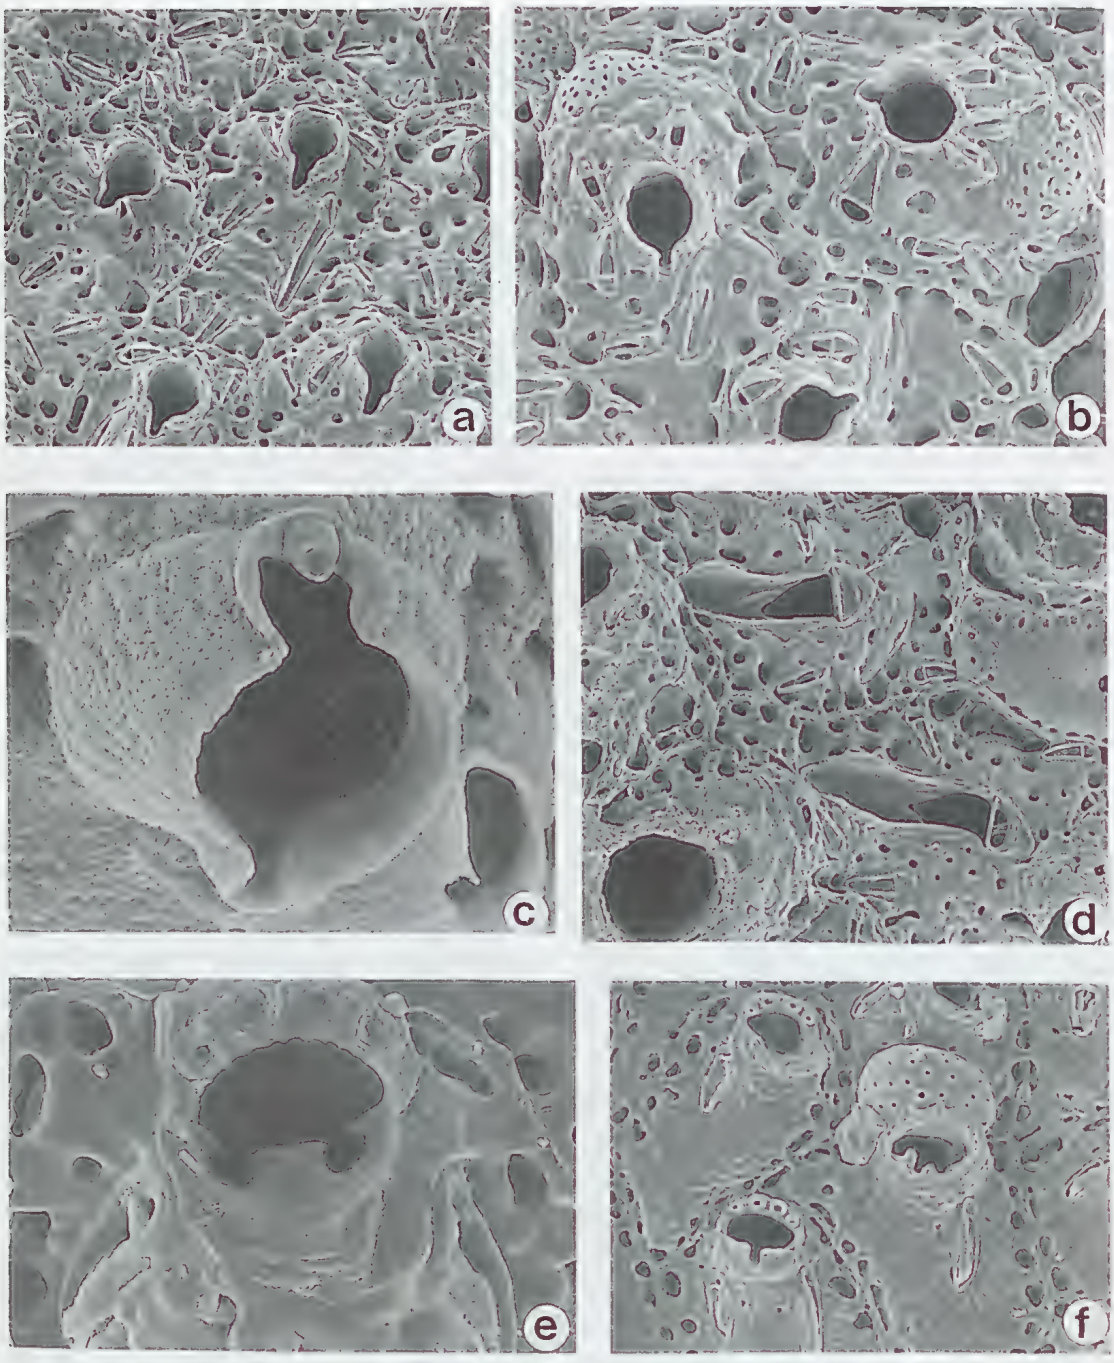

FIG. 23. a-d, *Parasmittina turbula*; a, ×70; b, ×95; c, primary orifice, ×340; d, giant avicularia, ×60. e,f, *Parasmittina serrula*; e, primary orifice, ×350; f, ×80.

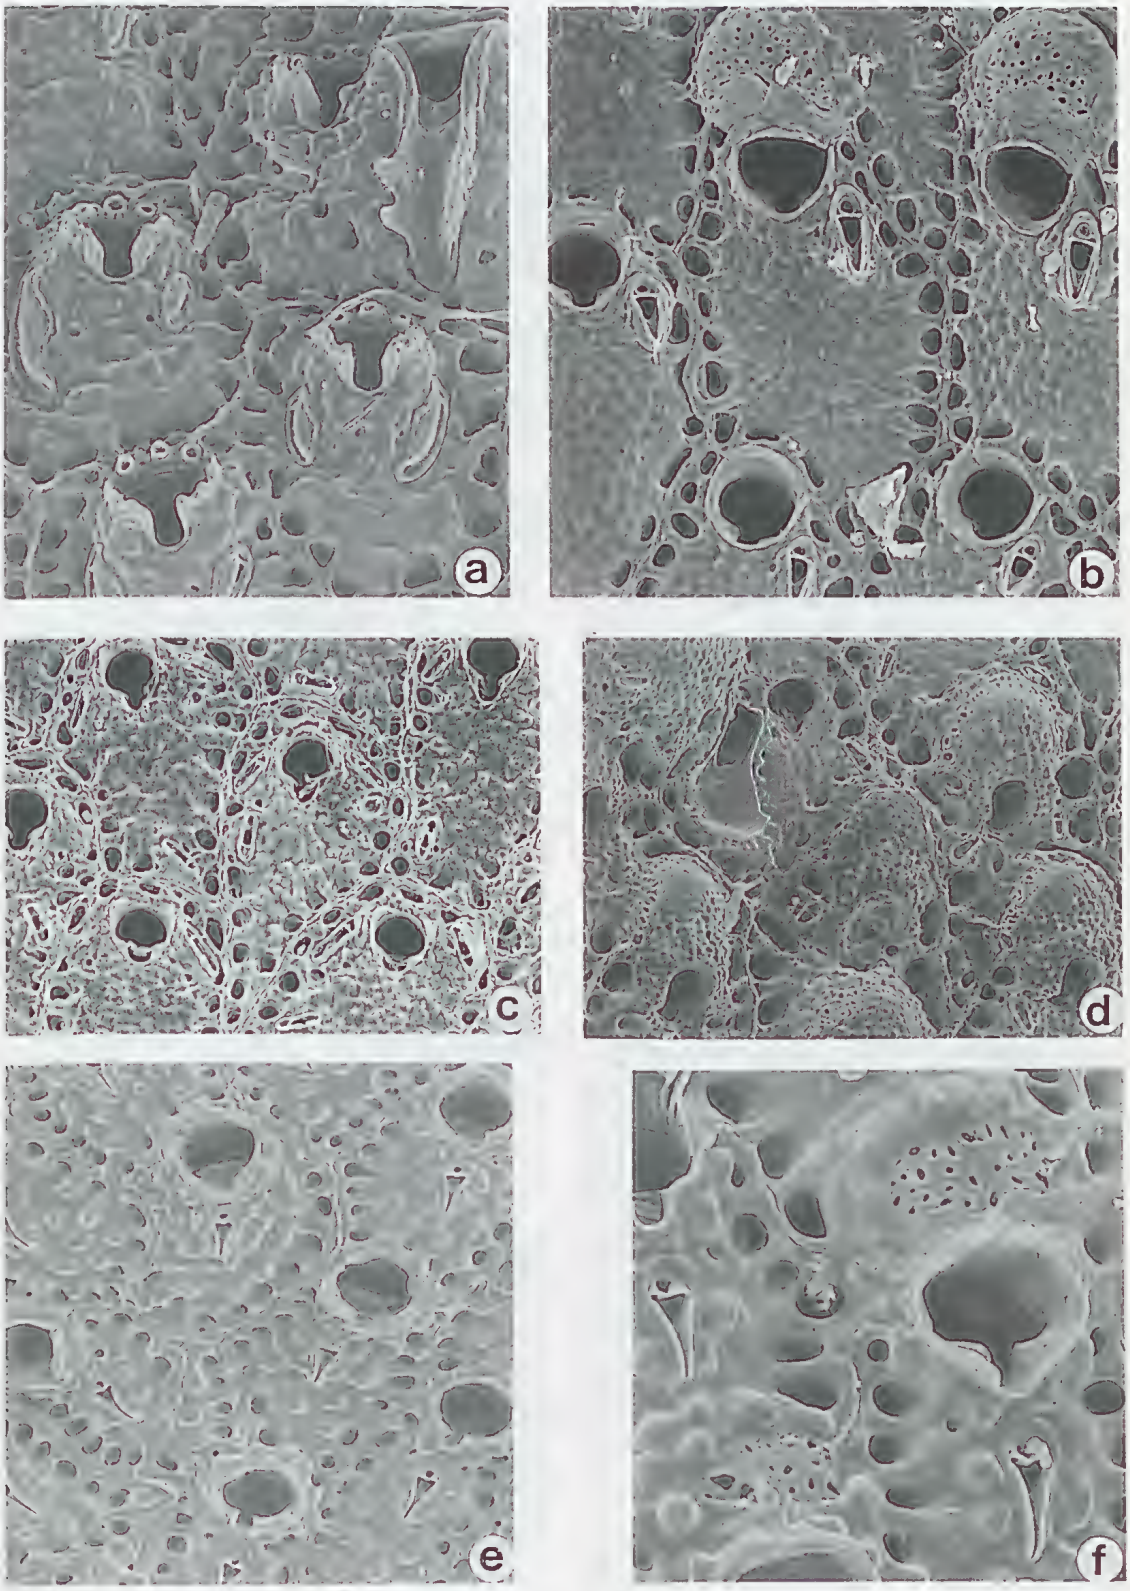
FIG. 24. a, *Parasmittina serrula*, ×130. b, *Pleurocodonellina signata*, ×90. c,d, *Pleurocodonellina clavicula*; c, ×60; d, ×60. e,f, *Smittoidea pacifica*; e, ×80; f, ×155.



a
b
c
d
e
f

Pleurocodonellina, and that suggestion is followed here. In all morphological characters *S. signata* conforms to the diagnosis of *Pleurocodonellina*. In particular, the flaring peristomial rim which obliterates the distal spines present in early ontogeny is closely similar to that of the type species, and only a more pronounced development of the paired lateral condyles is necessary to produce the narrow, rounded sinus seen in *P. signata*.

DISTRIBUTION

This species is practically circumtropical in distribution. It ranges throughout the Indo-West-Pacific realm, and has been reported from Mauritius, East Africa, West Africa, and the Caribbean. It is quite common in shallow reef habitats, and at Heron Island occurred in five of the samples studied.

Pleurocodonellina clavicula sp. nov.
(Fig. 24c,d)

TYPE MATERIAL

HOLOTYPE: GH5234, Heron Island, Stn 12, 12 Apr 1972.

ETYMOLOGY

Latin *clavicula*, diminutive of *clavis*, a key.

DESCRIPTION

Colony a broad, encrusting, multilaminar sheet. Autozooids rectangular, hexagonal or irregularly polygonal, rather flat, separated by distinct, thickened sutures. Frontal wall thickly calcified, coarsely nodular, bordered by a single series of large marginal pores. Primary orifice longer than wide, the proximal third comprising a deep, broad, U-shaped sinus, delimited by flat, rounded triangular condyles; encircled by a thin, low, peristomial rim. No oral spines. Avicularia present lateral to orifice in newly budded autozooids, later developed elsewhere along margins of autozooids; slender, parallel-sided, rounded distally and proximally; not infrequently a giant avicularium present, extending down whole length of autozooid, the rostrum 0.4mm long, broadly spoon-shaped, deeply cupped distally, with a coarsely denticulate rim. Ovicell prominent, globular, wider than long, with a crescentic series of irregular pores, developing a coarsely nodular ooecial cover.

Measurements (means and standard deviations of 20 values, mm): autozooid length 0.55±0.05; width 0.37±0.04; orifice length 0.11±0.008; width 0.10±0.01.

REMARKS

The sinuate orifice, encircling peristomial rim, lateral suboral avicularia and perforate ovicell all indicate that this undescribed species is appropriately placed in *Pleurocodonellina*. A single large colony was present in sample 12, from the reef flat west of the cay.

Family PETRALIELLIDAE Harmer, 1957

Colony encrusting; or forming erect, laminate plates. Autozooids with perforated frontal wall. Primary orifice with or without oral spines and condyles. Avicularia adventitious, often associated with orifice. Ovicell with small frontal pores. Vertical and basal walls with multiporous septula.

Sinupetraliella Stach, 1936

Colony encrusting, or erect and bilaminar. Autozooids with regularly perforate, cryptocystidean frontal wall. Primary orifice with asymmetrically developed condyles, defining a small sinus; bordered proximally by a low peristome incorporating a small avicularium. No oral spines. Frontal adventitious avicularia present. Ovicell with entooecium finely perforated, ectooecium largely membranous, developing patches or basal struts of calcification in later ontogeny. Vertical walls with multiporous septula.

Type species: *Petralia litoralis* Livingstone in Hastings, 1932.

Sinupetraliella litoralis (Livingstone in Hastings) (Fig. 25a)

Petralia litoralis Livingstone MS, Hastings, 1932: 438, pl. 1, fig. A, text-fig. 15.

Sinupetraliella litoralis: Harmer, 1957: 706, pl. 45, figs 11-13.

DESCRIPTION

Colony developing broad, loosely encrusting, unilaminar sheets; deep brown in colour. Autozooids rectangular to hexagonal, convex, separated by thin sutures; 0.8-0.9×0.4-0.6mm. Frontal wall thickly calcified, densely perforated by large, round pores. Primary orifice about as wide as long, with a pair of pointed condyles, asymmetrically developed, delimiting an oval,

proximal sinus. Peristome a low rim around proximal and lateral border of orifice, incorporating a small avicularium, 0.1mm long, transversely orientated, its plane perpendicular to orifice, situated immediately above the sinus; in later ontogeny the avicularium partly hidden by a stout mucro developed above it. Frontal adventitious avicularia sparsely developed, usually along margins of autozooids; rostrum slender, elongate oval, variably orientated. Ovicell slightly wider than long, partly overhanging autozooid orifice; entooecium finely perforate, appearing dimpled, ectooecial calcification limited to a narrow, peripheral band and a few radiating struts.

DISTRIBUTION

S. litoralis was described from the Low Isles (Hastings, 1932) and reported by Harmer (1957) from Celebes. Large colonies were present in three of the Heron Island samples.

Family CREPIDACANTHIDAE Levinsen, 1909

Colony encrusting. Frontal wall of autozooids with marginal pores and peripheral spines. Orifice with convex or distinctly rectangular proximal edge, appearing trilobed. Avicularia adventitious, with setiform mandibles. Ovicell hyperstomial, with frontal pores. Vertical walls with small basal pore chambers. Ancestrula tatiform.

Crepidacantha Levinsen, 1909

Colony encrusting, unilaminar. Autozooid frontal wall with marginal pores only; primary orifice contracted laterally, with pronounced lateral condyles, the proximal edge frequently concave, and thus appearing trifoliate; no oral spines. Avicularia adventitious, usually paired, lateral to orifice; mandible setiform. Ovicell hyperstomial, globular, closed by autozooid operculum; with an uncalcified area of ectooecium frontally, bordered by small pores in the entooecium. Small basal pore chambers present, with intervening spinous processes visible in autozooids at the growing margin. Ancestrula tatiform.

Type species: *Flustra poissonii* Audouin, 1826.

Crepidacantha crinispina Levinsen (Fig. 25c)

Crepidacantha poissoni var. *crinispina* Levinsen, 1909: 266, text- figs.1-3, 5, 6.

Crepidacantha crinispina: Brown, 1954: 248, fig. 1C; Gordon, 1984: 100, pl. 37, fig. B.

DESCRIPTION

Colony forming broad, irregular sheets. Autozooids oval to hexagonal, convex, separated by deep grooves; 0.35-0.50×0.25-0.45mm. Frontal wall finely granular, with indistinct marginal pores. Primary orifice longer than wide, with conspicuous lateral processes, appearing distinctly trifoliate. Avicularia paired, situated level with proximal corners of orifice; rostra oval, about 0.05mm long, directed proximally or proximo-medially. Ovicell about as wide as long, entooecium entirely exposed frontally, with only a peripheral band of ectooecium.

DISTRIBUTION

C. crinispina ranges in the western Pacific from New Zealand to the Philippines, and westwards to Indonesia and Thailand. Gordon (1984) reported it as a common intertidal species around North Island, New Zealand. It has also been reported from the southwest Atlantic (Lopez Gappa, 1977) and from Gough Island and Ascension in the central Atlantic (Hayward, 1980).

Crepidacantha carsioseta Winston & Heimberg (Fig. 25d)

Crepidacantha carsioseta Winston & Heimberg, 1986: 27, figs 64-66.

DESCRIPTION

Autozooids oval to hexagonal, 0.35-0.45×0.3mm. Frontal wall smooth, bordered by inconspicuous marginal pores. Primary orifice longer than wide, trifoliate, with a broadly rounded proximal lip. Avicularia paired, proximal to orifice, directed medially; mandible setiform. Ovicell spherical, smooth, with a curved band of pores crossing the frontal surface distally.

DISTRIBUTION

This species has recently been described (Winston & Heimberg, 1986) from two localities in Indonesia and is here reported from Australia for the first time. The material from Heron Island consists of small colonies from sample 25.

Family INVERSIULIDAE Vigneaux, 1949

Colony encrusting. Autozooids with tuberculate frontal wall evenly perforated by small pores;

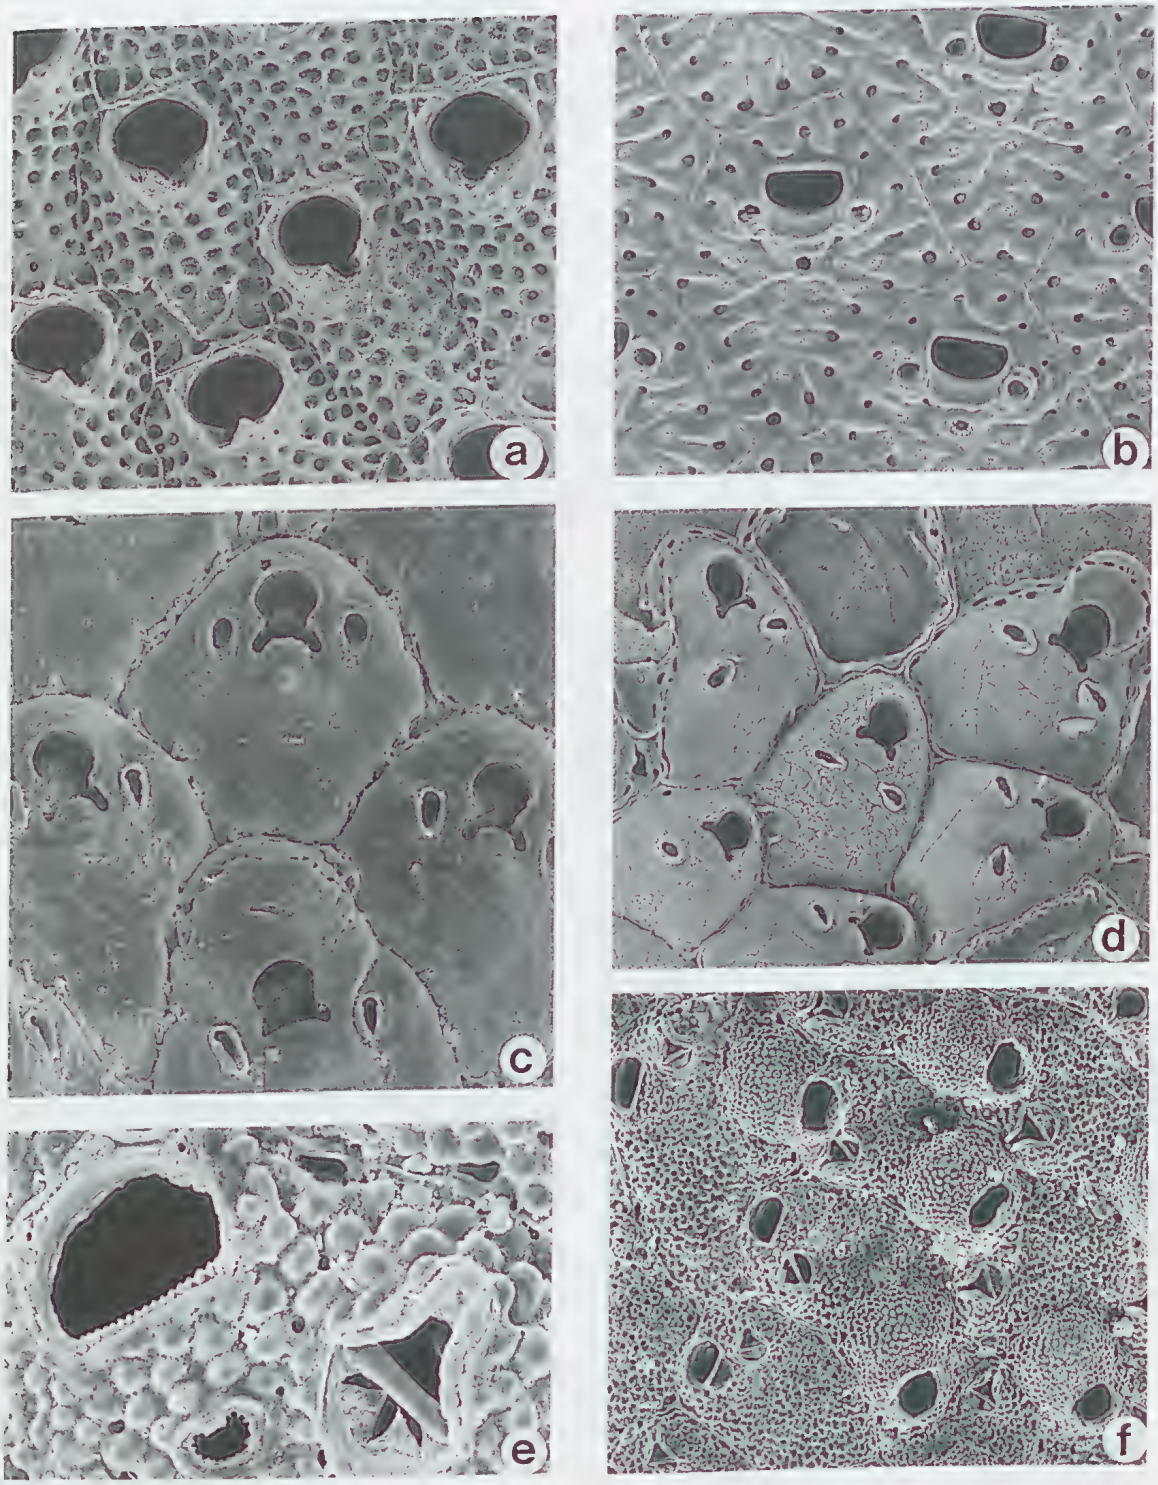


FIG. 25. a, *Sinupetraliella litoralis*, ×40. b, *Inversiula inversa*, ×70. c, *Crepidacantha crinispina*, ×90. d, *Crepidacantha carsioseta*, ×75. e,f, *Microporella orientalis*; e, ×220; f, ×50.

a prominent suboral ascopore present. Orifice with straight distal rim and concave proximal rim, the operculum hinged along its distal edge; no condyles; no oral spines. Avicularia adventitious. No ovicells.

Inversiula Jullien,1888

Colony encrusting, unilaminar. Autozooids with tuberculate frontal wall perforated by numerous simple or stellate pores; primary orifice with reversed orientation, the semicircular operculum hinged along its straight distal edge; ascus opening via a well-defined ascopore proximal to the orifice; no oral spines. Avicularia adventitious; typically paired, lateral to orifice. Embryos brooded internally. Small basal pore chambers present.

Type species: *Inversiula nutrix* Jullien, 1888.

Inversiula inversa (Waters) (Fig. 25b)

Porina? inversa Waters, 1887: 95, pl. 4, fig. 23.
Inversiula inversa: Harmer, 1957: 956, pl. 72, figs 24, 32, 33.

DESCRIPTION

Colony forming small, irregular patches. Autozooids irregularly hexagonal, separated by distinct sutures; 0.55-0.65×c.0.5mm. Frontal wall with raised ridges and tubercles, which form a radiating series around the edges; with distinct marginal pores immersed between thickened ridges, and large, stellate pores over the central part, each on a raised tubercle. Ascopore slightly larger than frontal pores, stellate, also on a thickened tubercle, immediately proximal to orifice. Avicularia proximo-lateral to orifice, paired, shortly columnar; with oval rostrum, 0.06mm long.

DISTRIBUTION

I. inversa has been reported sporadically along the eastern seaboard of Australia, from New South Wales to Torres Strait, and from the Philippine Islands. It was present in two of the Heron Island samples.

Family MICROPORELLIDAE Hincks, 1877

Colony encrusting; or forming erect, bilaminar plates, attached by an encrusting base; or arborescent, freely branching. Autozooid frontal wall evenly perforated, or with marginal pores only; a conspicuous ascopore present proximal to orifice. Orifice typically D-shaped, lacking condyles; oral spines present or absent. Avicularia adventitious, or absent. Ovicell hyperstomial. Vertical walls with basal pore chambers or mural septula.

Microporella Hincks, 1877

Colony encrusting. Autozooids with nodular frontal wall perforated by scattered pores; ascopore situated in distal half of autozooid, conspicuous. Primary orifice D-shaped. Distal oral spines present, but sometimes small, and impermanent. Avicularia adventitious, mandible setiform. Ovicell prominent, imperforate or with few, minute pores; closed by autozooid operculum. Large basal pore chambers present.

Type species: *Eschara ciliata* Pallas, 1766.

Microporella orientalis Harmer (Fig. 25e,f)

Microporella orientalis Harmer, 1957: 962, pl. 62, figs 25-28, 38.
[not] *Microporella orientalis*: Gordon, 1984: 103, pl. 39, fig. C.

DESCRIPTION

Colony developing broad, unilaminar sheets. Autozooids oval to hexagonal, convex, separated by distinct sutures; 0.5-0.7×0.35-0.5mm. Primary orifice wider than long, 0.08× 0.12mm, the proximal edge finely denticulate. Three slender, distal oral spines present in early ontogeny, missing in most autozooids distant from growing edge. Frontal wall appearing distinctly nodular, densely perforated by small, round pores. Ascopore separated from proximal edge of orifice by a distance slightly less than one orifice length, with slightly thickened rim and coarsely denticulate, crescentic lumen. A single avicularium on each autozooid, situated lateral to ascopore, with broad, thick crossbar and semicircular proximal opesia; the rostrum abruptly tapered and narrowest distally; mandible heavily sclerotized and appearing dark brown, 0.2-0.25mm long, setiform, or variously broadened on one or both sides of the median rachis, and typically with a pair of short, hooked, lateral processes close to the base. Ovicell more or less spherical, nodular, with minute pores scattered over its surface; brooding autozooids develop a thickened peristomial rim, peaked medially, which passes distal to the ascopore and fuses on each side with the ovicell.

REMARKS

Harmer (1957) possibly included more than one species in his account of *M. orientalis*, and his synonymy needs to be carefully re-examined. The Heron Island specimens have been compared with the holotype (Siboga Stn 50, W. Flores), and found to be almost identical to it; the size and shape of the primary orifice are characteristic for the species, as are the three delicate, distal oral spines. The avicularian mandible varies in form throughout a single colony and there is no utility in denoting those specimens with lanceolate mandibles as '*orientalis* var.' (Harmer, 1957:963). It is probable that *M. orientalis* occurs generally throughout the western Pacific, and perhaps extends into the Indian Ocean, but the wider geographical distribution accorded it by Harmer (1957) should not be accepted until all of the specimens and records listed by him have been scrutinized again. The *M. orientalis* described and figured by Gordon (1984) has four to six oral spines, a smooth proximal border to the orifice, an incomplete peristome in brooding autozooids, and a striking, saucer-like rim to the ascopore; it clearly represents a distinctly different species.

Microporella fimbriata sp. nov.
(Fig. 26a-c)

TYPE MATERIAL

HOLOTYPE: GH5235, Heron Island, Stn 25, 18 Apr 1972.

PARATYPE: GH5236, as for holotype.

ETYMOLOGY

Latin *fimbria*, a fringe.

DESCRIPTION

Colony forming an extensive unilaminar sheet. Autozooids oval to hexagonal, broad and rather flat, separated by distinct sutures; 0.5-0.65× 0.5-0.6mm. Primary orifice wider than long, proximal edge with a slightly curved, coarsely denticulate inner rim, the outer tooth on each side especially prominent. Four slender distal oral spines present in the youngest autozooids, lost in later ontogeny. Frontal wall coarsely nodular, densely perforated by regularly distributed, round pores; ascopore close to orifice, separated from its proximal edge by a distance equivalent only to one-third of orifice length; rim oval, thickened, smooth, lumen shallowly crescentic, with fine denticulations. Each autozooid with a single avicularium lateral to ascopore, without a pronounced rostrum, but with its frontal surface symmetrical about a pair of stout, median condyles; mandible thin, setiform, up to 0.7mm long, laterally directed when at rest. Ovicell comparatively small, slightly wider than long, coarsely nodular, with scattered, minute pores; aperture rather angular, with a smooth, thickened border.

REMARKS

This is possibly the species described from Sumbawa, Indonesia by Harmer (1957), who referred it to the North Pacific species *M. vibraculifera* Hincks.

Fenestrulina Jullien, 1888

Colony encrusting, unilaminar. Frontal wall of autozooid with pores in marginal series, or scattered over its entire surface; pores typically stellate or complexly reticulate; ascus opening via a conspicuous ascopore proximal to primary orifice, often denticulate or reticulate. Primary orifice D-shaped, with straight proximal edge; spines present or absent. Avicularia absent. Ovicell with membranous ectooecium, calcified entooecium, and marginal pores. Large basal pore chambers present.

Type species: *Cellepora malusii* Audouin, 1826.

Fenestrulina caseola Hayward
(Fig. 26d)

Fenestrulina caseola Hayward, 1988: 325, pl. 10, fig. d.

DESCRIPTION

Colony forming flat, unilaminar sheets. Autozooids oval to irregularly hexagonal, broad, gently convex; commonly 0.6×0.5mm. Frontal wall densely perforated by large, round, stellate pores; ascopore separated from proximal edge of orifice by a distance equivalent to orifice length, with crescentic, denticulate foramen. No oral spines. Ovicell broader than long, depressed and not very prominent; frontal surface with a thickened transverse ridge; marginal pores small, indistinct.

DISTRIBUTION

A single large colony was present in sample 25. This species was recently described from the Mascarene Islands, Indian Ocean (Hayward, 1988), and the Heron Island record thus marks only its second reported occurrence.

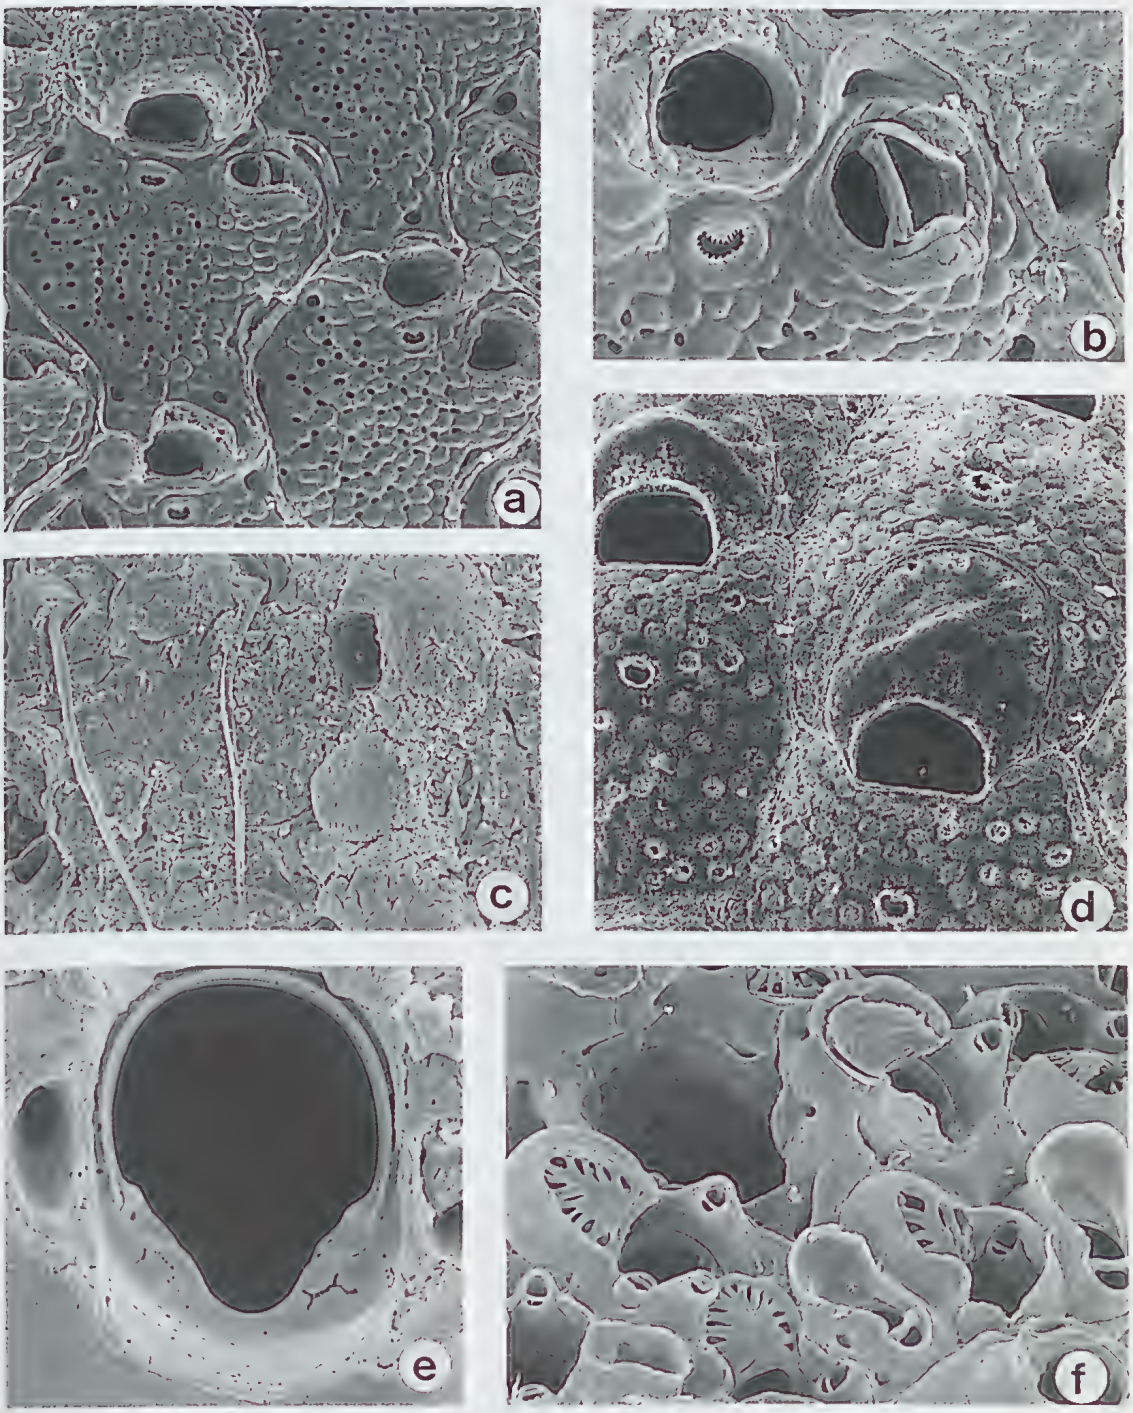

FIG. 26. a-c, *Microporella fimbriata*; a, ×80; b, ×170; c, uncleaned autozooids, to show avicularian mandibles, ×80. d, *Fenestrulina caseola*, ×90. e,f, *Celleporina reginae*; e, primary orifice, ×330; f, ×110.

Family MARGARETTIDAE Harmer, 1957

Colony erect, branching, jointed, attached by cuticular rhizoids. Autozooids with ridged frontal wall, perforated by minute pores, with a median ascopore. Primary orifice rounded, hidden by a projecting, tubular peristome. No spines. No avicularia. Ovicell submerged in peristome, which is conspicuously inflated in brooding autozooids. Ancestrula erect, resembling later autozooids, with a chitinous basal attachment.

Margaretta Gray, 1843

Colony erect, branching, jointed, attached by cuticular rhizoids; consisting of cylindrical, straight or curving, internodes linked by brown cuticular nodes, each arising from a short, calcified basis rami developed by the parent internode. Each node and basis rami consists of single, double or triple tubes. Autozooids ordered in whorls of two to eight around the axis of the internode; frontal wall granular, densely perforated and appearing reticulate; a disto-medial ascopore present. Primary orifice orbicular, visible only in earliest ontogeny, obscured by a long, cylindrical peristome, typically perforated and longitudinally ridged. No spines. No avicularia. Ovicell peristomial, hidden; brooding autozooids with dimorphic peristomes, typically longer, curved, or with a modified secondary orifice.

Type species: *Cellaria cereoides* Ellis & Solander, 1786.

Margaretta tenuis Harmer
(Fig. 27a)

Margaretta tenuis Harmer, 1957: 840, pl. 55, figs 13-18.

Margaretta tenuis: Hayward, 1988: 330, pl. 11, fig. a.

DESCRIPTION

Colony generally sparsely branched, internodes 2-3mm long, 0.5mm wide. Autozooids in triple whorls, 0.8-1.0×c.0.4mm, fusiform, with finely and regularly reticulate frontal shields, the boundaries between adjacent autozooids not distinct. Basis rami tripartite; nodes consisting of short, tripartite tubes. Peristomes of fertile autozooids projecting at right angles to internode axis, but otherwise not markedly different from others.

DISTRIBUTION

M. tenuis has been reported from Queensland, Torres Strait, the Philippine Islands, and from many Indonesian localities; it ranges westwards to Mauritius and the Red Sea.

Margaretta triplex Harmer
(Fig. 27b)

Margaretta triplex Harmer, 1957: 841, pl. 55, figs 8-11.

Margaretta triplex: Ryland, 1984: 72, fig. 39.24; Winston & Heimberg, 1986: 30, figs 70-72.

DESCRIPTION

Colony stout, richly branched, up to 100mm high; internodes straight or curved up to 30mm long, 1mm wide. Autozooids in whorls of four, 1.2-1.4×c.0.6mm, elongate oval, the frontal walls finely reticulate, boundaries between autozooids generally distinct. Basis rami and node tripartite. Peristomes of fertile autozooids projecting at right angle to internode axis, short, very broad based and appearing volcano-like in profile.

DISTRIBUTION

M. triplex is known from Queensland, Torres Strait and Indonesia, and has also been reported from Zanzibar.

Superfamily CELLEPOROIDEA Johnston, 1838
Family CELLEPORIDAE Johnston, 1838

Colony encrusting, multilaminar, pisiform, nodular or mamillate; or erect, attached by an encrusting base, irregularly lobed or branched. Autozooids without regular orientation; frontal wall smooth, with marginal pores. Orifice with concave or conspicuously sinuate proximal border; condyles present; spines present or absent. Avicularia adventitious, and/or vicarious or interzooidal; frequently polymorphic. Ovicell present, variously perforated, not closed by autozooid operculum.

Turbicellepora Ryland, 1963

Colony encrusting, multilaminar, often nodular or massive, or erect and branching. Frontal wall of autozooid with marginal pores only. Primary orifice with sinus; oral spines present or absent. Avicularia polymorphic: adventitious, lateral-oral; vicarious, varying in size. Ovicell with scat-

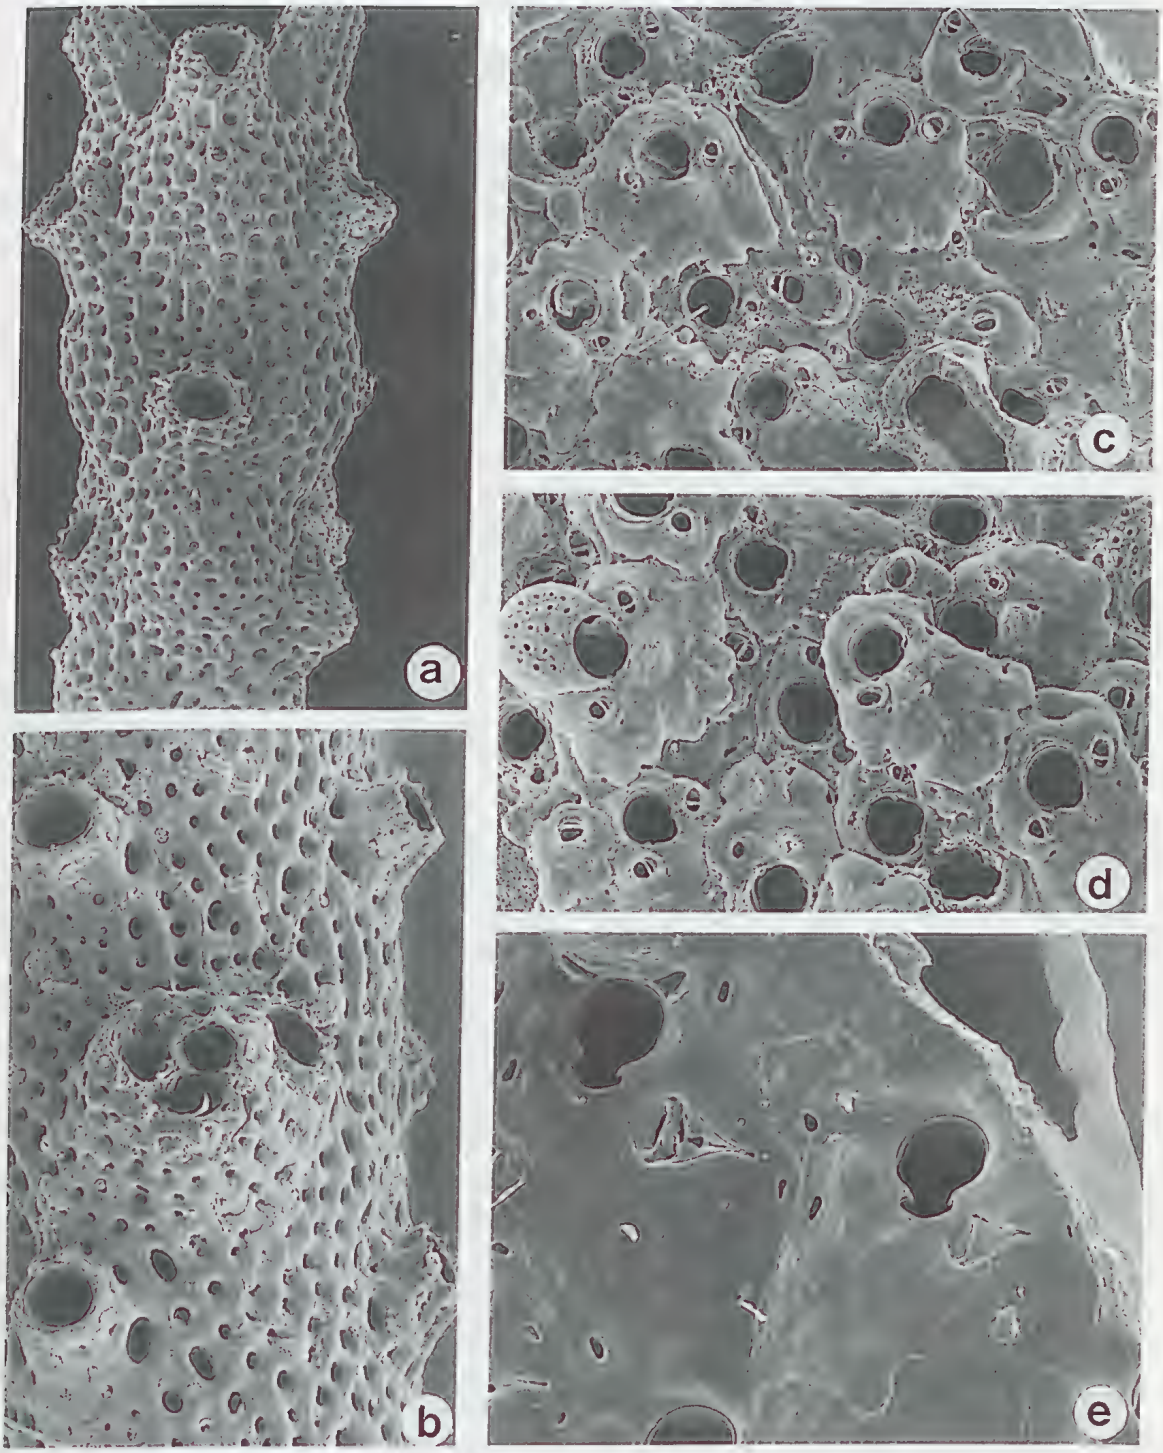

FIG. 27. a, *Margaretta tenuis*, branch tip, ×50. b, *Margaretta triplex*, part of a branch showing a triple branch base, ×50. c,d, *Turbicellepora ampla*; c, ×50; d, ×55. e, *Schedocleidochasma porcellanum*, ×90.

tered frontal pores, not closed by autozooid operculum. Basal pore chambers present.

Type species: *Cellepora coronopus* Wood, 1844.

Turbicellepora ampla (Kirkpatrick) (Fig. 27c,d)

Schizoporella ampla Kirkpatrick, 1888: 76, pl. 7, fig. 4.

Stephanosella bernardii: Harmer, 1957: 1051, pl. 74, figs 21-23.

Turbicellepora ampla: Hayward, 1988: 341, figs 6d,e.

DESCRIPTION

Colony forming multilaminar, nodular encrustations. Autozooids strongly convex, with distinct, lobed, boundaries; the frontal wall smoothly calcified, with indistinct, radiating folds; marginal pores small and inconspicuous. Primary orifice 0.12mm long, with a broad, V-shaped sinus comprising about one-third its length; with a pronounced distal and lateral peristomial rim; no oral spines. Lateral oral avicularia single or paired; rostrum oval, acute to frontal plane, disto-laterally directed. Vicarious avicularia dimorphic: with oval rostrum similar to, but larger than, the lateral oral type, or larger with broadly spatulate rostrum. Ovicell with numerous small, papillate frontal pores.

DISTRIBUTION

This species was originally described from Mauritius (Kirkpatrick, 1888). It is known from a number of localities in the Indo-Malayan region, but its presence in the Red Sea has yet to be substantiated (Hayward, 1988).

Celleporina Gray, 1848

Colony encrusting, pisiform or lenticular, multilaminar. Orifice with a sinus; flanked by paired lateral oral avicularia, with columnar chambers, incorporated into the peristome. Ovicell prominent, spherical, with a perforated area of entooecium, the tabula, frontally; not closed by the zooidal operculum. Small basal pore chambers present.

Type species: *Lepralia hassallii* Johnston, 1847.

Celleporina reginae sp. nov. (Fig. 26e,f)

TYPE MATERIAL

HOLOTYPE: GH5237, Heron Island, Stn 16, 13 Apr 1972.

ETYMOLOGY

Latin *regina*, queen.

DESCRIPTION

Colony encrusting, mamillate. Autozooids at growing edge convex; 0.4-0.45×0.25-0.35mm; frontal wall smooth, with few, relatively large marginal pores. Primary orifice longer than wide, with a broad, U-shaped sinus comprising more than one-third its total length; condyles thickened and rounded; no oral spines. Paired lateral oral avicularia present, with slender, columnar cystids; rostra elliptical, with finely dentate distal edges, acute to plane of orifice and invariably directed laterally. A low, thin peristome encloses the proximal half of the orifice, between the two avicularia, but does not obscure it. Vicarious avicularia frequent, up to 0.25mm long, the rostrum broadly spatulate and deeply cupped distally; crossbar stout, lacking a columella. Ovicell slightly longer than wide; ectooecium thick and smooth, with a thickened ridge bordering the frontal area of entooecium; frontal marginal pores large, elongate and slit-like, so that the entooecium appears to consist of a radiating series of fused struts.

Measurements (means and standard deviations of 20 values, mm): orifice length 0.11±0.007; width 0.10±0.007.

REMARKS

C. reginae is distinguished from other western Pacific species of *Celleporina* by its deeply sinuate orifice, and laterally directed lateral oral avicularia. A single large colony was present in sample 16, from the reef crest northeast of the cay.

Family PHIDOLOPORIDAE Gabb & Horn, 1862

Colony encrusting, unilaminar or multilaminar, often massive; or erect, attached by an encrusting base, forming bilaminar plates, or dichotomously branching arborescent forms, or complex, anastomosed, reticulate structures. Autozooid frontal wall with marginal pores only. Primary orifice with concave or conspicuously sinuate proximal border, the distal border finely denticulate; condyles present; oral spines present or absent. Avicularia adventitious, and/or vicarious or interzooidal. Ovicells present, with uncalcified area of ectooecium frontally; often with a well developed

labellum; median longitudinal fissures characteristic of some genera; not closed by autozooid operculum.

Reteporella Busk, 1884

Colony erect, attached by an encrusting base; branching dichotomously, developing an open arborescent structure, or with the branches anastomosing to form regular reticulate structures; fan-shaped, or cup-shaped, or complexly folded. Autozooids in two to many longitudinal series, on a defined frontal surface; abfrontal surface of colony consisting of blind kenozooids, usually bearing adventitious avicularia. Primary orifice with denticulate distal border, frequently obscured by a sinuate peristome. Avicularia adventitious, polymorphic. Ovicell with a median longitudinal fissure, variably developed.

Type species: *Reteporella flabellata* Busk, 1884.

Reteporella graeffei (Kirchenpauer) (Figs 28c,d, 29a)

Retihornera graeffei Kirchenpauer, 1869: 30.
Reteporella graeffei: Harmer, 1934: 573, pl. 35, figs 12-15; pl. 38, figs 13-15; text-figs 25E, 31, 32; Ryland, 1984: 74, figs 38.11, 40.31-34.

DESCRIPTION

Colony forming an irregular, open or shallowly cupped fan; branches narrow, rather flat, irregularly curved or twisted, dividing dichotomously at irregular intervals, remaining free or anastomosing to leave long, narrow fenestrulae between. Autozooids in four to eight alternating longitudinal rows, flat, or only slightly convex, broadly hexagonal, separated by distinct raised sutures in early ontogeny, but boundaries later rather indistinct. Frontal wall smooth, with two to four proximal marginal pores. Primary orifice wider than long, the proximal border shallowly concave between small, rounded condyles; obscured by a tall proximal peristome, with a longitudinal median fissure, broadened basally to form a labial pore; peristomial rim with two or three short processes proximally, and with one long spine on its inner (i.e., axial) lateral margin, and four on its outer lateral margin. In later ontogeny only a single spine persists on each side. All spines segmented, up 0.3mm long. Avicularia present on frontal walls of autozooids, polymorphic: most frequently 0.1mm long, with semi-elliptical rostrum, and the proximal part produced as a projecting, linguiform process; occasionally larger, with the rostrum acute, and hooked or dentate distally; gigantic avicularia with abruptly hooked rostrum, up to 0.4mm long, present on some marginal autozooids. Ovicell slightly longer than wide, with an elongate median slit. In later ontogeny the proximal regions of the colony are grossly thickened, peristomes become deeply immersed, and additional avicularia are budded.

DISTRIBUTION

R. graeffei is common in shallow reef environments throughout the tropical western Pacific, from Queensland to Japan; it ranges throughout the Indo-Malayan region and westwards to Sri Lanka and East Africa.

Triphyllozoon Canu & Bassler, 1917

Colony erect, fenestrate, attached by an encrusting base. Fan- or cup-shaped, or with the edges complexly folded to form a squat, three-dimensional bun shape. Autozooids opening on one face only of fenestrate sheet, in alternating series along the branches (trabeculae), which anastomose at regular intervals defining oval fenestrulae. Basal surfaces of colony crossed by thickened sutures. Primary orifice with denticulate rim, obscured by a deep peristome with a longitudinal slit (pseudosinus), often partly closed except for a proximal pseudospiramen, typically with a small peristomial avicularium. Oral spines present. Frontal wall with few, large marginal pores. Avicularia adventitious, polymorphic. Ovicell prominent, with a conspicuous, trilobed frontal suture, and a well developed labellum overhanging the aperture.

Type species: *Retepora monilifera* MacGillivray, 1860.

Triphyllozoon mucronatum (Busk) (Fig. 28a,b)

Retepora mucronata Busk, 1854: 120, pl. 26, figs 6a-e.
Triphyllozoon mucronatum: Harmer, 1934: 620, pl. 35, fig. 35; pl. 40, figs 13-20; text-fig. 42.
Triphyllozoon sp.: Ryland, 1984: 74, fig. 40.36.

DESCRIPTION

Colony developing a low bun shape, up to 30mm high with a horizontal spread of up to 60mm, consisting of finely reticulate, deeply lobed folds, anastomosing frequently to form a compact structure. Fenestrulae small, regularly oval, 1.0×0.5mm; trabeculae comprise three to

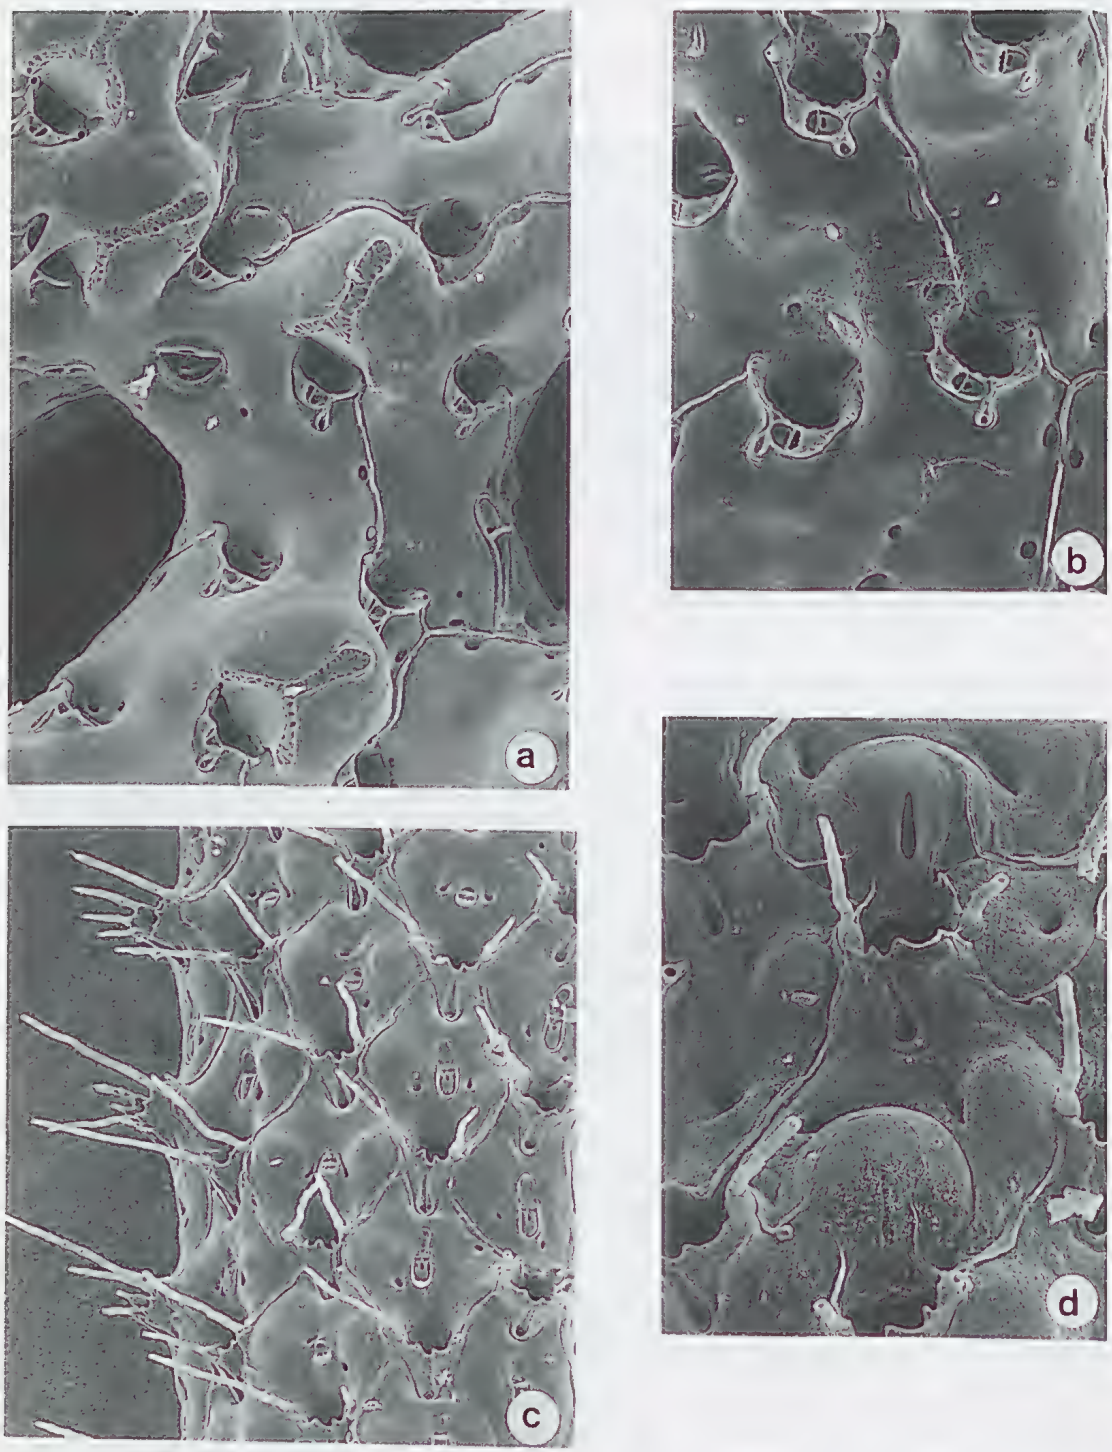

FIG. 28. a,b, *Triphyllozoon mucronatum*; a, ×80; b, ×120. c,d, *Reteporella graeffei*; c, ×60; d, ×130.

five longitudinal autozooid series. Autozooids commonly 0.4×0.2mm, with smooth, convex frontal wall, bordered by a few large, widely spaced marginal pores; sutures between autozooids distinct at growing edge, later progressively obscured. Primary orifice D-shaped, hidden by a deep peristome enclosing its proximal and lateral borders; lip of peristome reflected, with a series of coarse crenulations on its inner edge: medio-proximally a short fissure connects the peristomial rim with the small labial pore, to one side of this is a small peristomial avicularium, acute to frontal plane, laterally directed, with rounded, finely denticulate rostrum. Four short, distal oral spines present in newly budded autozooids, only the proximal pair persisting in later ontogeny. Frontal adventitious avicularia frequent, rostrum 0.1mm long, oval or slightly spatulate. A single large vicarious avicularium present distal or proximal to each fenestrula, with a swollen cystid supporting a narrowly crescentic rostrum; other, larger avicularia occur sporadically, typically within each fenestrula an avicularium with a narrow, elongate rostrum, broadened and denticulate distally; elsewhere, elongate triangular avicularia may be present. Ovicell slightly longer than wide, with a short, square-edged labellum; median frontal fissure longer than proximal fissures.

DISTRIBUTION

This species is known from a few localities in the Philippine Islands, northern New Guinea and eastern Indonesia. It has not been identified previously from Australia.

Schedocleidochasma Soule, Soule & Chaney, 1991

Colony encrusting, uni- or multilaminar. Primary orifice of autozooid cleithridiate (keyhole-shaped), with a deep, arrowhead-shaped or transversely oval sinus below prominent condyles; distal rim of orifice smooth. Oral spines present or absent. Frontal wall with few marginal pores. Avicularia adventitious. Ovicell hyperstomial, partly immersed, not closed by autozooid operculum; with a frontal area of uncalcified ectooecium, and a well-marked labellum. Vertical walls with basal or mural pore chambers.

Type species: *Schedocleidochasma porcellaniforme* Soule, Soule & Chaney, 1991.

Schedocleidochasma porcellanum (Busk) (Fig. 27e)

Lepralia porcellana Busk, 1860: 283, pl. 31, fig. 3.
Cleidochasma porcellanum: Harmer, 1957: 1042, pl. 71, figs 5, 16; Cook 1964b: 11, pl. 1, fig. 4; pl. 2, figs 1, 2; text-figs 4A-E; Winston & Heimberg 1986: 34, figs 85-87.
Schedocleidochasma porcellanum: Soule, Soule & Chaney, 1991: 481.

REMARKS

This familiar species has a circumtropical/subtropical distribution in shallow coastal waters, and may be particularly common in reef flat habitats, on coral rubble, or other hard substrata. At Heron Island it forms flat, silvery, unilaminar sheets, often exceeding 3cm^2. It is readily recognised by the shape of the primary orifice, the lateral suboral avicularium, and its thick, porcellanous secondary calcification. It was present in abundance in seven of the Heron Island samples.

The major revision of *Cleidochasma* by Soule et al. (1991) was published after this paper had been submitted for publication. The specimen illustrated here appears to conform to their concept of *S. porcellanum*, especially in its shallow, transversely oval sinus but, in view of the fact that several previous West Pacific records of this species were shown by Soule et al. to represent their new species, *S. porcellaniforme*, it will be necessary subsequently to review the Heron Island material attributed to *S. porcellanum*.

Rhynchozoon Hincks, 1895

Colony encrusting, multilaminar; discoid, domed, or more usually irregularly spreading, extensive, nodular. Autozooids distinct only at growing edges of colony, or in new, frontally budded laminae; elsewhere immersed to a varying degree in thick secondary calcification. Primary orifice with distal border (anter) beaded or denticulate; proximal border (poster) broadly concave to narrowly sinuate; condyles usually distinct. Oral spines sometimes present in newly budded autozooids. Orifice encircled, and later partly obscured, by marked peristomial thickening, frequently produced into erect or cylindrical, knob-like processes; typically with a distinct notch (pseudosinus) in the proximal border. A transversely or obliquely laterally orientated avicularium located on the proximo-lateral border of the orifice, large and conspicuous, with hooked rostrum and apical process (umbo), or

small and concealed within peristome; often with a stout process (uncinate process) projecting towards the orifice from the inner, proximal edge of the avicularium. Additional, large or small, avicularia present on frontal wall of autozooid, or around peristome rim, often numerous. Frontal calcification of autozooids thick, frequently pearly or distinctly nodular, with marginal pores only. Ovicell typically elongate oval, with a distinct lip (labellum) above the aperture; frontal surface with the outer layer (ectooecium) uncalcified, exposing a smooth or granular area of entooecium (tabula); most often immersed in thickening calcification in early ontogeny and becoming indistinct. Vertical walls with small basal pore chambers.

Type species: *Lepralia bispinosa* Johnston, 1847.

Species of *Rhynchozoon* are common on all tropical reefs and can be particularly difficult to identify. Ontogenetic thickening of the frontal calcification, accompanied by progressive immersion of the primary orifice, and the proliferation of frontally budded avicularia may completely mask those features important for identification. In practice, it is usually impossible to identify any specimen of *Rhynchozoon* without first bleaching a sample to reveal details of the primary orifice. Size and shape of the primary orifice (in particular the sinus), and the morphology of the proximal suboral avicularium are the most important taxonomic features in this genus. In some species, the frontal avicularium and the ovicell provide useful, confirmatory characters.

Rhynchozoon ardeolum sp. nov.
(Fig. 30d,e)

TYPE MATERIAL

HOLOTYPE: GH5238, Heron Island, Stn 25, 18 Apr 1972.

ETYMOLOGY

Latin, diminutive of *ardea*, a heron.

DESCRIPTION

Colony forming broad, multilaminar patches. Autozooids irregularly oval to polygonal, strongly convex, separated by well-marked sutures; commonly 0.45-0.5×0.35-0.4mm. Frontal wall thickly calcified, distinctly corrugated, with a single series of round marginal pores. Primary orifice slightly wider than long, with a short, rounded sinus, bounded by thickened cusps, below blunt, rounded condyles. No oral spines. Many autozooids bearing a very large lateral oral avicularium, with a swollen cystid occupying much of the frontal wall of the autozooid; rostrum broadest proximally, the distal portion, bearing the mandible, elongate, narrow, curved and rounded at the tip, acute to the frontal plane of the autozooid and directed disto-laterally; total length of rostrum 0.3-0.35mm. Additional avicularia sparsely developed, shorter than the lateral oral type, with a narrowly triangular rostrum distal to the mandibular condyles. In later ontogeny frontal calcification thickens, the marginal pores become much accentuated, and three or four stout, conical processes develop around the disto-lateral borders of the orifice, which, however, remains distinct, though partially immersed, and never completely hidden. Ovicells not present.

Measurements (means and standard deviations of 20 values, mm): orifice length (incl. sinus) 0.12±0.004; width 0.12±0.005.

REMARKS

This species is readily distinguished from all other presently known species of *Rhynchozoon* by its unusually large lateral oral avicularium, and by its very distinctive primary orifice. It was present in two of the Heron Island samples.

Rhynchozoon bifurcum Harmer
(Fig. 29b-d)

Rhynchozoon bifurcum Harmer, 1957: 1070, pl. 70, figs 6, 13-15.

DESCRIPTION

Colony a multilaminar, mamillate sheet. Autozooids at growing edge oval, convex, separated by shallow grooves; about 0.5× 0.3mm. Primary orifice wider than long, about 0.16×0.10mm; proximal border shallowly concave between inconspicuous proximo- lateral condyles; no oral spines. Frontal wall nodular, with closely spaced, conspicuous marginal pores. Lateral suboral avicularium present in all autozooids, prominent, with swollen cystid, and broadly triangular, distally hooked rostrum; proximally, a slender subtriangular uncinate process projects above the primary orifice. A stout mucro developing on avicularium, contributing to the peristomial rim, which develops early in ontogeny, obscuring the avicularium and orifice, and eventually consists of six or seven stout, conical processes more or less evenly spaced around the secondary orifice. Frontal

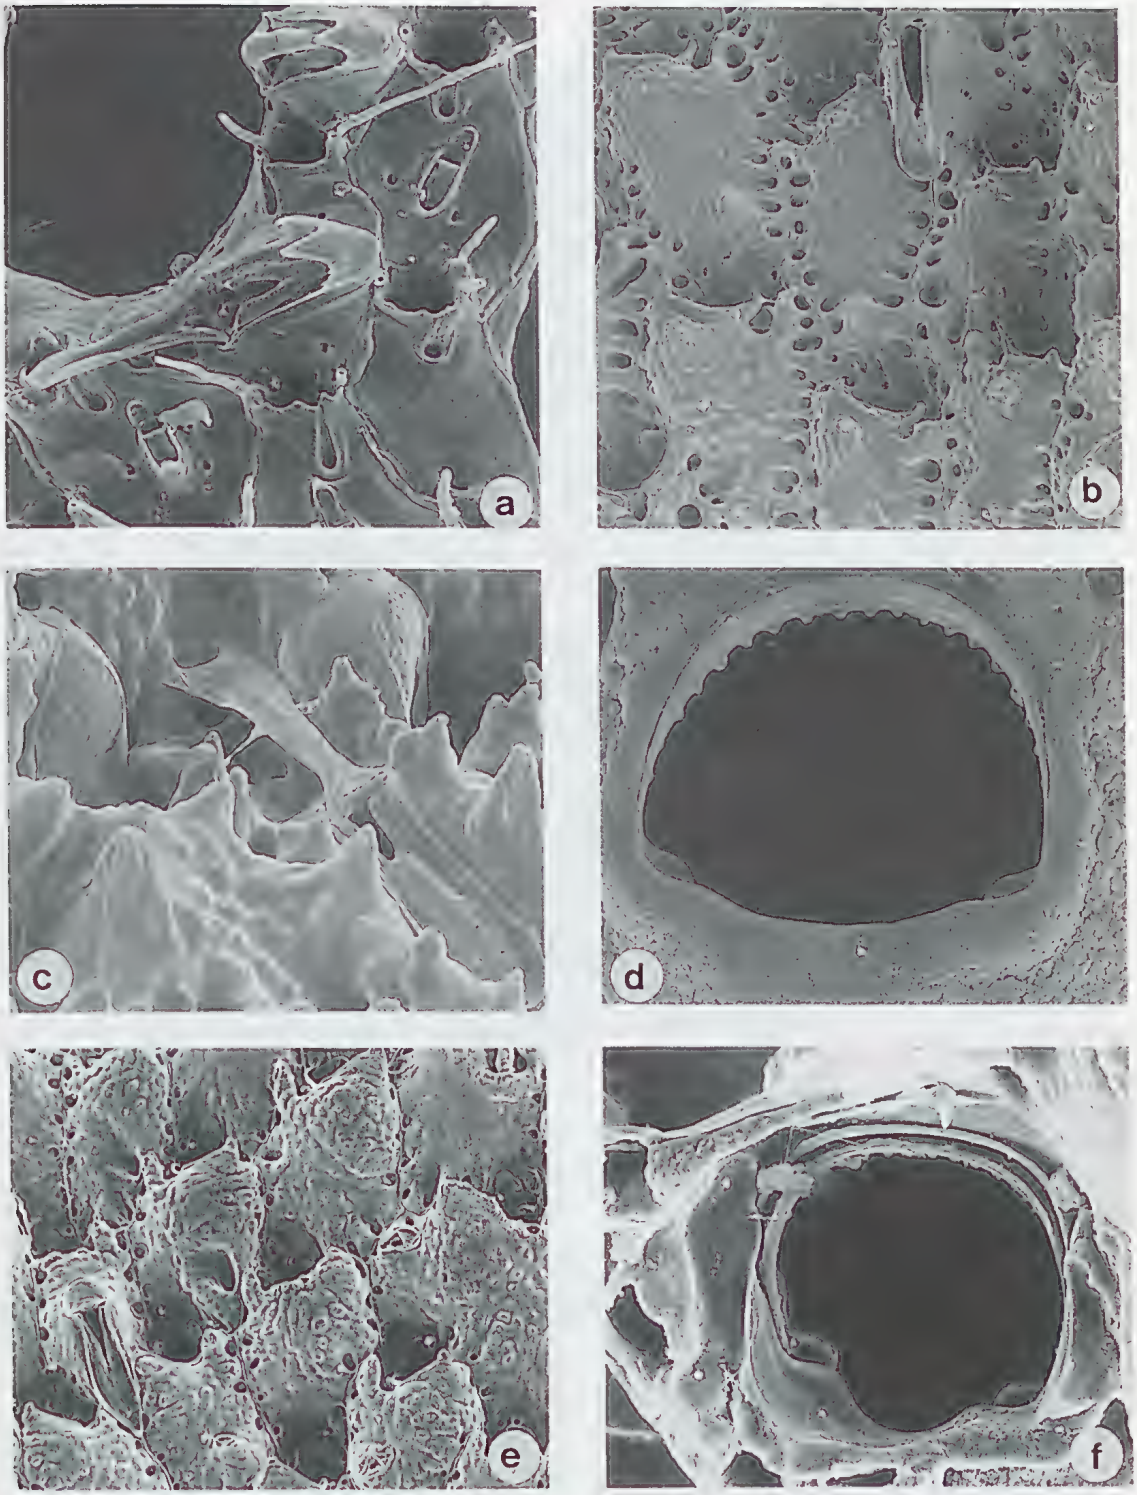

FIG. 29. a, *Reteporella graeffei*, ×90. b-d, *Rhynchozoon bifurcum*; b, ×55; c, an avicularium with bifurcate mandible, ×130; d, primary orifice, ×320. e,f, *Rhynchozoon scopulorum*; e, ×50; f, primary orifice, ×270.

avicularium elongate oval to narrowly spatulate, 0.25-0.5mm long, the mandible in the largest always deeply forked. Ovicell elongate, the frontal surface flat and very finely tuberculate.

DISTRIBUTION

This species is known from Torres Strait, Singapore, and the Chagos Archipelago, but has not been recorded previously from Queensland. The specimen from Japan discussed by Harmer (1957) perhaps does not belong to *R. bifurcum*.

Rhynchozoon compactum (Thornely)
(Fig. 30b,c)

Cellepora compacta Thornely, 1905: 126, pl. fig. 17.
Rhynchozoon compactum: Harmer, 1957: 1076, pl. 70, figs 21-25.

DESCRIPTION

Colony forming irregular, multilaminar patches. Autozooids at growing edge oval to hexagonal, strongly convex, smoothly calcified, about 0.5-0.6×0.35mm. Primary orifice almost circular, about 0.09mm diameter, with a small, U-shaped sinus. No oral spines. A single, lateral-oral, avicularium present in many, but not all, autozooids, the hooked rostrum perpendicular to the plane of the orifice and proximo-laterally orientated. Ovicell as wide as long, the frontal entooecium smooth, labellum indistinctly curved. In later ontogeny the frontal calcification of the autozooid thickens and becomes faintly corrugated; boundaries between autozooids remain distinct, however, and the few small marginal, pores are accentuated. A broad, thick ridge develops around the distal and lateral borders of the primary orifice, characteristically developing two or three knob-like processes, but the orifice remains clearly visible in frontal view. With the development of frontal buds, the primary orifices of the first layer of autozooids become immersed in deep, peristomial tubes, but are not completely hidden. Additional frontal avicularia are sparsely developed, most frequent in later ontogeny; these are up to 0.15mm long, with an elongate oval rostrum.

REMARKS

Heron Island specimens of this distinctive species have been compared with the type material from Sri Lanka, and found to be identical to it. Harmer (1957) listed a specimen from Torres Strait, which it is probably safe to assume belongs to *R. compactum*, but his records from Japan need to be confirmed following re-examination of the specimens listed.

Rhynchozoon haha Hayward
(Figs 30f, 31a,b)

Rhynchozoon haha Hayward, 1988: 334, pl. 11, figs f,g.

DESCRIPTION

Colony developing broad, irregular, spreading sheets. Autozooids at growing edge oval to hexagonal, or rectangular, convex, separated by distinct sutures; 0.5-0.6×0.3-0.35mm. Primary orifice wider than long, with a broad, U-shaped sinus occupying about three-quarters its proximal width; condyles knob-like, small, no oral spines. Frontal wall smooth, with a single series of large, distinct marginal pores. A large, lateral suboral avicularium present on most autozooids; cystid swollen, frequently with a small umbo on its frontal surface; rostrum acute to frontal plane, directed disto-laterally, acuminate but with only a slight distal hook; proximally the avicularian rostrum thickens to form a short, blunt, uncinate process. Frontal adventitious avicularia characteristic: typically one per autozooid, 0.2mm long, directed proximally or proximo-laterally; lozenge-shaped, with the narrowly triangular rostrum about twice as long as the proximal opesia. Ovicell short, smooth frontally, completely immersed by ooecial cover and not readily visible in frontal view. With ontogenetic thickening the primary orifice becomes deeply immersed, hiding the suboral avicularium; four or five stout, conical umbones develop on the peristomial rim, with the proximalmost pair flanking a pronounced proximo-medial notch. The frontal avicularia remain distinct, however, and the autozooid boundaries can be recognised by the deep, conspicuous marginal, pores.

DISTRIBUTION

R. haha was founded on material collected from reef habitats around Mauritius (Hayward, 1988). This is only the second occurrence, but it will probably prove to be generally distributed in the Indo-West-Pacific region, in shallow reef habitats.

Rhynchozoon limatulum sp. nov.
(Fig. 31c-e)

TYPE MATERIAL

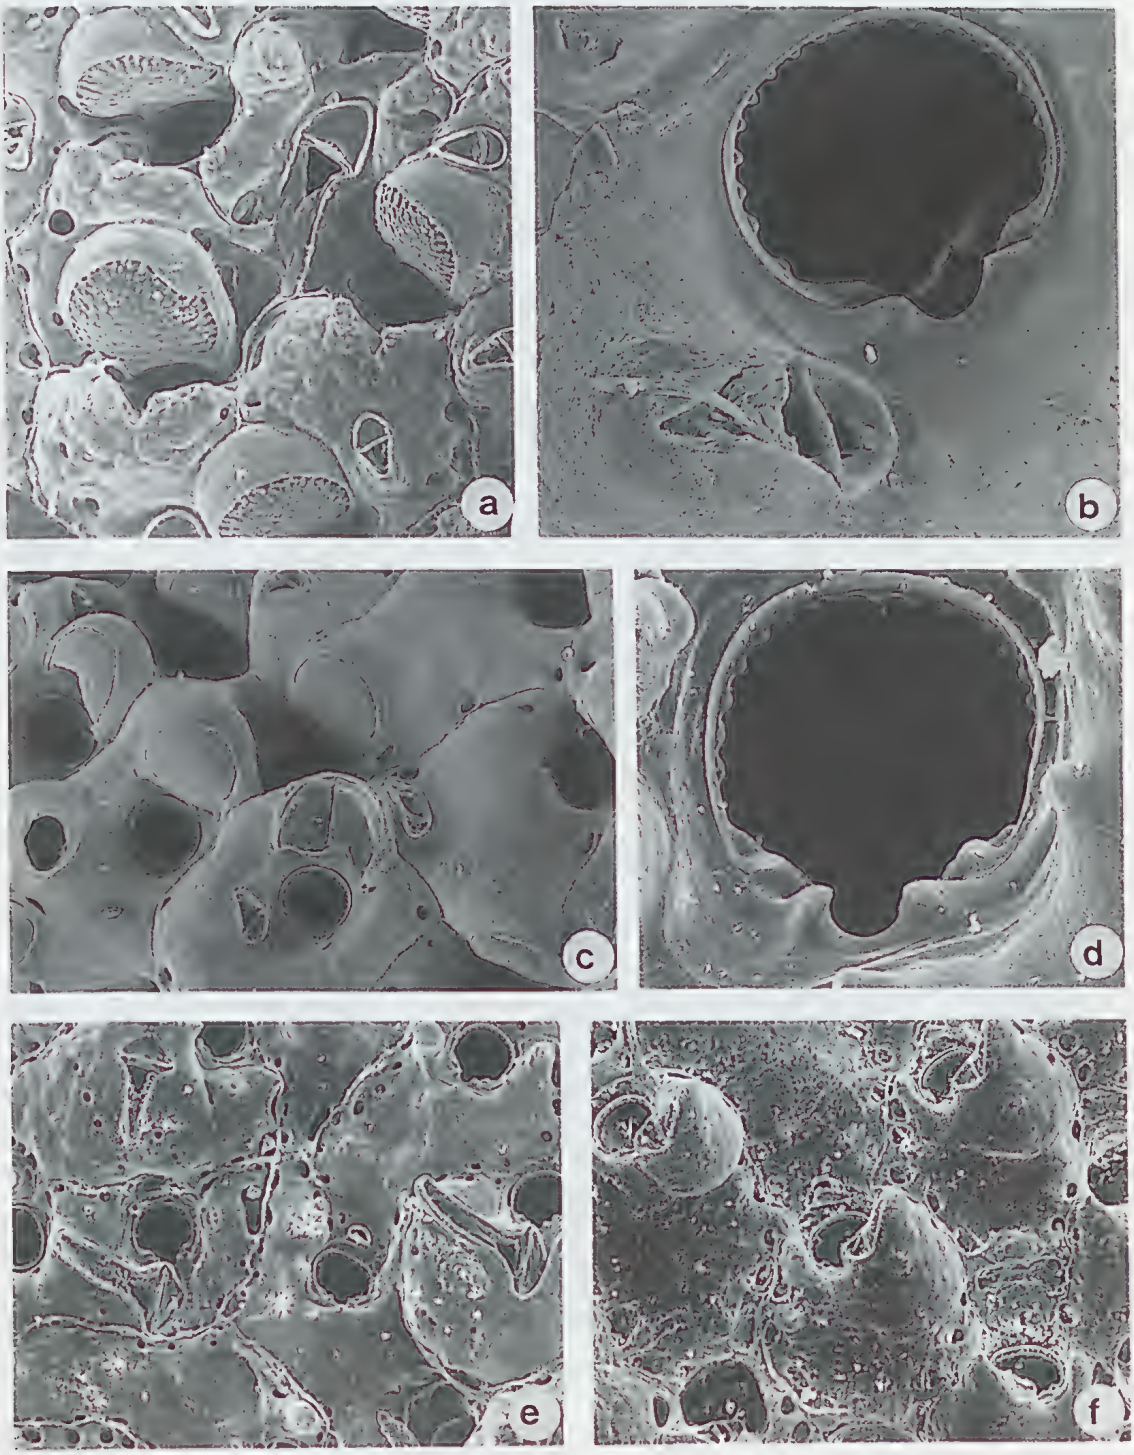

FIG. 30. a, *Rhynchozoon scopulorum*, ×70. b,c, *Rhynchozoon compactum*; b, ×350; c, ×80. d,e, *Rhynchozoon ardeolum*; d, ×350; e, ×60. f, *Rhynchozoon haha*, ×70.

HOLOTYPE: GH5239, Heron Island, Stn 14, 12 Apr 1972.

ETYMOLOGY
Latin, diminutive of *limatus*, polished.

DESCRIPTION
Colony forming irregular, multilaminar sheets. Autozooids at growing edge broadly oval, convex, separated by distinct sutures. Primary orifice distinctly wider than long, with a deep, U-shaped sinus occupying most of proximal width; condyles thickened, conspicuous. No oral spines. Frontal wall smoothly calcified, bordered by small, widely-spaced marginal pores; typically developing two or three prominent, conical processes proximally, forming part of the peristome of the preceding autozooid. Peristome spinous, typically with a single medio-proximal process, paired lateral processes, and two or three distal processes, all prominent, tapered, and occasionally bifurcate apically. Most autozooids with a lateral oral avicularium enclosed within the peristome, the rostrum slender, triangular, hooked distally, and laterally directed. One to three smaller avicularia present on frontal wall; rostrum slender, triangular, laterally directed. Ovicell with a very short labellum and a conspicuous frontal fenestra; rapidly immersed in a smooth ooecial cover.

Measurements (means and standard deviations of 20 values, mm): autozooid length 0.41± 0.04; width 0.30±0.04; orifice length 0.08±0.004; width 0.10±0.003.

REMARKS
This species is distinguished from others in the Heron Island reef flat fauna by its short, wide primary orifice, and comparatively deep sinus. The smooth frontal calcification, spinous peristomes and small frontal avicularia are also characteristic.

Rhynchozoon scopulorum sp. nov.
(Figs 29e,f,30a)

TYPE MATERIAL
HOLOTYPE: GH5240, Heron Island, Stn 16, 13 Apr 1972.

ETYMOLOGY
Latin *scopulosus*, rocky.

DESCRIPTION
Colony forming broad, spreading sheets. Autozooids at growing edge oval to hexagonal, convex, separated by distinct sutures. Primary orifice about as wide as long, with shallow, U-shaped sinus occupying about half proximal width; condyles rounded, distinct; distal and disto-lateral denticulations fine, closely spaced. No oral spines. Frontal wall distinctly nodular, with few, widely spaced, marginal pores. Lateral suboral avicularium large and prominent; rostrum acute to frontal plane, laterally directed, hooked distally; proximally, the rostral rim is produced as a stout, conspicuous uncinate process, almost reaching the opposite side of the peristome, delimiting a rounded pseudosinus. A small adventitious avicularium present on the frontal wall of most autozooids, the rostrum triangular, acute to frontal plane, usually directed proximally. Large frontal avicularia sporadic: 0.4mm long, occupying most of autozooid frontal wall, proximally directed; rostrum lanceolate, often asymmetrical, with upturned tip. Ovicell longer than broad, projecting well above peristomial rim and remaining distinct in later ontogeny; frontal surface slightly flattened, minutely tuberculate. In later ontogeny the suboral avicularium becomes submerged within the peristome, and the proximal peristomial rim bears a pair of short, conical umbones, with a shallow, U-shaped notch between.

Measurements (means and standard deviations, mm)): autozooid length (n = 20) 0.56±0.05; width 0.33± 0.03; orifice length (n = 10) 0.11± 0.005; width 0.14± 0.000.

REMARKS
This species is similar to the Indonesian *R. detectum* Harmer, 1957, recently described and figured by Winston & Heimberg (1986). However, *R. detectum* is distinguished from *R. scopulorum* by its primary orifice, which is only very shallowly concave proximally, and by its large frontal avicularia, which are narrower and more distinctly pointed than in *R. scopulorum*. The large avicularia of the latter are in fact almost identical to those of *R. triangulare* Harmer, 1957, also described from Indonesia; the primary orifice of *R. triangulare*, however, has a slit-like proximal sinus. *Rhynchozoon scopulorum* seems to be common at Heron Island; large colonies were present in six of the samples studied.

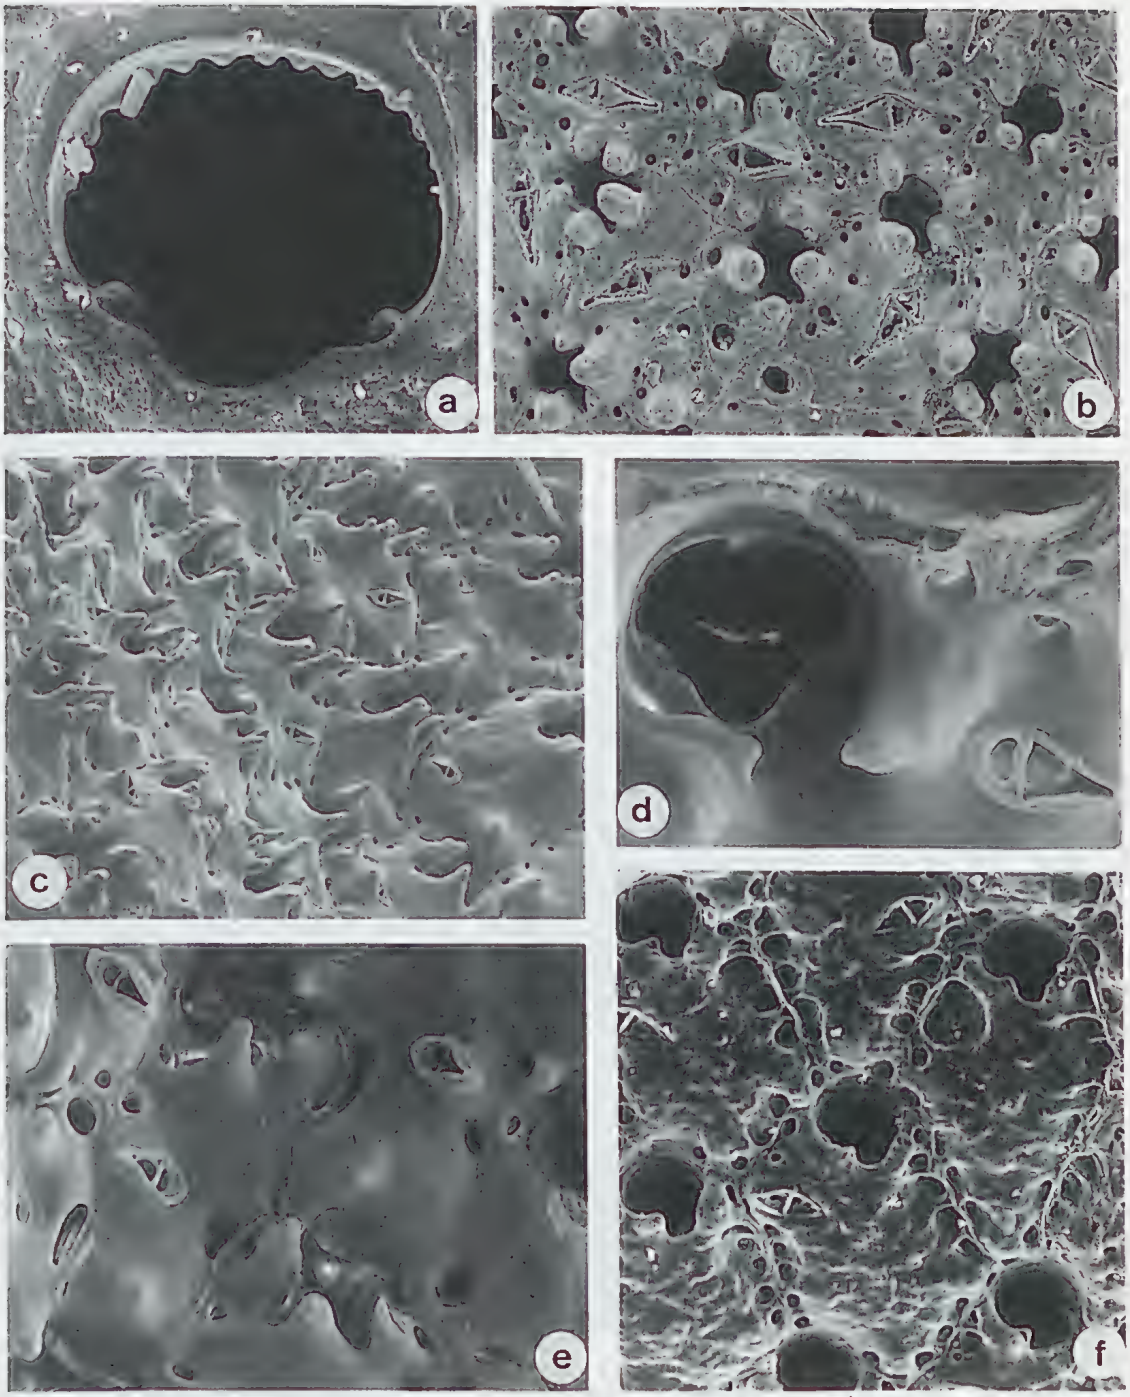

FIG. 31. a,b, *Rhynchozoon haha*; a, ×450; b, ×55. c-e, *Rhynchozoon limatulum*; c, ×70; d, ×300; e, ×140. f, *Rhynchozoon splendens*, ×80.

Rhynchozoon splendens Hayward
(Figs 31f, 32a,b)

Rhynchozoon splendens Hayward, 1988: 335, pl. 13, figs f,g.
Rhynchozoon rostratum: Winston & Heimberg, 1986: 38, figs 95-98.

DESCRIPTION

Colony forming spreading, multilaminar sheets. Autozooids at growing edge oval, convex, separated by distinct grooves; commonly 0.45-0.50×0.3mm. Primary orifice 0.12mm wide, about as long as wide; sinus short, U-shaped, occupying about half proximal width of orifice; condyles indistinct. No oral spines. Frontal wall at first smooth, but becoming coarsely and irregularly nodular; bordered by large and conspicuous marginal pores. Peristomial rim markedly thickened, produced into a series of projecting, knob-like, conical process, the most constant being a medio-proximal pair which may be especially prominent; most autozooids with a single, lateral, suboral avicularium enclosed within the peristome, with triangular, hooked rostrum directed laterally or disto-laterally; the inner proximal corner of the rostral rim is produced as a short, blunt, uncinate process. Small frontal avicularia present, typically one proximo-lateral to peristome, and sometimes a second, more proximally situated; rostrum diamond-shaped, with variable orientation. Ovicell with a short, broad labellum; developing a finely nodular ooecial cover, generally rather inconspicuous.

REMARKS

R. splendens was recently described from Mauritius (Hayward, 1988), where it was found to be common in shallow reef habitats. Comparison of Heron Island specimens with Mauritian material confirms that they are all one species; the shape and size of the primary orifice, the conformation of the peristome, and the characteristic diamond-shaped avicularia are all remarkably similar in the two series of specimens. The species reported from Sanur, Bali, by Winston & Heimberg (1986) as *R. rostratum* (Busk) seems to be *R. splendens*. *R. rostratum* is similar to *R. splendens* in its diamond-shaped frontal avicularia and lobed peristome, which encloses a large lateral-suboral avicularium, but differs in its primary orifice, which has a wide, shallow sinus, and proportionately larger condyles. *R. splendens* was the most common species of *Rhynchozoon* collected at Heron Island; small colonies, and larger sheets, were frequent in eight of the samples described here.

Rhynchozoon tubulosum (Hincks)
(Fig. 32c-e)

Mucronella (?) *tubulosa* Hincks, 1880d: 383, pl. 17, fig. 7.
Mucronella tubulosa: Thornely, 1905: 124.
Rhynchozoon tubulosum: Harmer, 1957: 1064, pl. 65, figs 16-19; Gordon, 1984: 125, pl. 52, figs C-E; Hayward, 1988: 336 [in part; not pl. 14, figs a, b].

DESCRIPTION

Colony forming small, unilaminar patches. Autozooids at growing edge oval to hexagonal, steeply convex, separated by distinct sutures (indistinct in later ontogeny); 0.45-0.5×0.25-0.35mm. Primary orifice as wide as long; proximal edge broadly and shallowly concave between small, rounded, proximo-lateral condyles; distal/disto-lateral denticulations small and widely spaced. Frontal wall irregularly nodular, with few, large, widely-spaced marginal pores; proximal peristomial lip prominent, raised medially as a stout, knobbly mucro, occasionally spiky, or distinctly bifid apically; additional, shorter mucronate processes sometimes developed lateral to the median. Suboral avicularium transversely orientated, on the inner surface of the mucro, the rostrum sharply hooked distally, but without an associated uncinate process. Large frontal avicularia sporadically present, most frequent in older parts of colony; rostrum linguiform, about 0.35mm long, normal to frontal plane and proximally directed. Tiny adventitious avicularia, with short triangular mandible, often developed towards tip of mucro, and rarely elsewhere on the frontal wall. Ovicell about as wide as long, slightly flattened frontally, with a finely tuberculate surface, projecting well above rim of peristome.

REMARKS

With ontogenetic frontal wall thickening the primary orifice becomes deeply immersed and the mucronate proximal peristome especially prominent, so that autozooids appear to be vertically orientated. Hinck's (1880d) unfortunately inadequate figure shows a group of autozooids in late ontogeny, with prominent, mucronate peristomes, tuberculate ovicells clearly visible above the peristome rims, and large, linguiform frontal avicularia. No type specimen is known for *R.*

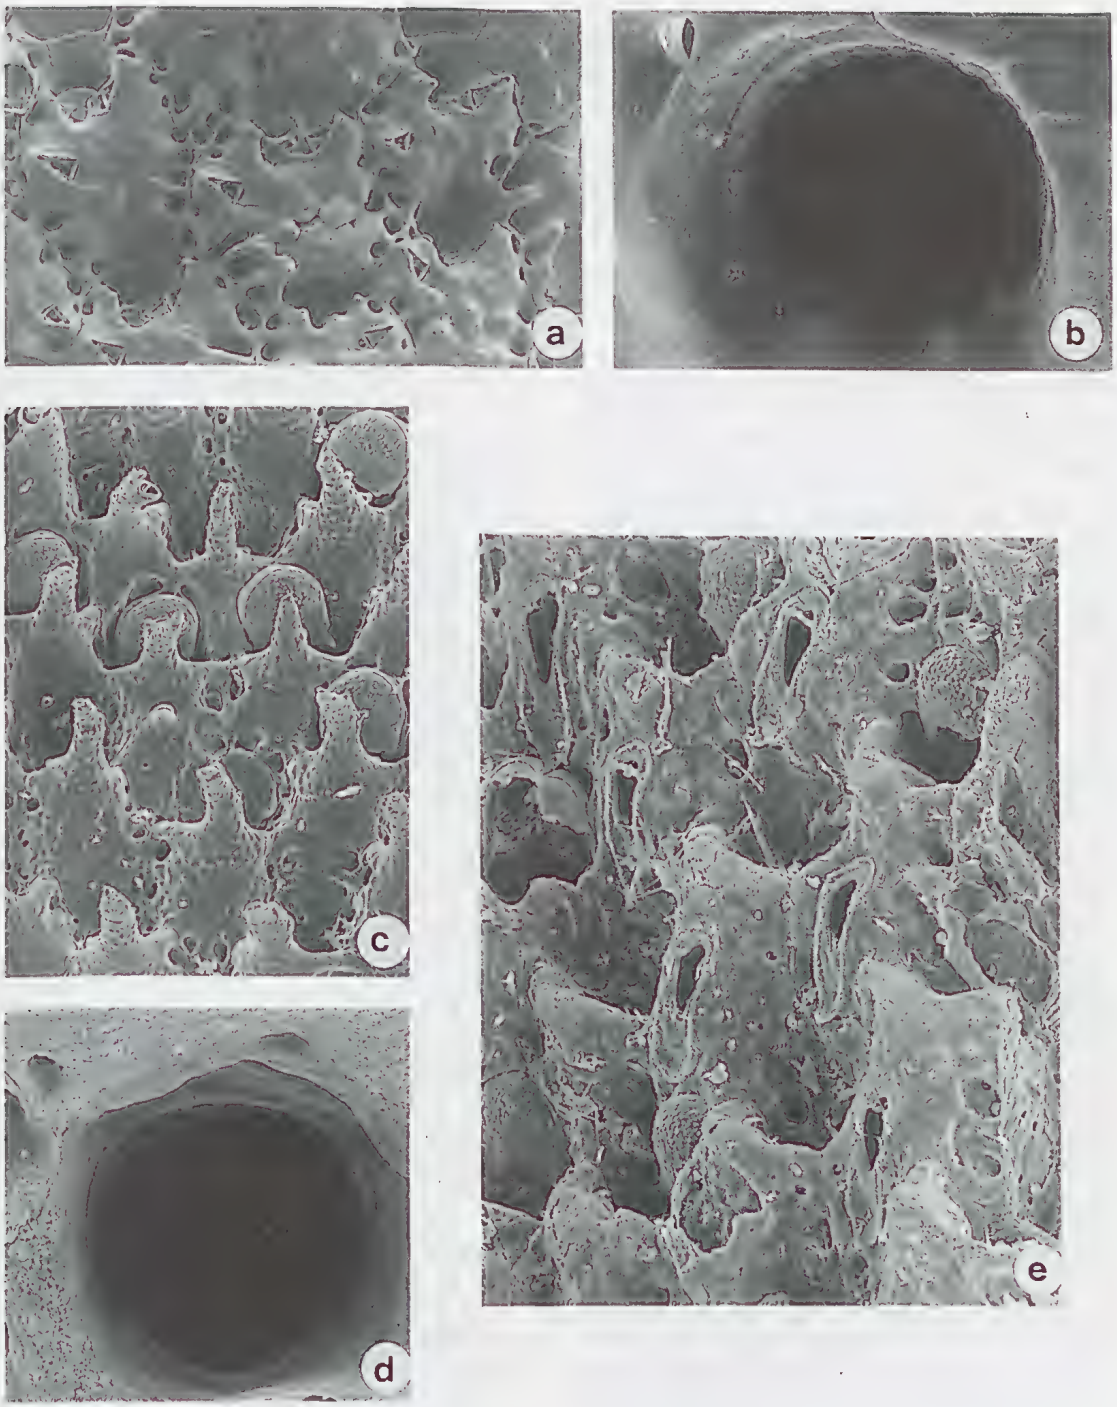

FIG. 32. a,b, *Rhynchozoon splendens*; a, ×60; b, ×350. c-e, *Rhynchozoon tubulosum*; c, ×45; d, ×260; e, ×70.

tubulosum, Hincks' original description is incomplete, and the identity of the Heron Island species described here depends entirely on the resemblance of older autozooids to Hincks' figure. Subsequent authors (see Harmer, 1957: 1064) considered that *Rhynchozoon longirostre* (Hincks), described from southern Australia, was the same as *R. tubulosum*, an assertion which was denied by the author himself (Hincks, 1891). In Hincks' original specimens of *R. longirostre* (e.g., BMNH 1899.5.1.1161, 1163), the suboral avicularium is associated with a massive uncinate process, which partly obscures the primary orifice, a feature not seen in any of the material of *R. tubulosum* examined here. Consequently, the synonymy of the two taxa should be rejected. Thornely's (1905) material of *R. tubulosum* from Sri Lanka (BMNH 1936.12.30.48A) and Harmer's (1957) Indonesian specimens are the same species as that occurring at Heron Island; Harmer's synonymy, however, cannot be accepted until all listed records of *R. tubulosum*, *R. longirostre* and *R. profundum* (MacGillivray) have been re-examined. The material described from Mauritius by Hayward (1988) unfortunately comprised two species, and the specimen figured (Hayward, 1988, pl. 14, figs a,b) is not *R. tubulosum*, but an undescribed species of *Rhynchozoon*.

CONCLUSION

The selection of Bryozoa described in this preliminary account comprises a single cyclostome, and 80 species of cheilostome, encompassing 46 genera in 27 families. Of these 80 species, 14 are new to science and 24 are reported for the first time from Australian seas. The remaining 43 species include at least 25 which are known to be widely distributed in the Indo-West Pacific realm, some of which (e.g., *Chorizopora brongniartii* and *Arthropoma cecilii*) appear to have almost world-wide distributions in shallow tropical and temperate seas. This group of 81 species includes the most abundant, most familiar and taxonomically least problematic members of the bryozoan fauna of the Heron Island reefs. While the range of genera represented gives some indication of the taxonomic diversity of the fauna, the total number of species is likely to be greatly increased as the rest of the collection is studied. It is worth noting that few of the species listed by Livingstone (1927) or described by Hastings (1932) from GBR localities have so far been found in these collections. Unfortunately, progress in taxonomic research on tropical Australian Bryozoa is hampered by the necessity to review all previous published sources critically, and whenever possible to refer to type and original specimens. Harmer's (1957) fourth Siboga Report, presently the most important of these sources, has serious shortcomings in that the synonymies of many of the species it describes can be shown to be erroneous, while a substantial number of others are founded on material which clearly consists of more than a single species.

FOOT-FLAGGING DISPLAYS OF SOME AUSTRALIAN FROGS. *Memoirs of the Queensland Museum 32(1): 302. 1992:-* Visual displays involving movements of the feet have been recorded for four anuran species: *Hylodes asperus* (Leptodactylidae), *Staurois parvus* (=*tuberilinguis*) and *S. latopalmatus* (Ranidae), and *Taudactylus eungellensis* (Myobatrachidae) (Davison, 1984; Harding, 1982; Heyer et al., 1990; Winter & McDonald, 1986). All of these species are diurnal and live along rainforest streams. This led Heyer et al. (1990) to suggest that visual displays might be a substitute for vocal communication in response to noisy streamside environments where vocal signals are difficult to hear, and may be less risky for frogs that have easy access to a safe refuge. They also noted morphological similarities between *Hylodes asperus* and the Australian hylid *Litoria nannotis*, and questioned whether *L. nannotis* also might exhibit visual displays.

In this note we confirm that *L. nannotis* does exhibit foot-flagging displays, and describe visual displays by three other Australian hylid frogs. These include the first records of nocturnal foot-flagging and foot-flagging displays exhibited outside a rainforest environment. Field observations were made in the wet tropics of northern Queensland and in northern New South Wales, between March 1989 and March 1992.

Litoria genimaculata: Three males were observed displaying on mossy rocks next to Birthday Ck, an upland rainforest stream in Mt Spec National Park. Observations were made over a 15 minute period beginning at 1100h on 16.2.90. One male slowly raised the right rear leg, stretched it out perpendicular to the body and rapidly vibrated the foot on a vertical plane with the toes outstretched. It then leapt onto a second male about 1m away. This second male retreated a further metre and exhibited the same display, once with each rear foot. A third male perched within 50cm then displayed vigorously more than a dozen times, with no apparent sequence of use of the two feet. There followed a series of leaps onto each other, several wrestling bouts, and sporadic displays by all three males until they dispersed approximately 15 minutes after the displays were initiated. All of the males called continuously during these bouts.

Litoria nannotis: Observations were made over a two hour period in November, 1990, on captive specimens maintained in a large aquarium. Visual displays were initiated by a resident male when a second male was placed into the same aquarium. Immediately following the introduction, the resident male called vigorously as he approached the intruder, and then extended the right rear leg out and back in an arc, spreading the toes to reveal the webbing, before returning the leg to the side of the body. This display was repeated continuously with both back legs until the intruder retreated into a crevice. The display was reinitiated each time the intruder appeared. Male *L. nannotis* have been observed in the field to wave their front legs in an arc above the head in similar inter-male displays (A. Dennis, pers. comm.).

Litoria rheocola: Three males were observed displaying along rainforest streams in the vicinity of Mt Finnigan, northern Queensland. All observations were made at night between 2200 and 2330 on 17.12.91. All involved interactions between calling males. The first male was perched on a leaf at a height of 38cm and facing another calling male 40cm away. The first male waved its front right foot twice in an arc over its head. It then made two rapid flicks with the rear leg so that the leg was extended fully, in a lateral plane perpendicular to the long axis of the body, and returned immediately to the side of the body. A second male displayed only with the rear legs, exhibiting seven similar leg flicks in four minutes. Six flicks were with the left leg and one with the right. A third calling male was observed for five minutes and did not display until another male called one metre away. It immediately began displaying with both rear legs in the manner described above. These displays were observed by moonlight.

Litoria fallax: Observations were made between 2150 and 2210h on 01.01.91 in the vicinity of Brays Ck, northern NSW, under well-moonlit conditions. The interaction was between a calling male perched 50cm above the water and a satellite, non-calling male, initially perched 35cm away. The calling male began a rapid clicking encounter call, when approached from behind by the second male. A wrestling bout ensued for approximately one minute during which the first male called continuously and ended with the second male sitting behind and facing the same direction as the first, about 10cm lower on the same branch. The first male then foot-flagged by alternately extending rear legs, starting with a stretch sidewards and slowly moving each leg through a backward arc to end in the lateral resting position. This was repeated seven times, ending when the second male leaped away. The remaining male resumed calling four minutes later. No species reported here has brightly coloured webbing between the toes.

The hylid species reported here to exhibit foot flagging behaviour are all nocturnally active and all use vocalisations to attract conspecific females. Displays were only observed in the presence of rival males. Isolated males, or males in the presence of females, have not been observed displaying.

The functional significance of foot-flagging appears to be related more to male-male aggression than to courtship. Previously reported displays may also prove to have an aggressive rather than a courtship function. More investigations of frog behaviour may reveal a greater diversity of visual displays than previously suspected. Also, observations are required to determine the effect of light intensity (moonlight) on visual displays in nocturnally active frogs.

K. McDonald and A. Richards assisted in the field. Field work was funded by ARC grants A18715284 and A18931875 to R. Alford, and a grant from the Wet Tropics World Heritage Agency. C. James was supported by an Australian Postgraduate Research Award.

A NEW SPECIES OF LIZARD (*TILIQUA*) FROM THE MIOCENE OF RIVERSLEIGH, QUEENSLAND

GLENN M. SHEA AND MARK N. HUTCHINSON

Shea, G.M. & Hutchinson, M.N. 1992 06 29: A new species of lizard (*Tiliqua*) from the Miocene of Riversleigh, Queensland. *Memoirs of the Queensland Museum* **32**(1): 303-310. Brisbane. ISSN 0079-8835.

A new species of *Tiliqua*, *T. pusilla*, is described from fossil dentaries from the Gag locality, Dwornamor local fauna, Middle Miocene of Riversleigh, Queensland. The new species is characterised by its distinctive rounded cheek teeth and very small size. □*Tiliqua, Scincidae, dentition, Miocene, Riversleigh.*

Glenn M. Shea, Department of Veterinary Anatomy, University of Sydney, New South Wales 2006, Australia; Mark N. Hutchinson, South Australian Museum, North Terrace, Adelaide, South Australia 5000, Australia; 24 June, 1991.

The limestone deposits of the Riversleigh area of northwestern Queensland (recently reviewed by Archer et al., 1989) are becoming widely known as a source of excellently preserved vertebrate fossils, ranging in age from the late Oligocene to the Pleistocene. The limestone matrix has enabled acid preparation of delicate bones (e.g. bat skulls) in perfect condition and many thousands of specimens have already been recovered. The detailed preservation and the evident terrestrial nature of some of the faunas are factors suggesting that small reptiles such as lizards, which normally fossilise poorly, would be preserved, and such is the case. Members of the families Agamidae, Varanidae, Gekkonidae and Scincidae have been identified in the collections from Riversleigh. An initial survey of the agamids has just been completed (Covacevich et al., 1990) and we report here on one of the scincid lizards. The Scincidae is the most diverse family in the modern Australian fauna. It includes many highly characteristic forms, suggesting a long period of evolution in Australia about which almost nothing is known. The Riversleigh deposits are the first from the Australian Tertiary known to be rich in fossil skinks (Hutchinson, 1992).

To date, most of the remains identified as lizards are partial or fragmentary lower jaws. These are difficult to identify because there are too few data concerning taxonomic variation in skeletal characters of the very diverse modern Australopapuan fauna. However, one of the most distinctive Australian genera, *Tiliqua* (s.l.), has long been recognised as having unusual teeth (e.g. Smith, 1937), with several of the posterior cheek teeth markedly enlarged and having conical or rounded crowns. Shea (1990) described the *Tiliqua* lineage: a revised *Tiliqua* (including *Trachydosaurus*), plus *Cyclodomorphus*, the latter including the slender species *gerrardii*, *casuarinae* and the *branchialis* complex. Both genera have characteristic dental morphology which allows isolated dental arcades to be identified to species (Archer and Brayshaw, 1978; Bartholomai, 1977; Shea, pers. obs.).

Amongst the material from Riversleigh are two partial dentaries with the enlarged, round-crowned teeth of the *Tiliqua* lineage. These specimens are here described as a new species of *Tiliqua*, the first extinct member of the genus to be described.

MATERIALS AND METHODS

Prepared fossil specimens of lizard jaws were provided by Dr M. Archer, University of N.S.W. These had been sorted from concentrate obtained by the acid processing of limestone blocks from Riversleigh Station, northwest Queensland. Reference material of modern taxa was obtained from the the following collections: American Museum of Natural History, New York; Australian Museum, Sydney; Queensland Museum, Brisbane (QM); Queen Victoria Museum, Launceston; South Australian Museum, Adelaide (SAMA); Western Australian Museum, Perth; Zoologisches Museum, Humboldt Universität, Berlin. Specimens were examined, measured and drawn using a Wild M3Z stereomicroscope with an eyepiece micrometer and drawing tube.

SYSTEMATICS

Family SCINCIDAE

Subfamily LYGOSOMINAE Mittleman, 1952

Tiliqua Gray, 1825

Tiliqua pusilla sp. nov.
(Figs 1-2)

MATERIAL EXAMINED

HOLOTYPE: QM F16876 (formerly M. Archer collection no. AR5337a).

PARATYPE: QM F16877 (formerly M. Archer collection no. AR4183).

TYPE LOCALITY: Gag locality, one of the lowest of the Tertiary System C group of sites on the Gag Plateau, Riversleigh Station, Queensland (precise details of site available from University of NSW Vertebrate Palaeontology Laboratory). Matrix of freshwater limestone. The Gag site has yielded the Dwornamor local fauna and is of probably early Middle Miocene age (c.15 Myr BP; Archer et al., 1989).

DIAGNOSIS

A small species (estimated dentary tooth row length of the holotype, 9mm), cheek teeth enlarged, with crowns blunt and slightly rounded in lingual profile, more conical in mesial profile, apices bearing a shallow central pit from which radiate striae.

DESCRIPTION

HOLOTYPE: (Fig. 1 a-b) A partial left dentary, missing its rostral third and the caudal, non-tooth bearing extremity, including all of the coronoid process and the apex and ventral margin of the angular process. Meckelian groove closed, no trace of suture. Rostral end of ventral margin with a low ridge, presumably the caudoventral extremity of the symphysial crest. Apex of splenial notch (rostral margin of inferior alveolar foramen) lies at midpoint of interval between coronoid border of dorsal medial lamina and caudal margin of symphysial crest. Coronoid margin of dorsal medial lamina obtusely angulate. Lateral surface with a deep, well-defined arcuate muscle scar caudal to level of last tooth, presumably for the M. adductor mandibulae externus superficialis (AMES) (part IV, Wineski and Gans, 1984).

Internal septum fused ventrally along entire length to ventral medial lamina, completely separating inferior alveolar canal from Meckelian canal. Caudal margin of internal septum with two notches (caudodorsal and rostroventral) for articulation with surangular.

Labial wall of dental sulcus tall and robust, lingual wall almost absent, but lingual margin well-defined and sharply angulate. Dentition pleurodont. Seven closely-packed teeth of even occlusal height and two unfilled tooth loci present, in order from mesial to distal: a tooth locus for a similar-sized tooth to those immediately caudal, at the level of the caudal extent to the ventral symphysial crest; a tooth, missing crown, with a small resorption pit at base; an intact, unresorbed tooth; a tooth largely resorbed at the base, but with intact crown; a tooth with a small resorption pit basally, but with mesial margin of crown missing; a very large empty tooth locus for a tooth approximately twice the diameter of the preceding teeth; a large tooth (only slightly less in diameter than the preceding locus) with intact crown, but with a large resorption pit basally; two intact teeth, the second with a small resorption pit, both abruptly narrower and shorter (occlusal surface lower) than the preceding tooth. Tooth crowns bluntly rounded in lingual profile, slightly more conical in mesial profile, the largest extant tooth even more flattened; mesial teeth with a shallow apical notch, from which striae radiate towards the periphery of the crown; similar, shallower striae present on more caudal teeth.

PARATYPE: (Fig. 1 c-d) The entire rostral half of a left dentary, broken at the level of the 11th tooth and apex of splenial notch, but with most teeth either broken or missing. The portion overlapping with the holotype (tooth loci 5-11) is similar to it in all respects, but slightly smaller. In dorsal view, dentary nearly straight. Symphysis flattened, angle between symphysial surface and lingual surface obtuse, slightly rounded. Angle between mandibles (as estimated by apposition of a mirror image) 41° internally, 50° externally.

Lateral surface with six irregularly spaced mental foramina. Teeth and loci are present as follows, from mesial to distal: Five teeth, obliquely fractured at base to leave only the implanted portion, the fifth level with the end of the ventral symphysial crest; a tooth missing lateral surface of crown; an empty tooth locus of similar size to the preceding teeth; a tooth broken transversely at level of margin of mandible, missing entire crown; an entire, unworn tooth with a fracture line below the crown; a very large empty tooth locus for a tooth approximately twice the diameter of the preceding teeth, and a large tooth stump, similar in diameter to the preceding empty tooth locus, missing crown. Resorption pits are present in the bases of the second, fifth, eighth and eleventh teeth. The single intact tooth (ninth) slanting labially about 30° from vertical. In mesial profile, lingual wall nearly straight, labial wall of crown slightly bulbous, apex moderately narrow, conical, but with a prominent mesiodistal apical notch. In lingual view, crown more rounded, slightly

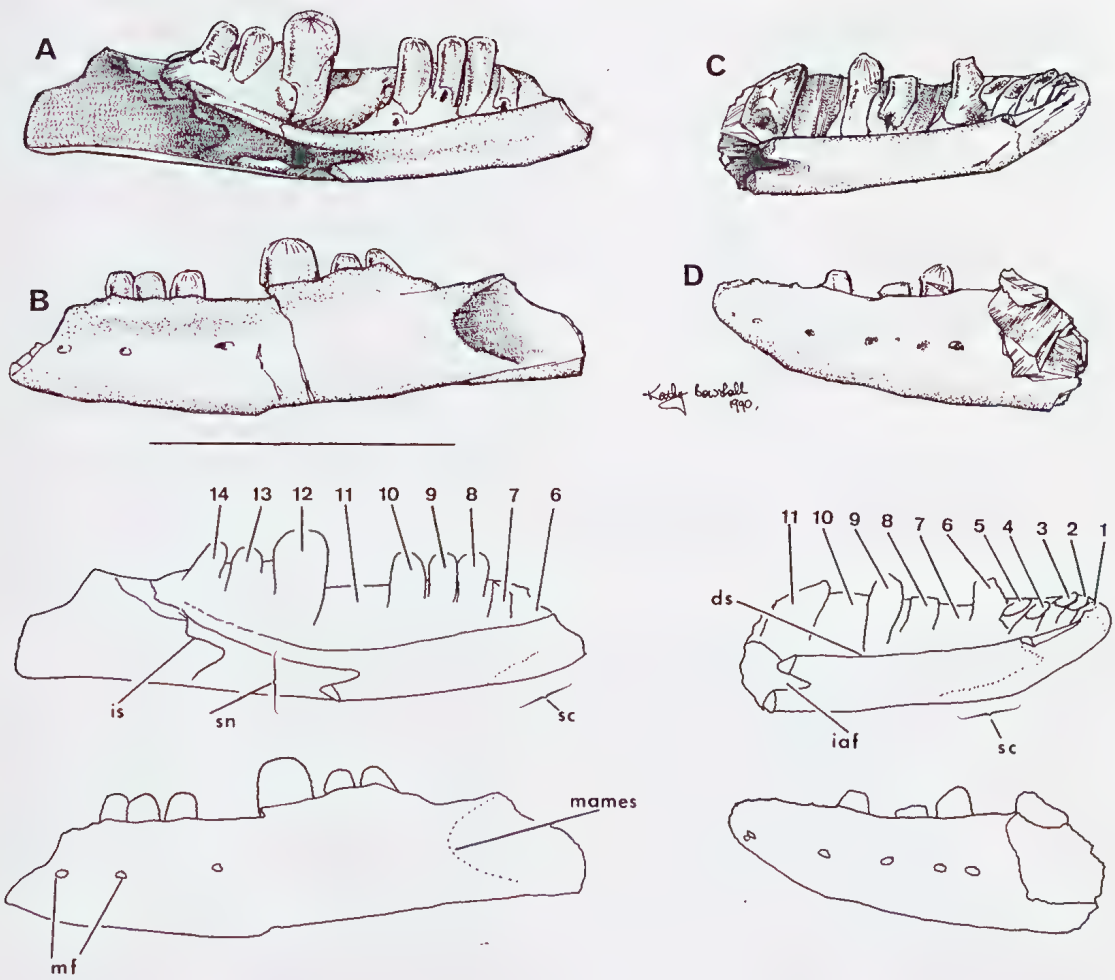

FIG. 1. *Tiliqua pusilla* sp. nov. Holotype (QM F16876, A-B) and paratype (QM F16877, C-D) partial left dentaries in lingual (A, C) and labial (B, D) views. Scale bar equals 5mm. Abbreviations: ds, dental sulcus; iaf, inferior alveolar foramen; is, internal septum; mames, scar for mandibular adductor musclulature; mf, mental foramina; sc, symphysial crest; sn, splenial notch; numbers indicate tooth positions.

higher distally. Crown with radiating striae in occlusal view.

Etymology

From *pusilla*, Latin adjective meaning very small.

Comparison with other Taxa

The closed Meckelian groove of *T. pusilla* is a synapomorphy of both the *Egernia* and *Eugongylus* groups within the subfamily Lygosominae (Greer, 1979). Within these two groups, presence of enlarged teeth in the caudal part of the dental arcade, with the tenth or subsequent dentary tooth largest, is a synapomorphy of the *Tiliqua* lineage (Shea, 1990).

Both specimens are nearly identical in size and morphology and presumably come from different individuals of the same species. The difference in shape of the tooth crowns in mesial profile is probably due to wear in the holotype. The paratype is complete enough to determine that the tenth and (especially) the eleventh teeth are enlarged and, by matching the positions of the symphysial crest and inferior alveolar foramen, it is possible to overlay the two specimens to show that the large tooth preserved in the holotype is the twelfth. Figure 2 shows a composite restoration of the mandible.

Tiliqua pusilla differs from all but one of the

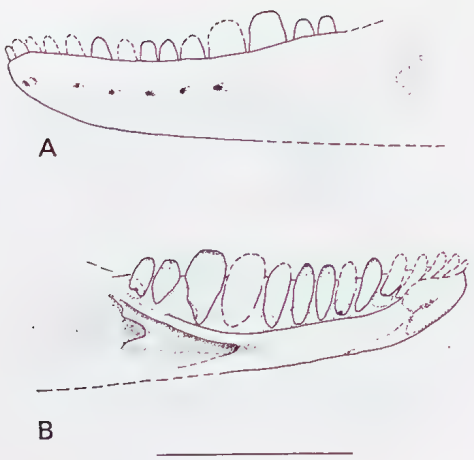

FIG. 2. *Tiliqua pusilla* sp. nov. Diagrammatic restoration of left dentary (A, labial view. B, lingual view) based on holotype and paratype specimens. Scale bar 5mm.

modern species of *Tiliqua* in its lesser size and also in tooth shape. With an estimated dentary tooth row length of 9mm, the holotype is smaller than even neonates of all *Tiliqua* except *T. adelaidensis* (neonate dentary tooth row length of other *Tiliqua* >10mm; neonate dentary tooth row length of *T. adelaidensis* not known, but adult dentary tooth row length of *T. adelaidensis* (8.2-9.3mm, n = 3). Based on the proportions of living members of the *Tiliqua* lineage, this tooth row length indicates a midline skull length of no more than 20mm. Of the seven other species of *Tiliqua*, *T. nigrolutea*, *T. occipitalis* and *T. rugosa* (Fig. 3 a-c) have conical tooth crowns in both lingual and mesial profiles, with a cutting edge directed obliquely across the crown. *T. multifasciata* (Fig. 3d), while having lower, broader teeth, also has a conical apex to the crown, but with a pronounced apical notch. *Tiliqua adelaidensis* (Fig. 3e), while more similar in size to *T. pusilla* has teeth with parallel sides, capped by a low, angulate crown in lingual profile, and slightly compressed in mesiodistal view. *Tiliqua scincoides* and *T. gigas* (Fig. 3f-g) have rounded crowns to the largest teeth and slightly more conical crowns to the more mesial teeth, but in both species a low crest obliquely crosses the occlusal surface. In *T. pusilla*, a distinct notch is present, both on the single unworn tooth of the paratype, and the slightly more worn teeth of the holotype.

Tiliqua pusilla also differs in dental morphology from *Cyclodomorphus*. The teeth of the *C. branchialis* complex (Fig. 3h-i) and *C. casuarinae* (Fig. 3j) have more acutely conical crowns, with the apex towards the distal margin in lingual profile, or even slightly distally recurved. The other two *Cyclodomorphus* species, *C. gerrardii* (Fig. 3k) and *C. maximus*, have very rounded crowns to the largest teeth. In *C. gerrardii*, the teeth are more widely spaced, and the single enlarged tooth is both grossly larger than adjacent teeth, and much lower than in *T. pusilla*. In *C. maximus*, the teeth lack the apical notch and are relatively narrower relative to their height. Further, the mandible of *C. maximus* is relatively more gracile, which is reflected by the much narrower splenial notch in the caudal part of the dentary, and the dentary is larger overall.

Our placement of the species in *Tiliqua* rather than *Cyclodomorphus* is based on one synapomorphy and one character of uncertain polarity. *Tiliqua pusilla*, like modern *Tiliqua*, has a long, low, ventral symphysial crest, extending caudally to the level of the fifth tooth. *Cyclodomorphus* and the closest outgroup to the *Tiliqua* lineage, *Egernia* (Shea, 1990), have a much shorter crest, which may project medially giving a hooked outline. Secondly, the angulate nature of the coronoid margin of the dorsal medial lamina is similar to that seen in modern *Tiliqua*, where it is due to enhancement of a medial buttress on the rostral process of the coronoid. In most *Cyclodomorphus* and *Egernia* the buttress is less developed and more oblique, leaving a more evenly sloping coronoid margin to the dentary.

Tiliqua pusilla is unusual compared with living *Tiliqua* in two features: its small size and the low number of dentary teeth. Both small adult size and reduced number of dentary teeth are common in *Cyclodomorphus*. Thus an explanation for the similarity between *T. pusilla* and *Cyclodomorphus* is needed. The first possibility is that the similarity in size and reduced tooth number is because the specimens of *T. pusilla* are juveniles. However, the specimens are clearly not juvenile as they have a well-defined dental sulcus with a sharply angulate lingual margin, two large teeth and the more mesial teeth subequal in size and showing several cycles of tooth replacement. In juveniles of all *Tiliqua* and *Cyclodomorphus* species, the dental sulcus is poorly-defined, its lingual margin blending with the adjacent dorsal medial lamina. There is only a single large tooth, and the teeth mesial to this one show a distinct alternation in size (Shea, MS).

Since both specimens are adult, the number of dentary teeth is lower than for adults of other *Tiliqua* species, which have more than 14 dentary

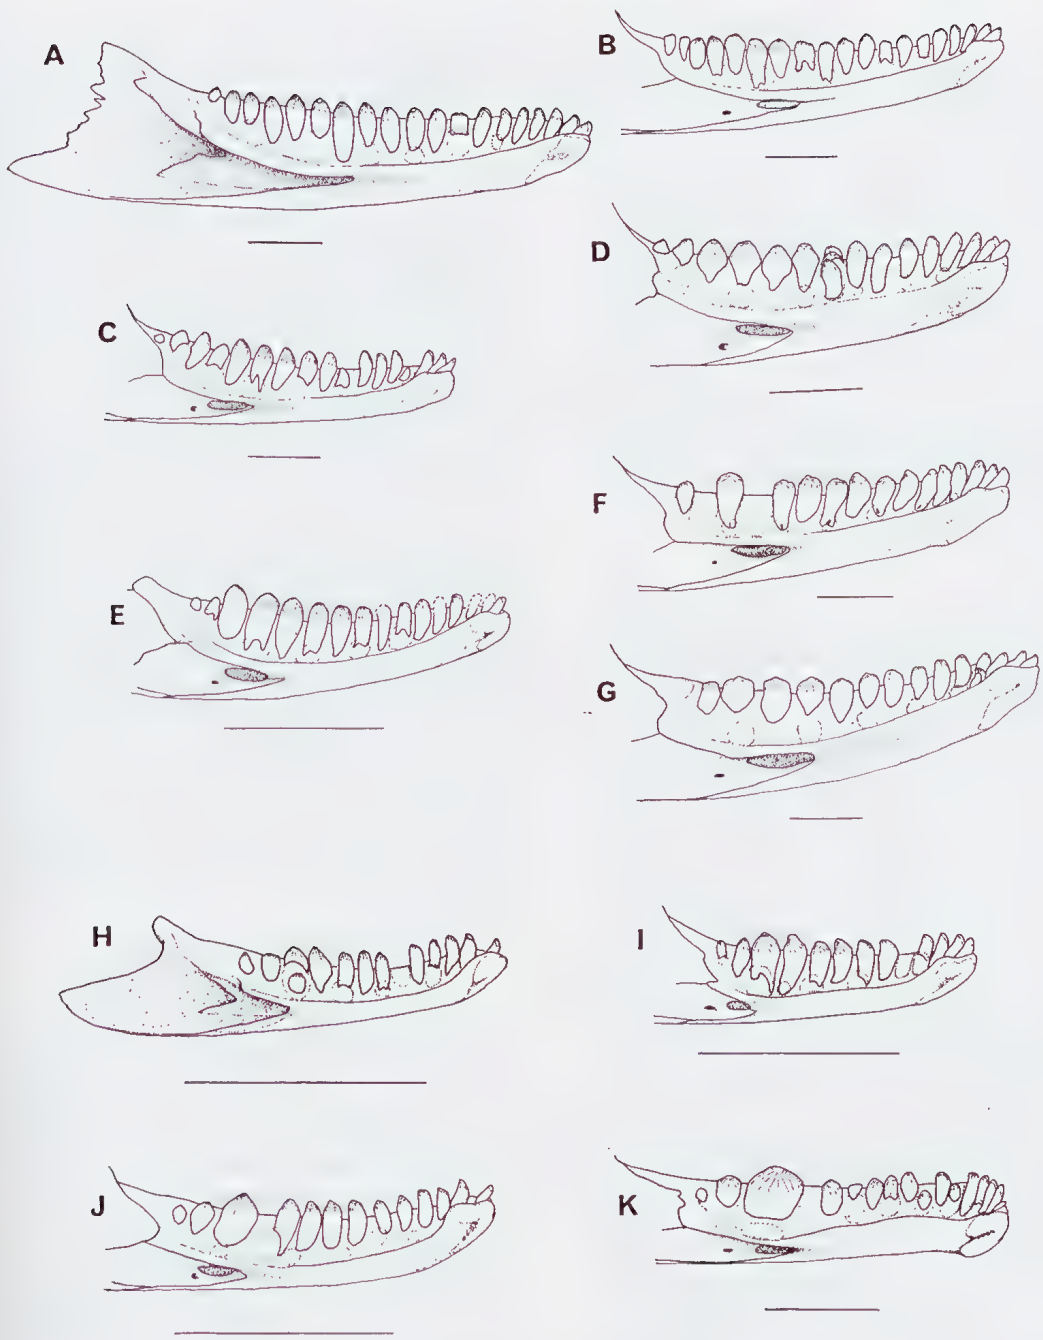

FIG. 3. Lingual views of dentaries of living species of the *Tiliqua* lineage showing variation in proportions, tooth number and shape. A and H are isolated dentaries showing the internal structure and E lacks the coronoid; the remainder are intact mandibles. A, *T. rugosa* (SAMA R27584). B, *T. occipitalis* (SAMA R35758). C, *T. nigrolutea* (SAMA R2725). D, *T. multifasciata* (SAMA R35757). E, *T. adelaidensis* (SAMA R8589). F, *T. scincoides* (SAMA R27037). G, *T. gigas* (SAMA R11419). H, *Cyclodomorphus* cf *branchialis* (SAMA R38021). I, *C. melanops* (SAMA R37565). J, *C. casuarinae* (SAMA R35682). K, *C. gerrardii* (SAMA R35761). Scale bars 5mm.

teeth, and show a progressive distal shift in the number of the largest tooth with age, as estimated by increasing size (Shea, MS). In the *Tiliqua* lineage the two attributes (small size, reduced tooth count) are probably linked since in order to have teeth of sufficient absolute size, small species of the *Tiliqua* lineage may have to make do with fewer teeth overall in each dental arcade. Compared with the similarly-sized *T. adelaidensis*, *T. pusilla* has larger but fewer teeth (14, 11-12 largest, versus 16, 12-14 largest) and a more heavily-built jaw, and was evidently more strictly adapted for durophagy than *T. adelaidensis*, which has thinner, sharper-crowned teeth. This comparison supports the idea that the low number of teeth in *T. pusilla* is a consequence of allometric scaling, with a limit to reduction in tooth size of crushing teeth imposed by the necessity of preserving tooth strength.

Discussion

Tiliqua is one of the most characteristically Australian scincid genera. Morphologically (Greer, 1970, 1979; Shea, 1990), biochemically (Hutchinson, 1981; Baverstock and Donnellan, 1990) and karyologically (Donnellan, 1985), the only living relatives of *Tiliqua* are *Cyclodomorphus*, *Egernia* and *Corucia*, collectively comprising the *Egernia* group (Greer, 1979). Little is known of the history of *Tiliqua* (or of any other skink genus) in Australia.

Tiliqua has been recorded numerous times from Pleistocene to Recent deposits (Krefft, 1867, 1870, 1871; Stirling, 1889; Hale and Tindale, 1930; Tindale, 1933; Cook, 1960, 1963; Mulvaney, 1960; Mulvaney et al., 1964; Trezise, 1970; Lampert, 1971; Thorne, 1971; Marshall, 1973; Bowdler, 1974; Ryder, 1974; M. J. Smith, 1976, 1982; Bartholomai, 1977; Hope et al., 1977; Archer and Brayshaw, 1978; Molnar, 1978, 1982; Williams, 1980; Hope, 1981; M. A. Smith, 1982; Wells et al., 1984) but is almost unknown from the Tertiary. There is one record from the Pliocene Wellington Caves (Hand et al., 1988) and one from the Miocene, based on a statement by Estes (1984) that a specimen of *Tiliqua* had been identified by J. Gauthier among the Kutjamarpu local fauna (Middle Miocene of northern South Australia; Stirton et al., 1967). Both records remain undescribed. The Kutjamarpu local fauna is considered (Archer et al., 1989) to be just older than the Dwornamor local fauna, making the former the the oldest record of the *Tiliqua* lineage. The existence of this specimen in South Australia and *T. pusilla* in Queensland shows that the *Tiliqua* lineage was widespread in Australia by the Middle Miocene.

Identification of the Riversleigh species as *Tiliqua* rather than *Cyclodomorphus* suggests that these sister taxa had diverged prior to the Middle Miocene, pushing the diversification and ultimate origin of the *Egernia* group even further back, potentially to pre-Miocene times. This scenario is incompatible with a previous hypothesis for *Egernia* of rapid Pleistocene speciation following a Pliocene origin (Horton, 1972). A preliminary dating via the 'albumin clock' of around 12 Myr BP for the *Egernia- Tiliqua* split (Baverstock and Donnellan, 1990) is thus also too recent.

The mammal fauna of the Dwornamor local fauna is dominated by arboreal browsers and has a very high diversity (Hand, 1985: Archer & Flannery, 1985; Flannery & Archer, 1987a; 1987b; Archer et al., 1988) with minimally 58 species present (Archer et al., 1989, Table 1). Such diversity would today be found only in a rainforest environment, which has supported the idea of the Dwornamor local fauna as a tropical rainforest fauna. With the exception of *T. gigas*, living species of *Tiliqua* do not inhabit rainforests, so that *T. pusilla*, combining small size and rainforest-dwelling habits, represents a radiation of the genus with no modern parallel. Possibly *Tiliqua* was a more diverse taxon in the past, and/or modern bluetongues represent a recent open-country radiation descended from dwarfish rainforest ancestors.

ACKNOWLEDGEMENTS

MNH thanks M. Archer for the opportunity of describing the Riversleigh skinks. We thank R. G. Zweifel, A.E. Greer, R. Sadlier, J. Covacevich, R. Green, G. Storr and R. Günther who provided access to material in their care, and gave permission to extract skulls where necessary. A. E. Greer, H. Godthelp and R. Sadlier improved the manuscript with their comments. Fig. 1 was prepared by K. Bowshall-Hill. S. Donnellan provided useful information on New Guinean rainforest skinks. Fieldwork by Archer and coworkers at Riversleigh has been funded from the following sources: Australian Research Grants Scheme; Australian Department of Arts, Sport, the Environment, Tourism and Territories; National Estate Programme Grants Scheme; University of New South Wales; Wang Computer Pty Ltd; Australian Geographic Pty Ltd; Mount Isa Mines Pty Ltd; The Queensland Museum; the Australian Museum; The Royal Zoological

Society of NSW; the Linnean Society of NSW; Ansett/Wridgways Pty Ltd; Mt Isa Shire Council; The Riversleigh Society and Friends of Riversleigh.

PERMIAN ECHINODERMS FROM WESTERN AUSTRALIA

GARY D. WEBSTER AND PETER A. JELL

Webster, G.D. & Jell, P.A. 1992 06 29: Permian echinoderms from Western Australia. *Memoirs of the Queensland Museum* **32**(1): 311-373. Brisbane. ISSN 0079-8835.

A new study of the Permian echinoderms of Western Australia included field collection and restudy of several earlier collections. Significant morphologic and stratigraphic details are provided about previously described taxa. New taxa are the crinoids: *Neocamptocrinus barrabiddyensis, N. millyitensis, Stomiocrinus merlinleighensis, Neoplatycrinus callytharaensis, N. miamiaensis, Wrightocrinus wooramelensis, Litocrinus pansus, L. protuberans, Lampodosocrinus variabilis, Cosmetocrinus? middalyaensis, Spheniscocrinus australis, Minilyacrinus williamburyensis, Texacrinus goochensis, T. hardmanensis, T. gascoynensis, Galateacrinus australis, Cymbiocrinus cherrabunensis, Jimbacrinus donnellyensis,* and *Baryschyr? carnarvonensis* and the blastoids *Neoschisma extensum,* and *Rhopaloblastus cuspidus* and the stellaroid *Monaster coleyi.* Echinoid remains are recorded for the first time in the Permian of Western Australia. Ranges of several Carboniferous crinoids are extended into the Permian, including a coelocrinid and pentameric stem-bearing forms. The youngest Palaeozoic crinoids known are described from the Tatarian Hardman Formation of the Canning Basin.

Echinoderms in the Callythara Formation include 16 camerates, 37 inadunates, and 1 flexible among the crinoids, 5 blastoids, and 1 echinoid. Younger Permian strata yielded 3 camerates, 12 inadunates, 1 blastoid, and 1 starfish. Lineages of *Neocamptocrinus, Neoplatycrinus, Texacrinus, Jimbacrinus, Tapinocrinus,* and *Stomiocrinus* are recognised and offer potential for additional correlation of Permian strata throughout Western Australia. □ *palaeontology, Crinoids, Permian, Western Australia.*

Gary D. Webster, Department of Geology, Washington State University, Pullman, Washington 99164-2812, USA; Peter A. Jell, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101; 20 December, 1991.

Echinoderms from the Permian of Western Australia were first recorded from crinoid stems by Foord (1890) who described them from the Gascoyne River bed and by Etheridge (1903) who reported an endophytic fungal infestation of some crinoid columnals from the northern Carnarvon Basin. Teichert (1949, 1954) and Webster (1987, 1990) on crinoids, Breimer & Macurda (1972) on blastoids and Kesling (1969) on starfish provide the only detailed works on the fauna to date; Teichert (1951) gave a useful summary of the fauna as he knew it then. This paper describes new crinoids and blastoids as well as providing much new information on known species and recording echinoid remains for the first time. Fossil echinoderms are known from the Permian of the Perth, Carnarvon (previously referred to as the Northwest Basin and Canning Basins with the oldest occurring in the Sakmarian to Artinskian of the Carnarvon Basin and the youngest in the Tatarian of the Canning Basin. Echinoderm fossils dealt with herein include a crinoid cup from the Fossil Cliffs Formation of the Perth Basin, and a few crinoid and blastoid specimens from the Noonkanbah and Hardman Formations of the Canning Basin but principally derive from the Carnarvon Basin where the Callytharra Formation has yielded the most prolific echinoderm fauna.

Permian geology and stratigraphy of Western Australia has been detailed through the regional mapping efforts, since the late 1940s, of the Bureau of Mineral Resources and the Geological Survey of Western Australia in the 1:250,000 geological map series of the BMR. These results owe some of their success to earlier reconnaissance work of several people but in the context of Permian palaeontology that of Teichert was most significant. He contributed numerous papers and reports but none more significant than his landmark study (Teichert, 1949) on the crinoid *Calceolispongia* and biostratigraphic utility of its distinctive species. This work provided an intrabasinal biostratigraphic scheme for the Carnarvon Basin which remains virtually unchanged today. Studies of the Ammonoidea (several papers listed in Quilty, 1975) have been used to provide an international correlation. Summaries of the geology and stratigraphy were provided by the

Geological Survey of Western Australia (Playford et al., 1975), for the Carnarvon Basin by Condon (1954, 1967), and for the Canning Basin by Veevers & Wells (1961). We have confined our study to palaeontology and relied heavily upon these earlier works as a framework within which to place our findings. A generalised locality map and stratigraphic columns of the Carnarvon and Canning Basins were given in Webster (1990).

PRESERVATION

At Callytharra Springs most echinoderm material is disarticulated except for microcrinoids, microblastoids, and pleuricolumnal sections of stems. A few exceptions of articulated cups of crinoids and blastoids are known but disarticulated plates of these species are also found associated. Associated but disarticulated cup plates, brachials and columnals of particular species are present on the outcrop indicating minor displacement but definite disaggregation by currents or bioturbation. Distortion and fracturing, resulting from compaction, is most common in large relatively thin ossicles or thinner parts of more robust faunal elements. This is most noticeable on large camerates such as *Neoplatycrinus* and the stem of *Neocamp-tocrinus*, a result of the ease of seeing such features on the larger faunal elements. Careful collecting and microscopic investigation show that this also occurs in smaller elements of the fauna.

To the north, exposures of the Callytharra Formation from the vicinity of Mt Sandiman through Williambury Station and into the Gooch Range show carbonate grainstones with minor marls and shales forming hogback ridges with the formation tilted, usually to the west and eroded. Large pluricolumnals, dominated by *Baryschyr*? *carnarvonensis* sp. nov. up to 10cm long, are common in the lower part of the Callytharra Formation. Articulated crinoid cups and crowns, although rather infrequently found, occur on bedding surfaces. Specimens are exceedingly difficult to extract because they are the same hardness as the enclosing grainstones. Most specimens tend to weather at the same rate as the matrix and solution weathering of ossicles often precludes identification. The articulated crowns, often with proximal stem attached, deny postmortem transportation. Most are considered to have died in situ; the cause of death is not apparent. The matrix shows no graded bedding that could imply debris flows or tempestites, but bioturbation is obvious in some grainstones.

Considerable time walking bedding planes and looking at weathered scree, is required to find the rare good specimen. Rarely, sets of arms and crowns are found weathering from thin interbeds of shale or marl. We suggest that numerous crinoid species are to be found in these northern exposures of the Callytharra Formation with careful and patient collecting.

FAUNAL ANALYSIS

The faunal list of our collection from the Callytharra Formation (Table 1) shows that we found most of the species recorded by Webster (1987) except for *Tapinocrinus macurdai*, *T. ingrami*, *T.* sp., *Actinocrinites* sp. cf. *A. brouweri* and a few of the unidentified camerate and inadunate radials.

The Callytharra fauna contains 16 camerate species, 37 inadunates and 1 flexible. As briefly summarised by Webster (1987), most Permian crinoid faunas worldwide are dominated by inadunates. Only the Timor and possibly Bolivian faunas contain significant camerates and flexibles. The Callytharra fauna is the second most diverse Permian fauna in the world after Timor but the virtual lack of flexibles leads us to suggest that the flexibles could not adapt to the cooler water environment of the Australian Permian.

In this paper 2 camerates and 12 inadunates are added to the faunal list as outlined by Webster (1987). These include three holdover genera, a coelocrinid (*Dorycrinus*), barycrinid indet., and *Cosmetocrinus*, not previously recorded from the Permian (Moore & Teichert, 1978). The youngest possible ancestors are to be found in the Early Carboniferous of North America. The new inadunates include *Minilyacrinus* gen. nov. and new species of *Lampadosocrinus, Texacrinus, Galateacrinus* and *Baryschyr*? not previously recorded in the region. Only *Texacrinus* was previously reported from the Permian. The microcrinoids described are the first described from Australia. *Wrightocrinus, Litocrinus* and Timorechinidae indet. are known from Timor thus strengthening faunal links between the two areas.

The Basleo fauna of Timor is the most diverse Permian crinoid fauna known in the world. It contains 232 species as opposed to the 56 species so far recorded in the Callytharra Formation. Although study of the Timorese collections housed in European museums leads one of us (GDW) to believe that restudy of the inadunates may reduce the number of species recognised it will remain an incredibly diverse fauna. Teichert (1951) con-

TABLE 2. Lineage chart and stratigraphic distribution of the echinoderm fauna of the post-Callytharra Fmn Permian of WA. Taxa from Teichert (1949) are not included as they were well placed stratigraphically in the original work. Callytharra through Wandagee Fmns are in stratigraphic sequence for the Carnarvon Basin. The Fossil Cliffs Formation of the Perth Basin is temporally equivalent to the Callytharra Fmn. The Noonkanbah Fmn (equivalent to the Coyrie through Wandagee Fmns) and Tatarian Cherrabun Mbr, Hardman Fmn are in the Canning Basin.

warm water environment favourable to a higher carbonate productivity. In contrast the abundant clastic sedimentation of the Western Australian Permian and the type of sediment suggest not only nearer shore, more turbid environments but also cooler water environments with less carbonate production. The cooler water environment of the Permian deposits of Western Australia were recognized by Condon (1967) and Dickins (1978) among others. We consider the echinoderms of the Western Australian Permian to be those that could adapt better to the greater diversity of environments and note that a few are unknown in Timor (*Texacrinus*, *Cosmetocrinus* and the coelocrinid).

The post Callytharra crinoids of Western Australia, following the work of Teichert (1949, 1954), Webster (1990) and this paper, number 3 camerate and 12 inadunate genera. These forms occur mainly in sandstone or shale with rare exceptions such as *Stomiocrinus merlinleighensis* and *Jimbacrinus donnellyensis*. Many occur in clusters with multiple specimens of few species along bedding planes. Many specimens were disaggregated in part indicating postmortem current or scavenger activity. Cross-bedding, scour and fill and ripple marks were observed in these sandstones recording current activity. Bioturbation is evident but not extensively.

Crinoids of the Cherrabun Member, Hardman Formation in the Canning Basin (Table 2) are among the youngest Palaeozoic crinoids known. The age of this horizon, which also yielded the ammonoid *Cyclolobus persulcatus* Rothpletz, 1892, is discussed by Glenister et al. (1990) as Dzhulfian (i.e. within the Tatarian of the European scale). All three species represent lineages common in the Carboniferous of North America. *Cymbiocrinus* is known from the Permian of Thailand (Webster & Jell, in prep.); *Neocamptocrinus* is known only from Australia (Willink, 1980; Webster, 1990; herein).

LINEAGES

Teichert (1951) considered that only one crinoid showed a lineage of stratigraphic utility in Western Australia. Based on knowledge at the time his view was correct. However, the added information from the Callytharra and younger fauna reveals several parallel lineages; some may have biostratigraphic utility through Western Australia, the rest of Australia and even to Timor and India. The *Calceolispongia* lineage detailed by Teichert (1949) remains the most useful for Western Australia but it also needs revision in the light of extensive new collections and its potential for correlation in the Canning Basin has yet to be addressed.

Other lineages that we recognise in Western

Australia (Table 2) are species within each of *Neocamptocrinus, Neoplatycrinus, Texacrinus, Jimbacrinus, Tapinocrinus* and *Stomiocrinus*. Although these are considered independently it should be noted that *Neocamptocrinus, Neoplatycrinus* and *Calceolispongia* occur together at most horizons in the Permian of Western Australia suggesting that they needed similar living conditions.

Stems of *Neocamptocrinus* are found in most horizons with marine fossils from the Callytharra to the Hardman Formations. They have not been studied in detail. Specimens that we have observed show greatest size in the Wandagee Formation (Artinskian) (Fig. 3M,N). Cups, thecae and crowns of *Neocamptocrinus* are uncommon. They are known from the Bulgadoo Shale *N. barrabiddyensis* sp. nov., from the Cundlego Formation, *N. occidentalis*, and from the Hardman Formation, *N. millyitensis*. These three species are considered an evolutionary lineage with *N. occidentalis* evolving from *N. barrabiddyensis* by elongation of the cup with nearly vertical walls distally. In turn, *N. millyitensis* evolved from *N. occidentalis* with a more flattened basal circlet, reduction in the number of plates in the anal series above the primanal and modification of the ornament on tegmen plates. Webster (1990) discussed the relationship of *N. occidentalis* and *N.* n. sp. (=*N. millyitensis*) with eastern Australian species (Willink,1980).

Stomiocrinus merlinleighensis in the Bulgadoo Formation could be the ancestor of *S. ferruginus* in the Wandagee Formation by enlargement, modification of the arms by shortening and thickening the brachials and reduction of the relative size of the orals. Timor species of *Stomiocrinus* are probably derived from *S. merlinleighensis* by modification of oral plates and flattening of the tegmen. *Stomiocrinus* is unknown in eastern Australia.

Evolution of *Neoplatycrinus miamiaensis* from *N. callytharraensis* by modification of the ornament from one large prominent node to several large nodes and probably flattening of the basal circlet forming a low bowl-shaped cup. The "twist" nodals and internodals currently assigned to *Platycrinites/Neoplatycrinus* spp. and commonly found associated with the disarticulated plates of *Neoplatycrinus* probably belong to the genus. Unfortunately they were probably static in evolution during the Early Permian and show no significant differences or evolutionary trends. Although not reported, "twist" columnals are present in the Oxtrack Formation of the Cracow area, Queensland. Additional study of the platycrinid columnals of Australia is needed to fully evaluate their stratigraphic potential.

The tapinocrinids are known from Western Australia and Timor. In Western Australia, *Tapinocrinus macurdai* and *T. ingrami* are known from the Callytherra Formation with the former the likely ancestor of *T. spinosus* from the Wandagee Formation and Basleo fauna of Timor. Development of *T. spinosus* was by flattening of the cup into a disc shape, enlargement of the radials into a blunt spine and loss of granular ornament. Although the spine did not develop, *T. timoricus* also lost the ornament and developed a discoid cup. There is no record of *Tapinocrinus* in eastern Australia.

The texacrinids are represented in Western Australia by four species starting with *T. goochensis* in the Callytharra Formation followed by the more robust *T. gascoynensis* in the Cundlego or Wandagee Formation. No further form of this heavier stock is known. *Skaiocrinus granulosus* is a more elongate form with or without slightly peneplenary radial facets and pinnules with longitudinal ridges. The youngest form *T. hardmanensis* is a slender elongate form which may have evolved through *T. goochensis* from the same stock as *S. granulosus*. Texacrinids are unknown in eastern Australia.

Teichert (1949) considered the origin of *Calceolispongia* to be uncertain but perhaps derived from the Cromyocrinidae. Moore *et al.* (in Moore & Teichert, 1978) suggested that the Calceolispongidae were derived through the Cymbiocrinidae or Ampelocrinidae. We consider the Cymbiocrinidae line to be most likely based on the bowl-shaped cup, large single anal and cuneate arms. The lineage of *Jimbacrinus* is not as clear as that of *Calceolispongia* but may include a sequence from Calceolispongidae? sp. (Webster, 1987) from the Callytharra Formation to *J. donnellyensis* in the Bulgadoo Shale to *J. bostocki* Teichert, 1954 in the Cundlego Formation to *J. minilyaensis* Webster, 1990 in the Wandagee Formation and possibly to *Cymbiocrinus cherrabunensis* in the Hardman Formation.

Webster (1987) noted the resemblance of Calceolispongidae? sp. to the calceolispongids but considered differences in the lack of bulbous basals and presence of an isotomous branching on the third brachial in one ray. If the branching had been on the second brachial the specimen would have been assigned to *Cymbiocrinus*. Calceolispongidae? sp. probably derived from the same ancestor as *Calceolispongia*. *J. donnellyen-*

sis may have evolved from Calceolispongidae? sp. by thickening of the basals and loss of arm branching. In turn *J. bostocki* evolved by development of the spines on the bulbous basals whereas *J. minilyaensis* has a reduction in the bulbous basals, possibly representing a different lineage from Calceolispongidae? sp. *Cymbiocrinus cherrabunensis* is related to the calceolispongids mostly by the bulbous basals; the arm branching pattern, however, is not typical of that family.

The second largest Permian crinoid fauna of the Carnarvon Basin occurs in the Wandagee Formation in the east limb of a syncline on the north bank of the Minilya River, approximately 10km westnorthwest of Wandagee Homestead. This locality is the type locality for several species of *Calceolispongia* (Teichert,1949) and other crinoids (Webster,1990). Some confusion about the stratigraphy has resulted from nomenclatural changes. Teichert (1949) considered the Wandagee Formation to include the unit later named the Quinnanie Shale. Thus some of his material is reported as from the upper Wandagee on locality information at the University of Western Australia when it is actually from the lower Wandagee Formation as defined by Condon (1967) (see Material section under *Occiducrinus australis* and *Skaiocrinus granulosus* (herein; Webster,1990).

There has also been some confusion about the locality. Webster (1990), in citing locality data from the University of Western Australia, listed the locality as east of Coolkilya Pool. Teichert (pers. comm. 1990 to GDW) corrected this to west of Coolkilya Pool as shown on the Winning Pool-Minilya 1:250 000 Geological map (sheet SG50-13, 49-16, 1984). When we stopped at Wandagee Homestead the directions we received to Coolkilya Pool took us further west than the location shown on maps. It is obvious, when on the site, that the size and location of the pool or pools along the river bed shift with scour and fill during major runoff and evaporation and infiltration during subsequent dry seasons. Coolkilya Pool as designated on the map and as referred to by the locals are not the same. Teichert apparently used the local designation in his original field locations and recognized they differed when trying to reconcile the Bureau of Mineral Resources map locations.

In the base of the Wandagee Formation as defined by Condon (1967) *Occiducrinus australis, Eoindocrinus praecontignatus, Calceolispongia abundans*, and *Neocamptocrinus* sp. occur along the same bedding surface. *Tapinocrinus spinosus, Skaiocrinus granulosus* and *Jimbacrinus minilyaensis* occur at or close to the same horizon. *Stomiocrinus ferruginus* may also be from the equivalent horizon along the Lyndon River to the north. Several species of *Calceolispongia* occur at higher levels in the Wandagee Formation as described by Teichert (1949).

AGE AND CORRELATION

Discussion of the age and correlation of the Callythara Formation at its type section was given by Webster (1987). We accept the late Sakmarian age for the base of the Callytharra Formation based on ammonoids (Glenister & Furnish, 1961). New taxa reported herein do not alter Webster's (1987) interpretation that the crinoids suggest a slightly younger age of early Artinskian for the Callytharra Formation. The Sakmarian-Artinskian boundary may be within the lower part of the Callytharra Formation.

Notiocatillocrinus callytharraensis, Synbathocrinus constrictus, Neoplatycrinus callytharraensis and *Neocamptocrinus* sp. in the Callytharra Formation throughout the Carnarvon Basin suggests a similar age for the unit over this extent. Correlation of the Callytharra Formation with the Fossil Cliffs Formation of the Perth Basin, and Nura Nura Member of the Poole Sandstone in the Canning Basin were discussed by Teichert (1951) and Condon (1967). Webster (1987) discussed the crinoid correlation of the Callytharra Formation with that of eastern Australian faunas reported by McKellar (1969) and Willink (1978). The late Sakmarian-early Artinskian limestone interval in the basins of Western Australia, in the Oxtrack Formation in Queensland, and the Berriedale Limestone and limestone in the Crinoidal Zone of Tasmania represent a major sea level rise and change to warmer conditions in the Australian part of the Tethyan equivalent to the Sterlitamak and possibly Birshevian cycles (Ross & Ross,1985).

Correlation with the Permian crinoids of Timor remains somewhat of a problem. The crinoid bearing Maubisse Formation limestones of northern Timor were interpreted as reefs and thought to have been thrust onto the autochthonous non-crinoidal Permian strata of southern Timor (Audley-Charles,1965,1968). He considered the Timor Permian deposits to have formed in a trough to the northwest of Australia. Charlton (1989) suggested that the northern part of Timor was allochthonous but thought much of the struc-

FIG. 1. Coelocrinid indet. QMF21428. A, lateral view showing set of arms with distal part of spinose anal tube at upper right, ×1. B, incurved distal parts of flattened arms and spinose anal tube, ×1.6.

tural complexity was best explained by wrench faulting , not by vertical movements as postulated by Chamalaun and Grady (1978). All of these interpretations agree that the Permian deposits of Timor were formed in and along the distal side of a trough that was part of the Australian block as proposed by Hamilton (1979).

The crinoid bearing Maubisse Formation would have been the most distal deposits, an unknown distance, but perhaps as much as 1000km northwest of the Canning and Carnarvon Basins. Plate reconstructions of the Permian (Zonenshain, Kuzim and Kononov, 1985, among others) position Australia along the eastern part of Gondwanaland. The Carnarvon and Canning Basins would have been between 50° S and 40°S. Timor would have been at approximately 25°–30°S. The Timor faunas were considered Late Permian on reports of fusulinids at Amarassi (Schubert,1915) and cephalopods at Basleo (Wanner,1931; Gerth,1950). Haniel (1915) interpreted the cephalopods as middle Permian, on the Early to Late Permian boundary. Brachiopods (Broili,1916) and corals (Gerth, 1921) indicated a Permian age but did not specify Early or Late, whereas C. Wanner (1922) placed an Early Permian age on the gastropods and bivalves. The echinoderms were interpreted as Carboniferous (Bather, 1914; Springer,1920, 1924), in contrast to middle Permian (Wanner, 1924a) and Late Permian (Wanner, 1931).

The lack of stratigraphic control of the numerous crinoid and blastoid localities from Timor has been recognized for many years (Audley Charles, 1965; Glenister & Furnish,1987; among others). Some cephalopod reports with and without stratigraphic control at a few localities include Sakmarian from Somohole, Artinskian from Bitauni, and Late Permian from Amarassi and Basleo (Glenister & Furnish,1987). Grant (1976) considered the Bitauni brachiopods to be of Artinskian age. Sections with stratigraphic control have yielded brachiopods from the Chiddruan Maubisse Formation near Kasliu Village, West Timor (Archbold & Bird,1989) and from the late Sakmarian Khali and Bisnain Members of the Maubisse Formation near Bisnain Village, West Timor (Archbold & Barkham, 1989). The Bisnain brachiopods were correlated with the Callythara Formation by Archbold & Barkham (1989). Artinskian conodonts were recovered from matrix materials and *in situ* limestone blocks collected on early expeditions to Timor (Boogaard, 1987). Thus Timor Permian strata is thought to range from Sakmarian to Amarassian age. Wanner (1931) reported that 90% of Timor crinoids and 75% of all other Permian fossils of Timor are from the Basleo area. It is the age of the Basleo fossils which we consider to be the most problematic because a Late Permian cephalopod has been reported by Glenister and Furnish (1987) from the area. The stratigraphic relationship of the cephalopod and crinoids is unknown.

International correlation based on the crinoids and blastoids suggests an Early Permian age, probably Artinskian or Roadian for the Basleo echinoderms. The Basleo crinoids and blastoids correlate best with Artinskian faunas from the Callythara Formation (12 of the same genera, 3 species; 2 species with affinities and 3 genera with close affinities to Timor genera), the Wandagee Formation (4 of the same genera, 1 species) and the Sarginsk Horizon of the Urals (15 genera). There are few genera and no species in common with the Early Permian of Texas (3 genera), Nevada (7 genera), and Bolivia (2 genus). Few genera and no species are common to the Upper Permian of Russia (1 genus), Sicily (5 genera), Western Australia (1 genus), and eastern Australia (2 genera). These data have been compiled from crinoid occurrences indexed in Bassler & Moody (1943), Webster (1973, 1977, 1986, 1988), and unpublished data.

Until the structure and stratigraphy of the Basleo area are fully understood we consider the echinoderm fauna to be Early Permian recognizing that part of the fauna could be Late Permian based on the cephalopod reported by Glenister & Furnish (1987).

SYSTEMATIC PALAEONTOLOGY

Crinoid terminology follows Ubaghs et al. (in Moore & Teichert, 1978), with columnal patterns after Webster (1974). Blastoid terminology is from Beaver et al. (in Moore, 1967).

Material collected by us during July 1991 came from localities entered in the Queensland Museum Locality Register (QML), and is curated in the Queensland Museum Palaeontological Collection (QMF). Other collections referred to are indicated by the following prefixes: Commonwealth Palaeontological Collection, Bureau of Mineral Resources, Canberra (CPC), Museum of Victoria, Melbourne (NMVP); Western Australian Museum, Perth (UWAF) and Department of Geology, University of Western Australia, Perth (UWAF).

F, paratypes CPC30671, (lower right) and CPC30672, lateral views; note distal arm branching on CPC30672.

Subclass CAMERATA Wachsmuth & Springer, 1885
Order MONOBATHRIDA Moore & Laudon, 1943
Suborder COMPSOCRININA Ubaghs, 1978
Superfamily CARPOCRINOIDEA de Koninck & Le Hon, 1854
Family COELOCRINIDAE Bather, 1899

Coelocrinid? indet
(Fig.1)

MATERIAL

QMF21428, a large, weathered, partial set of arms with anal tube, found in three pieces, two of which fitted together, from the middle Callytharra Formation in the eastern line of the Gooch Range south of Carnarvon-Williambury Station road, GR922549 Gooch Range 1: 100,000 topographical sheet (no. 1850), 1974 edition.

DESCRIPTION

Arms spatulate, at least 63.8mm long, biserial, convex in section proximally (1.7mm wide), becoming externally flat distally (4.4mm wide); distally bearing short, laterally directed spines on every 7th to 9th brachial on each side of the arm, with the spines in alternating positions; distal tips incurved towards a slender elongate anal tube extending above the arms and bearing short spines along the tube walls.

REMARKS

This specimen bears remarkable similarity to the illustration (Wachsmuth & Springer, 1897, pl. 42, fig. 5) of *Dorycrinus cornigerus* (Hall, 1858). Anal tube spines of *D. cornigerus* are longer, extending beyond the arms when enclosed. Long spatulate arms are known in several genera of the Batocrinidae and Coelocrinidae (Wachsmuth & Springer, 1897); however, only those of *D. cornigerus* have short laterally directed spines along the sides of the arms. Thus we questionably refer the specimen to the Coelocrinidae.

This is the first Permian report of the otherwise Middle Devonian to Early Mississippian European and North American family (Moore & Teichert, 1978). Other camerates, such as *Actinocrinites*, *Pleurocrinus* and *Camptocrinus*, initially restricted to Early Carboniferous strata of Europe and North America were discovered in the Permian of Timor (Wanner, 1916, 1924a). Thus,

a possible coelocrinid in the Permian of Western Australia adds to the list of camerate holdovers lacking a Late Carboniferous record.

Superfamily HEXACRINITOIDEA Wachsmuth & Springer, 1885

Family DICHOCRINIDAE Miller, 1889

Subfamily CAMPTOCRININAE Broadhead, 1981

Neocamptocrinus Willink, 1980

TYPE SPECIES

Neocamptocrinus bundanoonensis Willink,1980, from the Kazanian Berry Formation, New South Wales; by original designation.

REMARKS

Willink (1980) recognised *Neocamptocrinus* on the inflated tegmen and a column that is elliptical throughout its length instead of round adjacent to the cup as is *Camptocrinus*. Carboniferous and Permian camptocrinid columns show that the elliptical shape is similar in both, that is nearly round, but definitely slightly elliptical, adjacent to the cup becoming progressively elliptical in a few centimetres distally and remaining elliptical throughout the remainder of the known column. The long axis of the columnal attains its greatest size in the Permian of Western Australia (Fig. 3M,N). Cups assigned by Willink (1980), Webster, (1990) and herein show an evolutionary and stratigraphic record of potential value for the Permian of Australia and Timor. We question the degree of inflation of the tegmen as a generic feature; however, for convenience we apply the name to these Permian forms including *Camptocrinus* cf. *C. indoaust-ralicus* Wanner (Webster,1987:102, fig. 5J-M).

Columnals of *Neocamptocrinus* are common in many parts of the Permian of Western Australia (Webster, 1987, 1990; herein). Even proximal, nearly circular columnals are easily recognised by the distinctive, off centre, axial canal and unequal length of culmina on the opposing long sides of the articulum. Additional study of *Neocamptocrinus* columnals in Western Australia is necessary to determine their strat-igraphic value. Columnals of *Neocamptocrinus* sp. are present in the Callytharra Formation at all localities we collected. No cups were found, but the radials listed as indeterminate camerate radial 4 and 5 by Webster (1987) probably belong to a new species of *Neocamptocrinus*.

Neocamptocrinus barrabiddyensis sp. nov. (Fig. 2A-C)

ETYMOLOGY

For Barrabiddy Creek.

MATERIAL

Holotype CPC30668, Bulgadoo Shale, east limb of Barrabiddy Anticline, Barrabiddy Paddock, 1/4 mile south of mill.

DIAGNOSIS

Radial notches relatively narrow; radials more expansive.

DESCRIPTION

Cup bowl-shaped, wider (29.1mm) than high (21.8mm), base truncated, widest at base of radial facets, sutures flush, no ornamentation. BB 2, suture faint, 5.6mm wide, 5.5mm high, upflared, slightly concave walls. RR 5, longer (19.4mm) than wide (16.0mm), gently convex transversely, convexo-concave longitudinally. Radial facets angustary, c. 2/3 radial width; transverse ridge elevated, with coarse ridges normal to ridge length; brachial canal circular in section; muscle fields elliptical, long axis subparallel to transverse ridge, moderately impressed; ambulacral groove narrow, sloping inward. Anal longer (19.6mm) than wide (11.3mm), narrower than and in line with radials. Columnal facet elliptical, 8.7mm long, 63mm wide, impressed; articulum narrow; culmen coarse, cog-like, areola wide, flat. Stem and arms unknown.

REMARKS

This robust cup was weathered out of red claystone containing abundant disarticulated plates of *Calceolispongia* cf. *barrabiddyensis*. It has narrower radial notches, radials that distally expand transversely at a greater rate and lower radial facets than *N. occidentalis* Webster, 1987 or *N. millyitensis* sp. nov. These two species probably evolved from *N. barrabiddyensis*.

Neocamptocrinus millyitensis sp. nov. (Fig. 3A-L)

Neocamptocrinus sp. nov. Webster, 1990:57, pl. 1, figs 7-11.

ETYMOLOGY

For the Millyit Range.

MATERIAL

Holotype CPC27054, paratypes CPC27455-27457 from the Millyit Range. Other material, QMF21420-

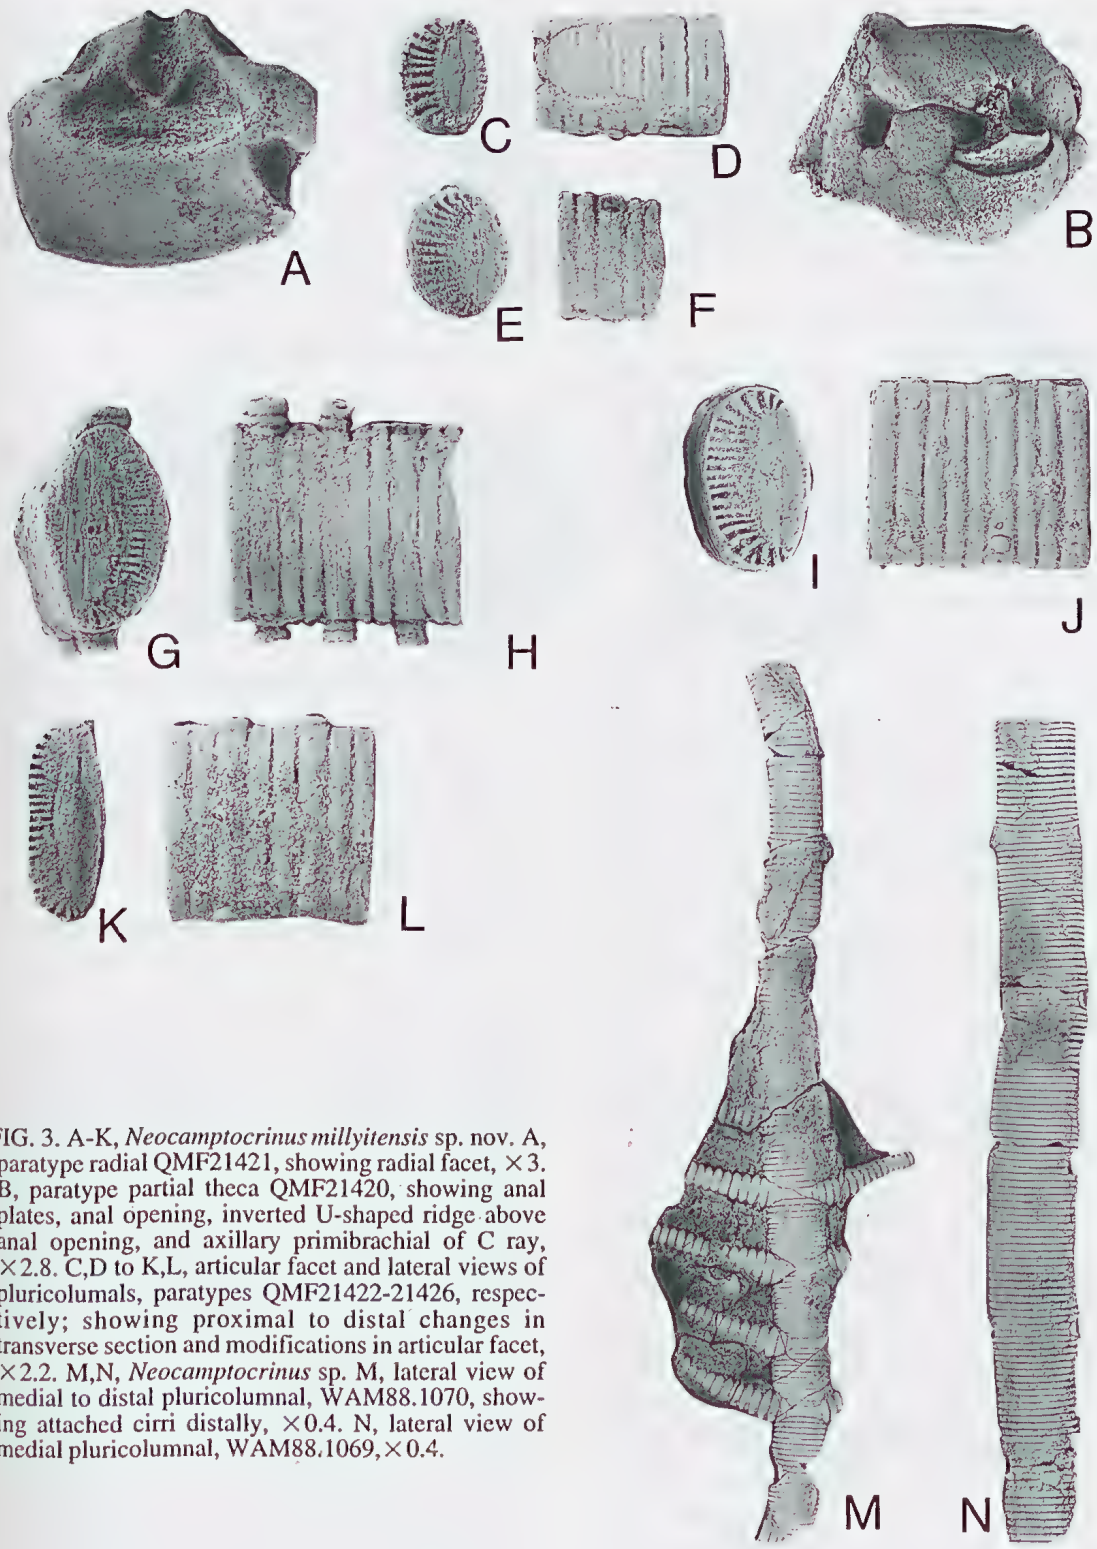

FIG. 3. A-K, *Neocamptocrinus millyitensis* sp. nov. A, paratype radial QMF21421, showing radial facet, ×3. B, paratype partial theca QMF21420, showing anal plates, anal opening, inverted U-shaped ridge above anal opening, and axillary primibrachial of C ray, ×2.8. C,D to K,L, articular facet and lateral views of pluricolumals, paratypes QMF21422-21426, respectively; showing proximal to distal changes in transverse section and modifications in articular facet, ×2.2. M,N, *Neocamptocrinus* sp. M, lateral view of medial to distal pluricolumnal, WAM88.1070, showing attached cirri distally, ×0.4. N, lateral view of medial pluricolumnal, WAM88.1069, ×0.4.

21426 from QML772,Millyit Range, Canning Basin from the Cherrabun Member, Hardman Formation,

DESCRIPTION

See Webster, 1990:57.

REMARKS

Webster (1990) left material available at that time in open nomenclature because its precise locality and horizon were unknown. We have now collected further material from a well-defined locality and horizon, which may well be the type locality.

The partial theca shows 3 anal plates, with a large primanal in the radial circlet, a small anal opening above the central anal plate and an inverted V-shaped ridge on the overlying oral. Both orals bear a coarse central node. Radial facet has a transverse ridge with a parallel shallow outer ligament pit, two shallow muscle fields and a T-shaped ambulacral track aborally.

Pluricolumnals are mostly short segments but show the change in sectional shape from nearly circular proximally to distally elliptical. The articular facet of the proximal columnals has long coarse culmina on the upper side of the columnal and very short culmina on the under side. Culmina become coarser laterally on the facet. The areola is higher on the upper side with faint traces of culmina across the surface. On the underside, the areola is smooth and half the width of that on the upper side. Axial canal is small and round.

Neocamptocrinus sp.
(Fig. 3M,N)

MATERIAL

Pluricolumnals WAM88.1069-88.1070 from north bank, Minilya River in the fourth massive sandstone of the Wandagee Formation, Coolkilya Pool area, Wandagee Station. Collected K.J. McNamara.

REMARKS

These are the longest articulated pluricolumnals of *Neocamptocrinus* known from Western Australia. They are 28cm and 28.5cm long with columnals 30mm wide, 9mm thick and 2.2mm high. In a proximal direction noditaxes consisted of 22, 23, 24, and 26 columnals each on WAM88.1069. Cirri are initiated at the junction between two columnals and may grow to extend over the height of four columnals; the axial canal is also shared by the two columnals. Columnal growth after initial growth of the cirrus extends beyond the distal edge of the proximal cirral to partly cover the proximal end of the second cirral. Cirri are round in section. Crenularium 1.8mm wide, slightly less than half cirral radius (4.1mm); culmina fine. Areola planar. Axial canal small and round. Cirri taper distally with semipointed ends. These large columnals lack the more rounded proximal and distal sections of the stem. They show that considerable lengths of the stem acted as a runner with the cirri extended out and down into the substrate. It is unknown if the flexures in the two stem sections reflect flexibility around substrate irregularities or diagenetic distortion.

Stomiocrinus Wanner, 1937

TYPE SPECIES

Stomiocrinus subglobosus Wanner, 1937 from the Permian of Timor; by original designation.

Stomiocrinus merlinleighensis sp. nov.
(Fig. 2D-F)

ETYMOLOGY

For the Merlinleigh Subbasin, Carnarvon Basin.

MATERIAL

Holotype CPC30669, paratypes CPC30670-30676 from micaceous limestone in the top of the Bulgadoo Shale, at type locality, near Donnelly's Well.

DIAGNOSIS

Orals elongate, steeply upflared, visible in lateral view.

DESCRIPTION

Crown small, cylindrical. Cup bullet-shaped, widest at radial summit, fine shagreen ornamentation. BB 2, equidimensional, forming lower 1/3 of cup, upflared steeply; interbasal suture in plane of symmetry. RR 5, longer than wide, outflaring gently longitudinally, moderately convex transversely, straight to slightly convex longitudinally. Radial facets angustary, approximately 1/3 greatest radial width, subhorizontal. Brachials rectilinear, longer than wide, strongly convex transversely, straight longitudinally; IBr2 or 3 axillary; one additional branching in some rays; all branchings isotomous. No pinnules. Anal in radial circlet, slightly narrower than radials. OO 5, elongate, steeply upflared, raised medial section flush to slightly inset to proximal brachials, mutual lateral edges underlay proximal brachials and form base of ambulacral groove from the base of the arms to the mouth. Posterior oral largest.

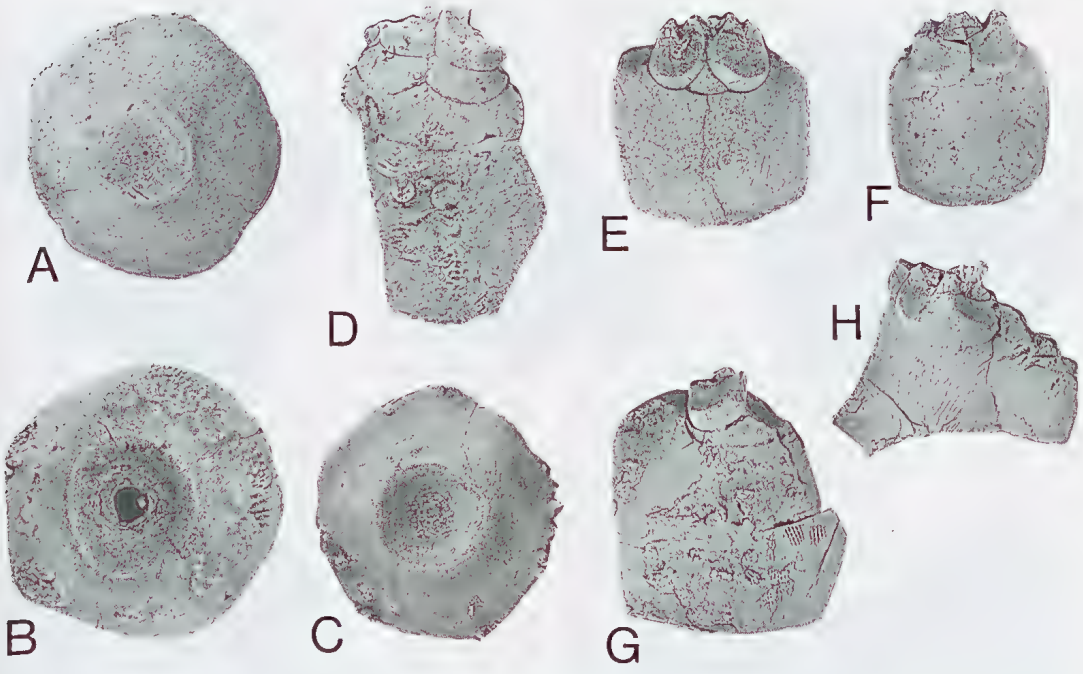

FIG. 4. *Neoplatycrinus callytharraensis* sp. nov. all from QML757, ×1. A-C, basal circlets QMF21594, 21593, and 21592, respectively. D–H, radials with primibrachs and in some cases secundibrachs attached, QMF21595, 21599, 21597, 21598, and 21596, respectively.

MEASUREMENTS (mm)

	Holotype	Paratype
Crown length	3.6 (incomplete)	3.3
Crown width	1.5	1.2
Cup length	1.6	1.2
Cup width	1.3	1.1
Basal circlet diameter	0.7	0.7
Basal circlet length	0.6	0.6
Radial length	1.0	0.8
Radial width	0.8	0.7

REMARKS

Stomiocrinus is reported from the Permian of Timor, Russia (Broadhead, 1981) and Western Australia (Webster, 1990). Broadhead (1981) assigned *Stomiocrinus* to the Camptocrininae based on Yakovlev's (in Yakovlev & Ivanov, 1956) combination of disassociated thecae and bilaterally symmetrical columnals. The crowns of *S. merlinleighensis* occur on three small blocks associated with *Jimbacrinus donnellyensis* and *Calceolispongia acuminata*. None of the crowns of *S. merlinleighensis* has the stem attached whereas the crowns of *J. donnellyensis* have the proximal stem attached. It is unknown if the proximal stem of *C. acuminata* is attached.

In the matrix there are numerous thin round pluricolumnals which contain columnals of 4mm diameter and 7mm length that might have been the stem of *S. merlinleighensis*. They differ from the short cirral segments (7mm diameter, 2mm long) which are articulated with the attached stems on *J. donnellyensis*. There are no bilaterally symmetrical columnals in the matrix. This leaves the subfamily affinity of *Stomiocrinus* in doubt until articulated thecae and columnals are found.

Superfamily PLATYCRINITOIDEA Austin & Austin, 1842

Family PLATYCRINITIDAE Austin & Austin, 1842

Neoplatycrinus Wanner, 1916

TYPE SPECIES

Neoplatycrinus dilatatus Wanner, 1916, from the Permian of Timor; by original designation.

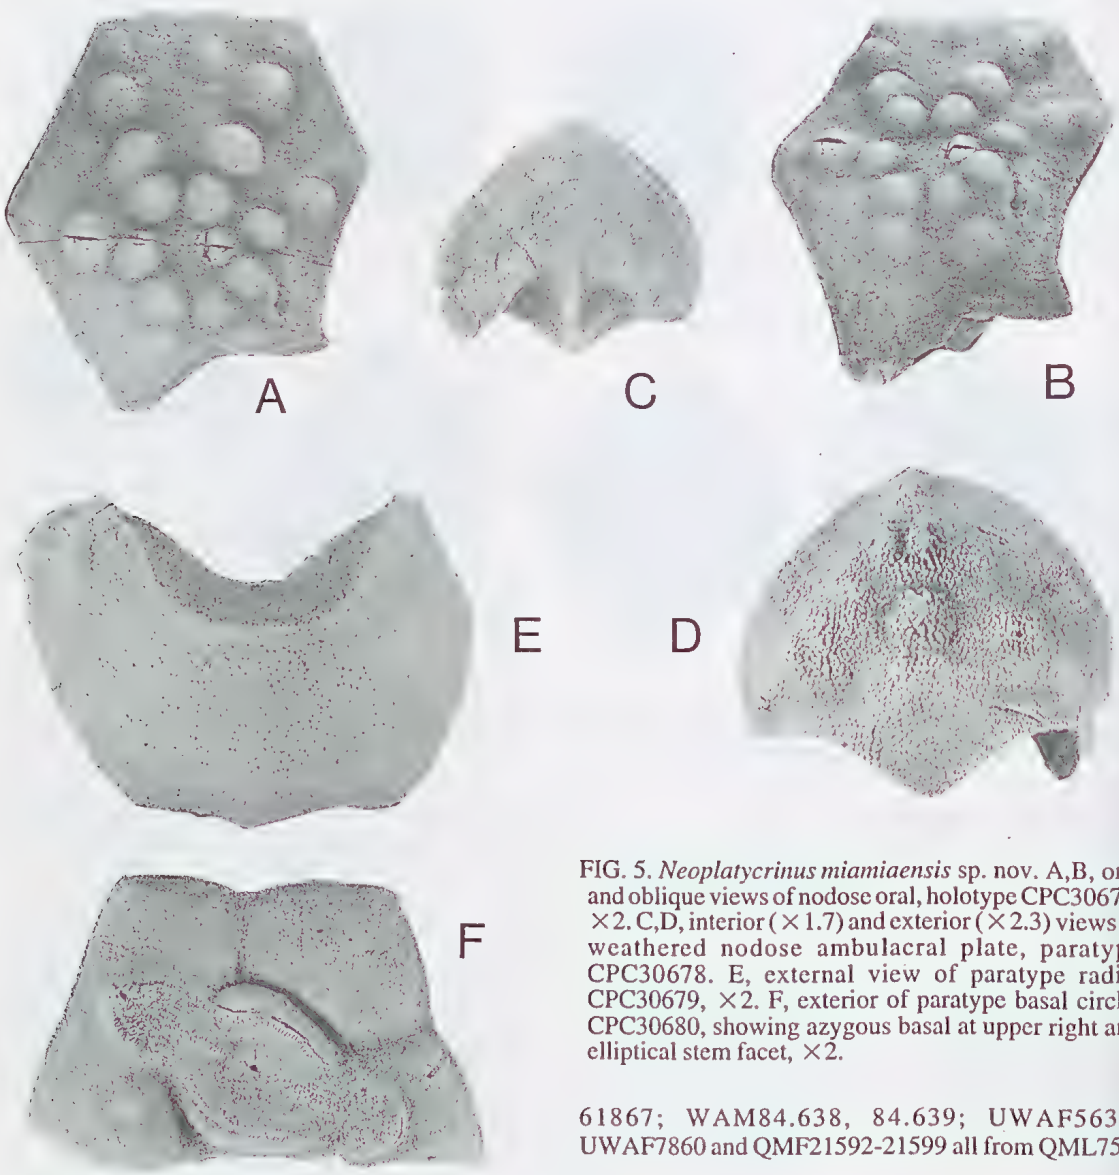

FIG. 5. *Neoplatycrinus miamiaensis* sp. nov. A,B, oral and oblique views of nodose oral, holotype CPC30677, ×2. C,D, interior (×1.7) and exterior (×2.3) views of weathered nodose ambulacral plate, paratype CPC30678. E, external view of paratype radial CPC30679, ×2. F, exterior of paratype basal circlet CPC30680, showing azygous basal at upper right and elliptical stem facet, ×2.

Neoplatycrinus callytharraensis sp. nov. (Fig.4)

Neoplatycrinus aff. *N. somoholensis* Wanner, 1916; Webster, 1987:100, figs 4A-O.
Pleurocrinus? sp. Webster, 1987:101, fig. 4P,Q.

ETYMOLOGY
For Callytharra Springs.

MATERIAL
Holotype UMMP61862. Paratypes UMMP61863-61867; WAM84.638, 84.639; UWAF5638, UWAF7860 and QMF21592-21599 all from QML757.

DIAGNOSIS
Oral and ambulacral plates with large node or coarse ridges.

DESCRIPTION
As given by Webster, 1987, p. 100-101.

REMARKS
This species is based on disarticulated oral and ambulacral plates bearing one very large node and secondary smaller nodes or very coarse discontinuous ridges. Basal and radial plates assigned lack these coarse nodes as is the case in *N.*

miamiaensis, described below. We found the ornamented orals and ambulacral plates disassociated in proximity to the unornamented basal circlets and radials.

Webster, 1987, referred the Callytharra Formation specimens to *N.* aff. *N. somoholensis*, a species based on internal molds (Wanner, 1916, 1924a). The ambulacral plates of *N. somoholensis* are divided distally by a deep V-shaped separation (Wanner, 1924a, pl. 3, fig. 2). Division on the ambulacral plates of *N. callytharrensis* is not as deep (Webster, 1987, fig. 4A). The upper distal part of oral plates of *N. somoholensis* would overhang the proximal vertical section whereas they do not on *N. callytharraensis*. All other described species of *Neoplatycrinus* lack ornamentation on the oral and ambulacral plates.

Neoplatycrinus miamiaensis sp. nov.
(Fig. 5)

ETYMOLOGY

For Mia Mia Station.

MATERIAL

Holotype CPC30677, paratypes CPC30678-30681 all from the lowermost fossiliferous horizon in the Artinskian Coyrie Formation, east of Mia Mia Homestead, 23°21'S, 114°34'E, northern Carnarvon Basin. Other material CPC30711-307153, a columnal, 2 radials and 2 tegmen plates from the lower part of the Noonkanbah Formation at the type section (BMR loc. KNF73), Canning Basin.

DIAGNOSIS

Basal circlet subhorizontal; orals and ambulacrals bearing coarse nodes in radiating to irregular patterns.

DESCRIPTION

Basal circlet large, estimated 32mm diameter, subhorizontal; bears elliptical stem facet, 2.3mm long, 9.3mm wide. BB 3, 2 large, 1 small (16mm long, 15.5mm wide) surface coarsely granulate, with coarse node (2.8mm diameter) on one plate. RR 5, wider (28.4mm) than long (20.7mm), convex longitudinally and transversely, surface with coarse granules, no nodes. Radial facet wide, 2/3 plate width, narrow, crescent shaped. OO 5, large, estimated 35mm long, 28.2mm wide, polygonal, proximally vertical, distally subhorizontal or upflared, with 8 to 18 coarse nodes (4.4mm diameter, 2.8mm high) in radiating or irregular pattern and coarse granular ornament. Proximal ambulacral quadrangular, 18.9mm long, 19.3mm wide, sharply pointed proximally and distally, side vertical, exterior with up to 9 coarse nodes and coarse granular ornamentation.

REMARKS

The description is based on disarticulated ossicles from one horizon in the Coyrie Formation. The theca is estimated to have been up to 75mm wide and 45mm high, with a low bowl shape having a flat base, low out-flared radials, and a broad flat to upflared tegmen. Interpretation of the theca is based on: 1, a flat wide basal circlet (Fig. 5F); 2, radials attached to the vertical facets on the basal circlet such that the proximal end of the radial was horizontal, expanding the low bowl laterally; 3, radials are convex longitudinally resulting in the distal parts of the radial being essentially vertical; the radial facet would have sloped down and out at an estimated 80°; and 4, the proximal end of the orals was probably nearly vertical and the distal part subhorizontal to upflared perhaps as much as 40°. Mutual facets on the radials and orals are not well preserved precluding firm estimate of reconstruction.

Secundibrachials associated with the thecal plates bear the same coarse nodes and granulate ornamentation. They are U-shaped with two deep V-shaped ambulacral grooves, one large and one smaller and lateral. Most plates show growth bands on the aboral side. Solution weathering has modified the surfaces of most plates, removing or obliterating the granular ornament is common, and in extreme examples nodes are reduced to small stellate elevations. Diagenetic distortion and fracturing followed by calcite cementation sealing the fractures is present on some plates.

Numerous internodals and nodals of the "twist" nodal columnals were found in association with the thecal plates. They are assigned to the species because all other crinoids in the fauna are non platycrinitids. No difference could be discerned between these columnals and ones found in the Callytharra Formation. This suggests that mosaic evolution was occurring in the theca while the columns were stable.

Neoplatycrinus is restricted to the Permian of Timor (Lane in Moore & Teichert, 1978) and Western Australia (Webster, 1987). The genus is recognized by the large oral plates. *N. miamiaensis* is distinguished from *N. callytharraensis* by its oral and ambulacral plate ornamentation. It differs from *N. somoholensis* by having a flat base instead of being upflared at 30° to 40°. Evolution of *N. miamiaensis* from *N. callytharraensis* occurred by modification of oral and ambulacral ornament.

The original field label on specimens of *N.*

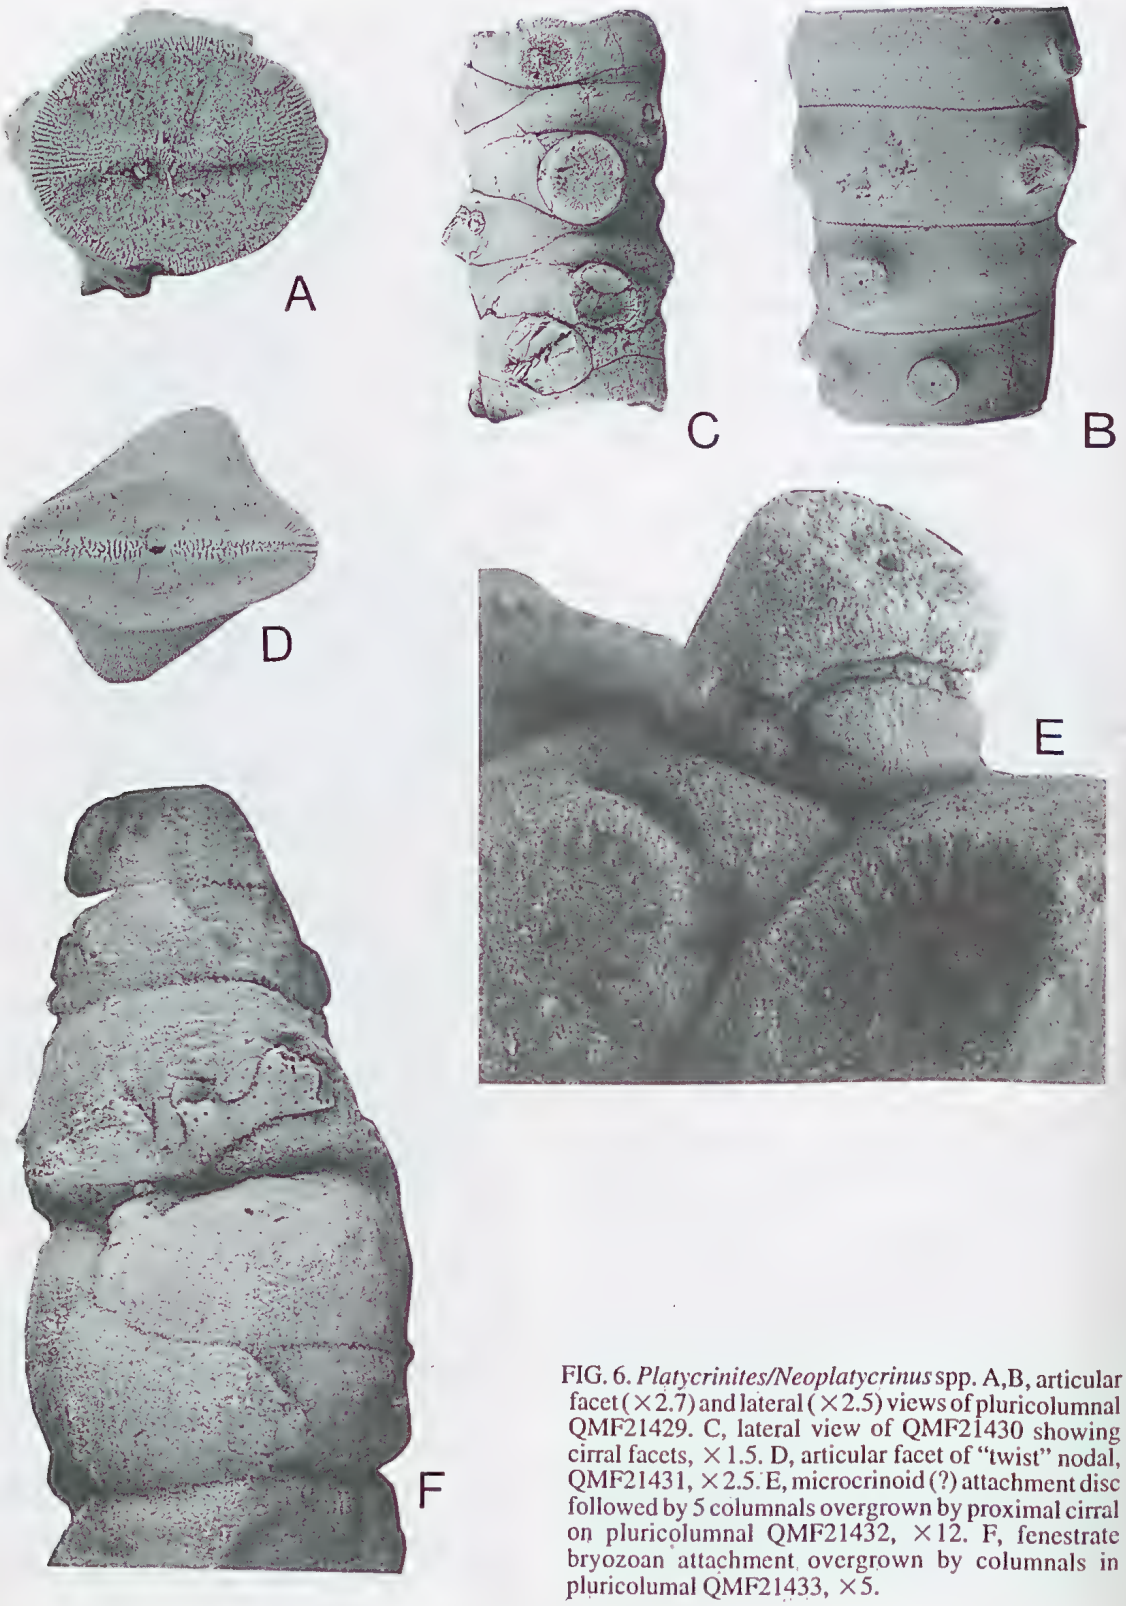

FIG. 6. *Platycrinites/Neoplatycrinus* spp. A,B, articular facet (×2.7) and lateral (×2.5) views of pluricolumnal QMF21429. C, lateral view of QMF21430 showing cirral facets, ×1.5. D, articular facet of "twist" nodal, QMF21431, ×2.5. E, microcrinoid (?) attachment disc followed by 5 columnals overgrown by proximal cirral on pluricolumnal QMF21432, ×12. F, fenestrate bryozoan attachment overgrown by columnals in pluricolumal QMF21433, ×5.

miamiaensis gave the stratigraphic unit as the Bulgadoo Shale. However the latitudinal coordinates place the locality in the Coyrie Formation as mapped on the Winning Pool-Minilya 1:250,000 Geological Sheet SF50-13, 1984.

The columnal, radials and tegmen plates from the Canning Basin bear the same ornamentation on the oral and brachial as described above.

Platycrinites/Neoplatycrinus spp.
(Fig. 6)

MATERIAL

Figured material QMF21429,21431 from QML760, QMF21430, 21432, 21433 from QML757 and other material 181 internodals, 102 nodals and 39 pluricolumnals QMF21578 (203) from QML757, QMF21579 (26) from QML758, QMF21580 (14) from QML759, QMF21581 (13) from QML760, QMF21582 (9) from QML761, QMF21583 (19) from QML758-761, QMF21584 (18) from QML769 and QMF21585 (6) from QML770.

DESCRIPTION

Internodals elliptical, opposing fulcral ridges parallel; nodals rectangular to subquadrate, opposing fulcral ridges at 15-80° with most 67° or 80°. All columnals wider than high, elliptical axial canal, very fine shagreen ornamentation. Noditaxis variable, 1-5 internodals. Articulum divided in half by prominent fulcral ridge. Fulcral ridge depressed below articular rim adjacent to axial canal, bears transverse vermiform to short medium coarse ridges proximally, 3 to 7 medium coarse slightly radiating culmina distally. Crenularium narrow; culmina short, medium coarse, lengthening near fulcal ridge, producing a fan shaped pattern, unbranched. Areola divided by fulcral ridges, each half crescent in outline, smooth, sloping into shallow trough paralleling fulcral ridge, deepest abaxial of axial canal. Axial canal small, elongate parallel to fulcral ridge. Latus gently to moderately convex on lateral sides, moderately convex to vertical to gently concave on ends of internodals, rarely bears small nodes. May bear cirri in distal most parts of stem.

Cirri round transversely; articulum round. Crenularium 1/3 radius; culmina coarse, cog-like, may branch isotomously once. Areola smooth, flat. Axial canal round.

REMARKS

The elliptical columnals vary from elongate (18.6 x 9.4mm) to subcircular (21.8 x 19.5mm) in adults. The more subcircular specimens are mostly cirral bearing and judged to be more distal columnals, whereas the more elongate elliptical forms lack cirri and are considered to be more proximal. Thickness of individual nodals and internodals is uniform except in the cirral bearing distal stem parts where they show pinching and swelling in lateral view.

Cirral facets occur on nodals or internodals and slant distally 5-10°. They are most commonly developed on one or both ends of the long axis but also occur along the short axis of the facet. There are up to 4 cirri per columnal, with one the most common. First cirrus is wedge shaped with distal facet sloping distally thereby increasing the distal slope of the cirrus. Cirri short, tapering distally.

Most specimens are weathered with loss of surface articulum and axial canal details and enhancement of growth bands. Up to 11-14 growth bands weathered as ridges and grooves. Similar growth bands on large cup plates of *Neoplatycrinus* aff. *N. somoholensis*, *Platycrinites wrighti* and *Pleurocrinus*? sp. were illustrated by Webster (1987). These columnals probably belong to those species and are therefore left in open nomenclature.

Organisms attached to the living column of *Platycrinites/Neoplatycrinus* spp. include bryozoans (Fig.6F) and other crinoids (Fig.6E) as both are found overgrown by columnals or cirri. *Phosphannulus* infestations are rare on *Platycrinites/Neoplatycrinus* spp. Columnals, as postmortem detrital grains were used as attachment sites by various sessile organisms but most commonly bryozoans. Diagenetic compaction distorts the areola of numerous specimens.

Wrightocrinus wooramelensis sp. nov.
(Fig. 7A,B, I-K)

ETYMOLOGY

For the Wooramel River.

MATERIAL

Holotype QMF21438 from QML757, paratypes

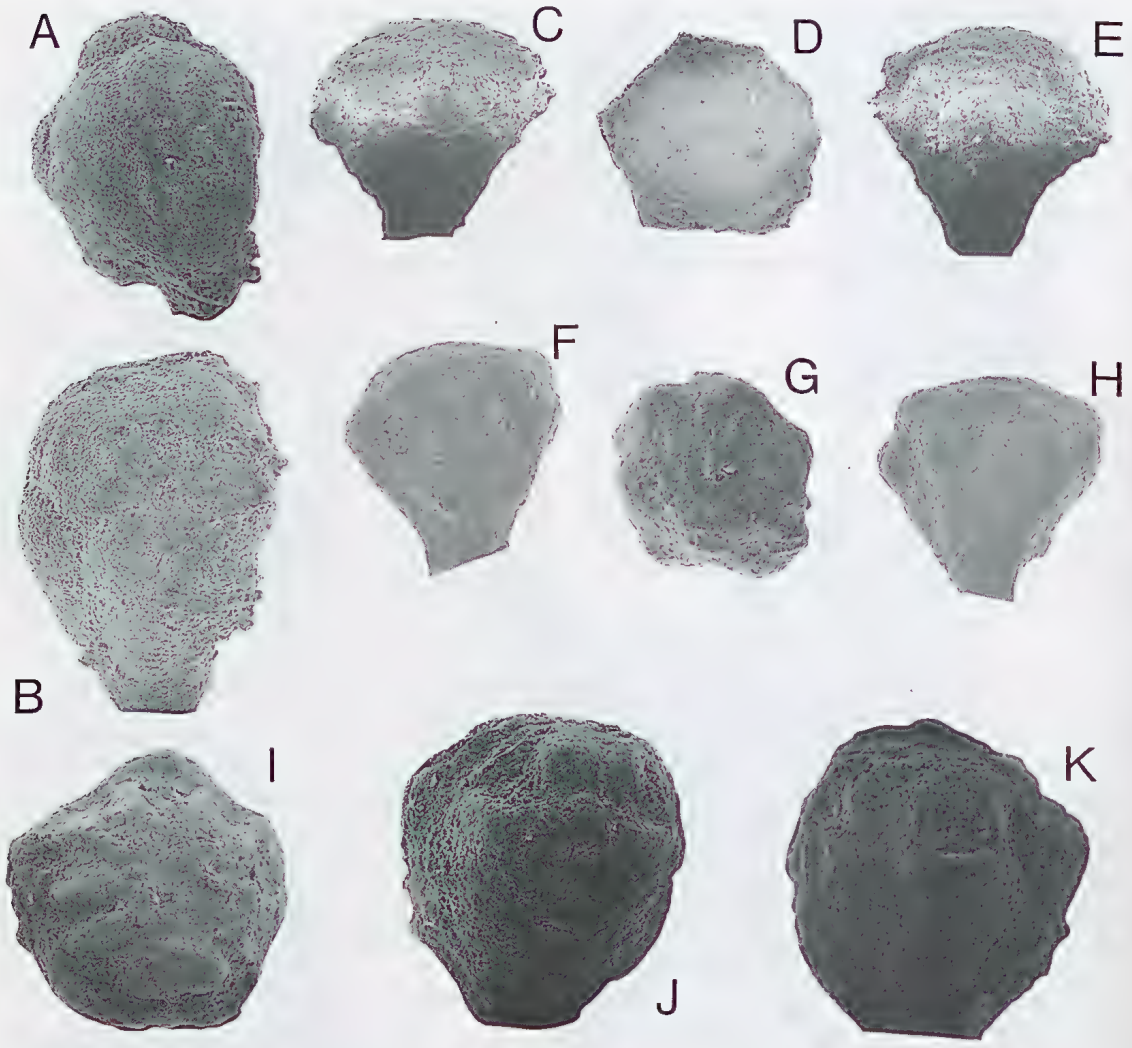

FIG. 7. A,B, I-K, *Wrightocrinus wooramelensis* sp. nov. oral and C ray views of partly crushed paratype QMF21439, A ×30; B ×40. I-K, oral, posterior and A ray views, of holotype QMF21438, ×30. C-H, *Litocrinus pansus* sp. nov. C-E, AB interay, oral and D ray views of holotype QMF21448, ×40. F-H, A ray, oral and posterior views of paratype QMF21449 ×40.

QMF21439 (QML760), CPC30692 (QML757-761) and three crushed thecae QMF21554 (QML759), QMF21555(QML761), all from west of Callytharra Springs.

DIAGNOSIS

Radials protuberent; radial facets narrow; basals short; orals with an elongate central depression.

DESCRIPTION

Theca 1.1mm high, 1.0mm wide, globose, convex walls in lateral view, rounded pentagonal outline in oral view, walls smooth. BB 2, suture slightly rotated off A-CD plane, low, proximally horizontal, bearing round articular facet for stem, distally upturned, flaring outward, forming lower 1/5 of cup. RR 5, 3/4 as wide as long, widest at midlength, outflared proximally, incurved distally, moderately convex longitudinally, transversely gently convex proximally, strongly convex distally, with one facet each; radial facets peneplenary, sloping inward, pit-like. Slight anal notch on mutual shoulders of C and D radials. OO 5, elliptical, slightly longer than wide, central linear depression bordered by rounded low ridge,

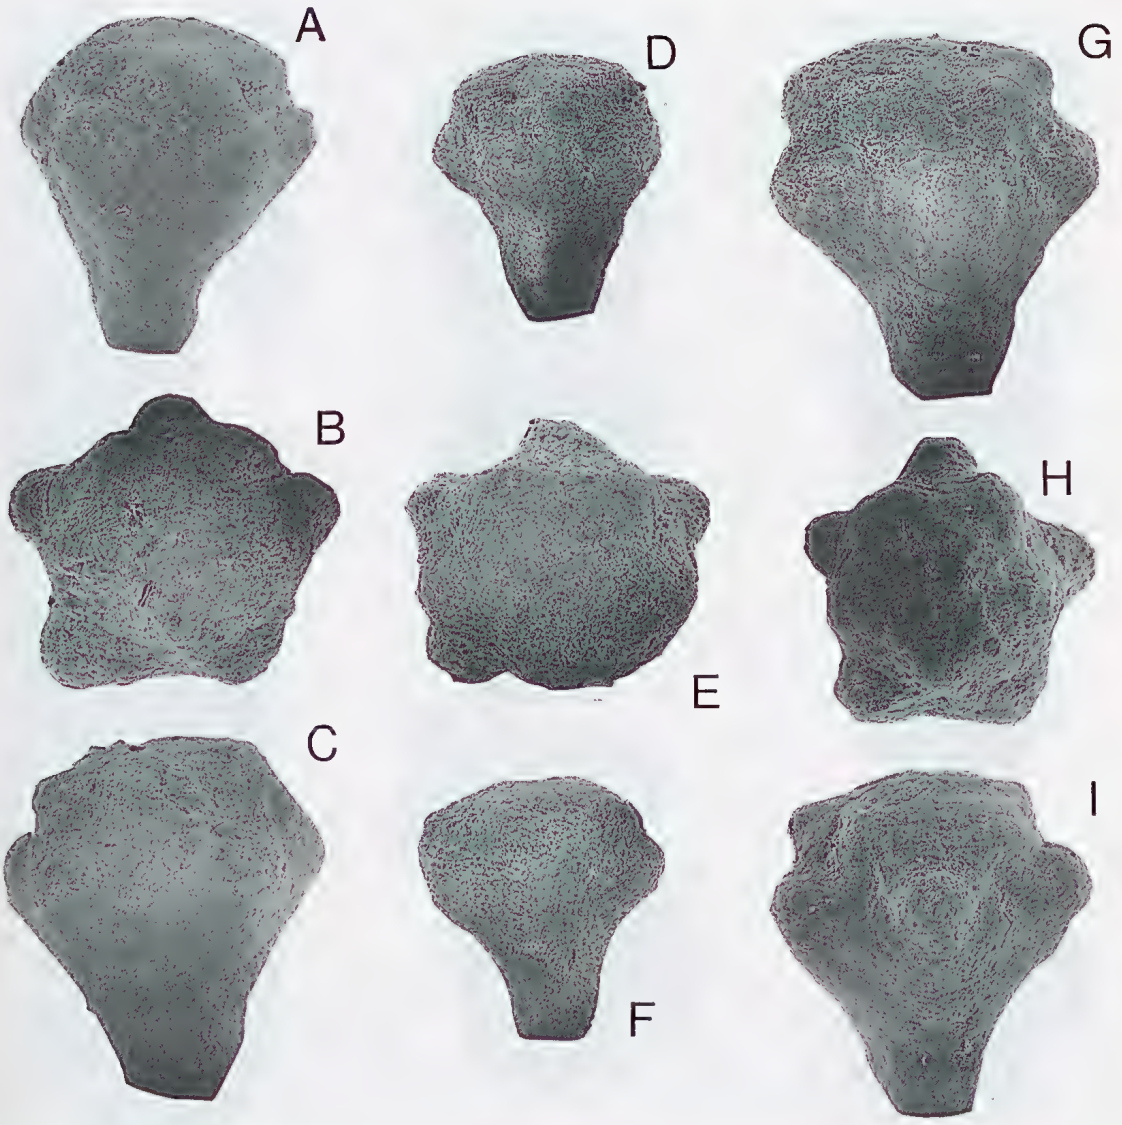

FIG. 8. *Litocrinus protuberans* sp. nov. A-C, BC interray, oral and posterior views of paratype QMF21441, ×40. D-F, A ray, oral and posterior views of paratype QMF21442, D ×40; E ×50; F ×40. G-I, A ray, oral and E ray views of holotype QMF21440, ×40.

form flat-topped elevated circlet slightly inset from radial summit. Posterior basal largest, as wide as long, separating BC and DE orals.

REMARKS

The holotype has a small calcite deposit on the EA oral extending onto the mutual shoulders of the E and A radials. At a cursory glance this falsely appears to be the posterior oral. The posterior oral is recognised by the suture with the other four orals and the small anal notch below it. All specimens of *W. wooramelensis* may be immature, lacking the development of additional arms in the A, C and D rays.

The globose appearance of *W. wooramelensis* is similar to immature specimens of *W. jakovlevi* (Wanner, 1929) but distinguished from it by having more protuberant radials, narrower radial facets, shorter basals and orals bearing an elongate central depression. Webster & Jell, in press, discussed the reasons, essentially that one is a

MATERIAL

Holotype QMF21448 from QML760, paratype QMF21447, 21449 from QML757, QMF21446 from QML759, and other material QMF21556 (1) from QML757, QMF21557 (3) from QML759, QMF21558 (1) from QML760 and QMF21559 from QML761.

DIAGNOSIS

Theca expanded markedly above narrow basal circlet; oral circlet dome-shaped.

DESCRIPTION

Theca small, equidimensional, 0.4-0.6mm, pyriform, walls concave. expanding rapidly above basal circlet, unornamented. BB 5 or fused, small, forming lower 40% of cup, gently outflared. RR 5, longer than wide, moderately convex transversely, concave longitudinally with straight to convex distal ends, may be weakly protruding distally. OO 5, rounded proximal edge in oral view, proximally steeply upflared, distally subhorizontal, may bear weakly elevated protrusion at upflaring to subhorizontal flexures, forming domed arch with diameter less than thecal max. just below radial summit; posterior oral larger, separating BC and DE orals.

REMARKS

L. pansus is variable in development of protrusions on orals and may develop a weak node distally on the radials. Without careful observation *L. pansus* could be considered a juvenile or variant of *L. protuberans*. However, the species differs from *L. protuberans* by the greater lateral expansion, lack of strongly protruded radials and

more rounded dome shape of the oral circlet. It is the smallest form in the Callytharra fauna.

Litocrinus protuberans sp. nov.
(Fig. 8)

ETYMOLOGY
Latin *protuberosus*, protuberant; for the radials.

MATERIAL
Holotype QMF21440 from QML759, paratypes QMF21441 from QML758, QMF21442, 21443 from QML759, QMF21444 from QML760, QMF21445 from QML757, and other material QMF21560 (8) from QML757, QMF21561 (3) from QML758, QMF21562 (15) from QML759, QMF21563 (19) from QML760, QMF21564 (3) from QML761, QMF21565 (5) from QML757-761.

DIAGNOSIS
Radials with evenly rounded large protuberances.

DESCRIPTION
Thecae small, largest specimen 1.1mm high, 0.9mm wide, turbinate to pyriform, walls expand rapidly from base of radials to large protuberances in distal part of radials, capped by oral circlet, strongly pentalobate in oral view, unornamented. Basals fused, bear circular stem facet proximally, gently outflaring distally, forming lower 1/3 of cup. RR 5, slightly longer than wide, expanding rapidly upward, longitudinally concave proximally to strongly convex distally, transversely gently convex proximally strongly convex distally; large smooth growth protuberance on distal part of radial. No anal notch on plates. OO 5, slightly longer than wide to subequal to wider than long, slightly irregular outer surface, vertical to slightly inflared proximally, subhorizontal to gently arched distally. Posterior oral largest, separating BC and DE orals, bearing small hydropore or madreporite. Oral circlet slightly inset on radial summits.

REMARKS
Growth sequence from 0.4-1.1mm present in the 67 specimens studied. Initially the theca is equidimensional and the radial protuberances are recognisable but not domineering as the cup wall flares moderately and evenly from the stem facet to the radial protuberances. As growth continues radials elongate and the protuberance expands to become the most noticeable morphologic feature of the theca. The base of the cup is relatively narrow and most of the wall flaring is with the radials.

No other species of *Litocrinus* has as strongly protruded distal parts of the radials as *L. protuberans*. There is a large node in the centre of each radial on the Late Permian *L. palermoensis* (Strimple & Sevastopulo, 1982) from Sicily that is a later evolved form.

Family CATILLOCRINIDAE Wachsmuth and Springer, 1886.

Notiocatillocrinus Willink, 1978

TYPE SPECIES
Notiocatillocrinus oakiensis Willink, 1978, from the Lower Permian of NSW; by original designation.

Notiocatillocrinus callytharraensis
Webster, 1987 (Fig. 14E)

Notiocatillocrinus callytharraensis Webster, 1987: 108, figs 7, 8.

MATERIAL
One weathered crown NMVP127202 from Fossil Hill, Bidgermia Station, GR351884 on Glenburgh 1:250,000 Geological Sheet SG 50. Collected by G.A. Thomas.

REMARKS
This is the largest specimen known. It is twice the length of the holotype and displays an excellent cross-section of the cup and tegmen.

Easily recognisable radials, showing the multiple arm facets, cups and the horseshoe-shaped tegmen plates of *N. callytharraensis* were found at every locality visited. Often they were embedded in the grainstones and not retrieveable without excessive labour. These plates make excellent index fossils in the Callytharra Formation throughout the Carnarvon Basin.

21466, 21478, 21479 from QML759, QMF21462 from QML758, QMF21464, 21467 from QMl757 and other material QMF21571 (23) from QML757, QMF21572 (3) from QML758, QMF21573 (37) from QML759, QMF21574 (7) from QML760, QMF21575 (1) from QML761, and QMF21576 (6) from QML758-761.

REMARKS

Articulated thecae of juvenile and adult specimens of *Synbathocrinus constrictus* are moderately abundant throughout the interbedded arenaceous shales and limestones of the lower fossiliferous part of the Callytharra Formation at Callytharra Springs. Juvenile spec-imens are 0.4-2.5mm high and include growth stages from the armless embryonic through 5-armed forms.

Early growth stages are dominated by inflated orals and protuberant radials with a low narrow basal circlet. Radials and orals increase in length rapidly, are approximately equal in height and are the most obvious plates in the theca during early development. Radials show an early development of the medial longitudinal ridge, whereas orals are initially inflated then gradually develop a shallow central depression. The CD oral is largest, adjoining all other orals, separating the BC and DE orals, and bearing a small central protuberance, the hydropore or madreporite. At 1.3mm thecal height radials are approximately twice the height of the oral circlet and the first radial facet develops on the E radial. Growth continues in a linear increase greater than transverse until approximately 2.5mm height when lateral expansion is rapid. Arms develop in sequence in the C, B, D and A

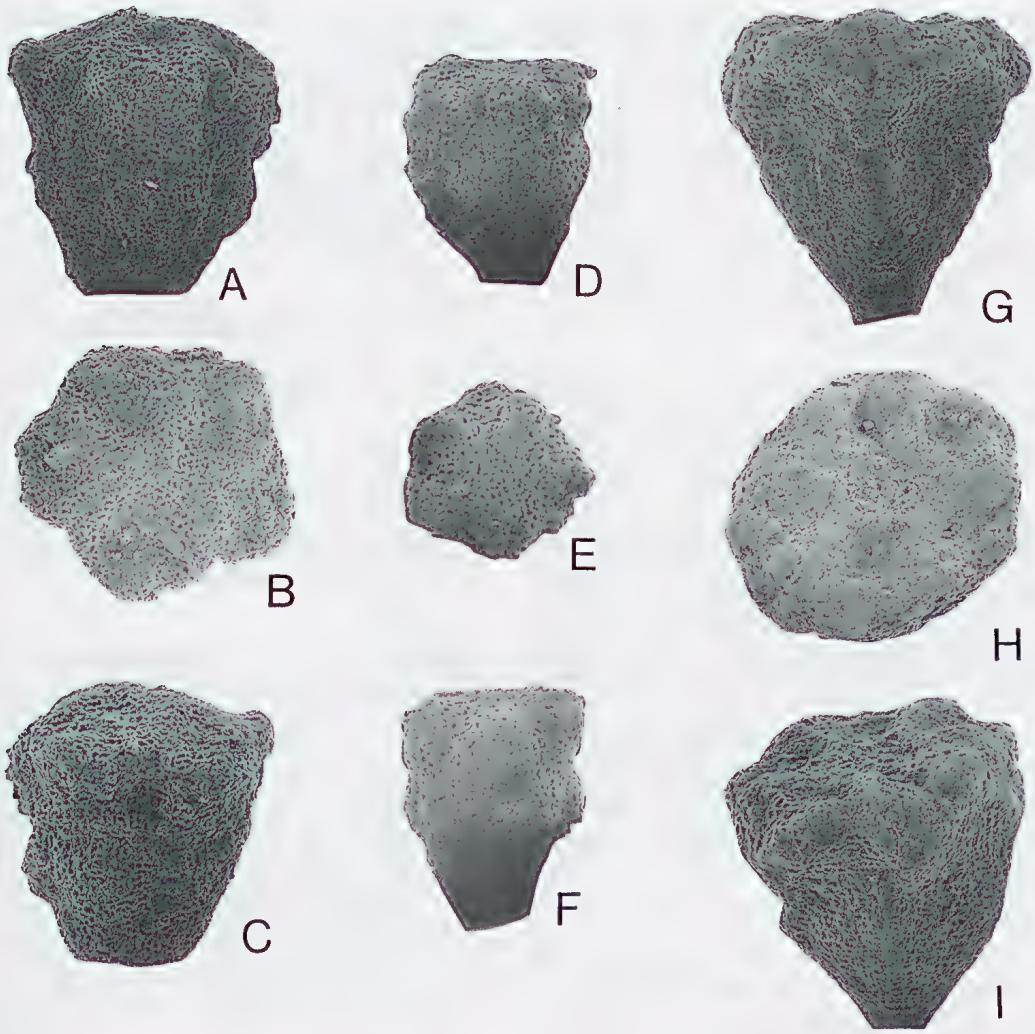

FIG. 13. *Lampadosocrinus variabilis* sp. nov. A-C, A ray, oral and C ray views of paratype QMF21451, ×40. D-F, A ray, oral and DE interray views of paratype QMF21452, ×40. G-I, E ray, oral and C ray views of holotype QMF21450, ×40.

rays. Only single specimens of most of the different arm stages are known. It is not known if the same sequential arm development is regularly followed. Orals are retained with the development of the fifth arm and the anal plate is not developed although a faint depression may occur in the radial circlet at the mutual shoulders of the C and D radials below the posterior oral. Macro specimens lack the oral circlet and were illustrated by Webster (1987).

Two abnormal specimens lack part or all of the fifth ray. One (Fig. 8G,H) has 4 radials and 4 orals. Except by careful examination it appears to be a normal 5 rayed theca. The other (Fig. 7F,G) has a partial fusing of the A and B radials and orals are distorted.

Small brachials up to 2.5mm long in the disarticulated washings are judged to be the beginning growth stages of arms of *S. constrictus* on the basis of the articular facet and the medial longitudinal ridge. Two of these brachials are illustrated to show the variation in longitudinal curvature, shape, ambulacral groove and distal tips.

These thecae are assigned to *S. constrictus* because they show the prominent radial ridge. Webster (1987) noted the gradation between *S. constrictus* and *S. campanulatus* so some of these

may be immature specimens of *S. campanulatus* but that form is not recognised until its adult stage.

Family UNCERTAIN

Microcrinoid holdfasts gen. et sp. indet.
(Fig. 10I-M)

MATERIAL
QMF21475-21477 from QML759 and QMF21577 from QML757-761 west of Callytharra Springs.

DESCRIPTION
Base hexagonal, rectangular or irregularly polygonal; sides scalloped to irregular; thickened centrally or towards one end extending as base of round columnal. Base concave.

REMARKS
Holdfasts 1.0-2.0mm long, 0.5-1.5mm wide and 0.6-1.0mm high. They range from Early Carboniferous in the United States (Webster, unpubl. data) to the Permian. They are illustrated for comparison in future studies and to demonstrate the scope of the Callytharra echinoderm fauna.

Occiducrinus Webster, 1990

TYPE SPECIES
Occiducrinus australis Webster, 1990 from the Artinskian Wandagee Formation, Minilya River, W.A.; by original designation.

Occiducrinus australis Webster, 1990
(Fig. 11B-D)

Occiducrinus australis Webster, 1990:60, pl. 2, figs 1-3.

MATERIAL
QMF21427 from the third thick sandstone bed above the base of the Artinskian Wandagee Formation, east limb of syncline, approximately 150m north of the Minilya River, Coolkilya Pool area, Wandagee Station, Western Australia.

REMARKS
This cup was weathering out as associated disarticulated plates on a bedding surface which also yielded *Eoindocrinus praecontignatus* and *Calceolispongia abundans*. The reconstructed cup lacked the anal, the D radial and the orals; it is nearly identical in size with the holotype.

The proximal columnal showing the articulum provides information not preserved on the holotype. Crenularium narrow; culmina short, widely spaced; crenellae wide, flat base, bearing rudimentary short ridges and V-shaped protrusions along irregularly walled outer side. Areola three times width of crenularium. Disarticulated columnals should be easily recognised.

Family BARYCRINIDAE Jaekel, 1918

Barycrinid? indet.
(Figs 12, 22D)

MATERIAL
Figured specimens QMF21434, 21436 from QML760, QMF21435 from QML761, QMF21437 from QML757. Other material QMF21586 from QML757 and QMF21587 from QML760.

DESCRIPTION
Columnals circular, pentameres; latus gently convex; heteromorphic type I pattern; symplexy articulation. Crenularium 1/3 radius on small columnals, may be more on large columnals, projects into areola at pentamere boundaries on some specimens. Culmina irregular, medium width, wider distally, may divide isotomously once; new culmina may be inserted distally. Areola 1/3 radius on small columnals, may be less on large columnals, sloping inward, smooth. Axial canal strongly pentastellate; claustrum narrow, thin, wedge-shaped, forms base of areola. Cirri circular in section, short, tapering rapidly distally, not divided into pentameres; latus straight; articulum same as pentamere articulum; axial canal narrow, slightly dumb bell-shaped transversely.

REMARKS
All pluripentameres (up to 4.95cm length) and pluricolumnals of articulated pentameres were recovered as loose specimens. Weathering destroyed many morphologic features but especially the claustrum on pluripentameres. Differentiated weathering resulted in irregular wavy thickness on external surfaces of some columnals (Fig. 22D). Most of the larger specimens are part of the holdfast or distal parts of the stem. The robust size suggests they supported a sizeable crown. It is unknown if the pentameres extended to the cup.

Pentameric columnals are present on several inadunates and camerates of Ordovician through Devonian age (Moore & Jeffords, 1968). Middle

Mississippian *Barycrinus* from Iowa are the previously recognized youngest pentameric stems (Moore et al. in Moore & Teichert, 1978). We refer these specimens questionably to the Barycrinidae and illustrate them because they are easily recognizable, have potential as Permian index fossils in the Carnarvon Basin and extend the geographic and stratigraphic range of pentameric columnals.

Superfamily CODIACRINOIDEA Bather, 1890

Lampadosocrinus Strimple & Koenig, 1956

TYPE SPECIES

Dichostreblocrinus minutus Peck, 1936 from the Lower Carboniferous St. Joe Formation, USA.

Lampadosocrinus variabilis sp. nov.
(Fig. 13)

ETYMOLOGY

Latin *variabilis* variable; refers to the variation in shape of the oral circlet, and number of infrabasal plates.

MATERIAL

Holotype QMF21450 from QML757-761 undifferentiated, paratypes QMF21451 from QML759, QMF21452 from QML757-761, QMF21453 from QML757, QMF21454 from QML758, QMF21455-21459 from QML759 and other material QMF21566 (5) from QML757, QMF21567 (2) from QML758, QMF21568 (24) from QML759, QMF21569 (2) from QML760, QMF21570 (5) from QML757-761.

DIAGNOSIS

Oral plates of variable shape; theca inflated; basals tumid.

DESCRIPTION

Theca small, conical, subcylindrical to widely inflated, widest at or slightly below oral summit, height/width ratio 1.0-1.4, surface ornament of minute pits.

IBB 1-5, most commonly fused; circlet low, narrowly to moderately outflared, pentalobate to circular transversely, forming lower 1/2 of cup, 1/4 of theca, bearing small impressed circular stem facet. BB 5, with variable length to width ratio, wider than long, subequal to longer than wide, convex transversely and longitudinally, tumidity gentle to moderately strong, rarely projecting into a short spine. OO 5, roundly to sharply protruded at or barely below thecal summit, oral surface inflated to depressed centrally, sutures flush to elevated along mutual narrow ridges. CD oral largest, protuberance more rounded than others, separates BC and DE orals. Oral circlet forming 2/5 thecal height, with slightly concave summit, horizontal or slightly inflated, sutures align with basal suture, rotated slightly or in normal alternate position. BC and DE oral protuberances commonly slightly down and outflared, EA and AE oral protuberances normally subhorizontal. No anal plates, BC basal left shoulder summit slightly below CD right shoulder summit; all other basal summits align.

REMARKS

Variation among the 47 specimens studied reflects growth changes and intraspecific variation. Two changes with growth are height/width ratios of the oral plates. In general elongation of the theca progresses from subequal height and width in immature forms to height greater than width in adult forms. Ratios in a growth series of 4 specimens calculated as 1.0, 1.4, 1.06, 1.11, smallest to largest. Oral plates of immature specimens are commonly roundly protuberant, rarely pointedly protuberant, and lack the rimmed depression on the summit typical of larger specimens. In immature forms the five protuberances project above the summit slightly, forming a slightly depressed summit. With growth the rimmed depression develops on each of the orals while the central oral summit is normally gently inflated forming the highest point on the theca. On the largest individuals the summit is commonly horizontal.

Intraspecific variation is noted in the following features. Most specimens are inflated moderately with only a few specimens having mildly inflated subcylindrical walls above the infrabasals. The angle of outflaring to the protuberances on the orals is variable. Tumidity of the basals ranges from slight to moderate and rounded to elongate in outline; rarely the tumidity is a short sharpened projection or blunt spine. Sharpness of the oral tumidity varies from rounded to angular and directed subhorizontal to gently upflared.

Cosmetocrinus(?) middalyaensis sp. nov.

(Fig. 14A)

ETYMOLOGY

For Middalya Station.

MATERIAL

Holotype UWAF113385 from QML770. Collected by John Williamson.

DIAGNOSIS

Right tube plate not in contact with the radianal.

DESCRIPTION

Crown tall (119mm), cylindrical (23.3mm wide maximum), plates smooth. Dorsal cup conical, flattened, approximately equidimensional, 22.6mm long, 22mm wide at summit, base flat, walls slightly convex proximally, slightly outflared distally. IBB 5?, large, 7mm long, 7mm wide, steeply upflared. BB 5, large, CD longer

(13.1mm) than wide (7.5mm), mildly convex transversely and longitudinally. RR 5, large, 7.8mm long, 7.8mm wide, mildly convex transversely and longitudinally. Radial facets plenary, sloping outward, with well developed transverse ridge and outer ligament pit; slight gape between radials and primibrachials. Anals 3, radianal narrow, in oblique position, adjoins C radial, BC and CD basal and anal X; anal X largest, 6.3mm long, 4.8mm wide, adjoining right tube plate, C radial, radianal, CD basal, D radial, and 2 tube plates, distal tip above radial summit; right tube plate nearly excluded from cup, only proximal tip below radial summit, not in contact with radianal. IBrr one per ray; in C and D rays, longer (8mm) than wide (6.6mm), constricted distally, strongly convex transversely, axillary. IIBrr, IIIBrr and IVBrr cuneate, strongly convex transversely. All branching isotomous. Second branching on IIBr8-10, one additional branching in some rays. Total number of arms exceeds 20 per ray if branching uniform in all rays. Pinnules small, slender. Anal sac tall, slender, mostly covered. Stem round transversely, heteromorphic, thin columnals, type II patterns for proximal 40mm, homeomorphic thick columnals distally; total of 130mm of stem preserved. Columnal latus convex, symplexy articulation. Non-cirriferous.

REMARKS

Radials of this species were described as inadunate radial #7 (Webster, 1987) based on loose radials found at Callytharra Springs approximately 250km to the south. *C.? middalyaensis* is widespread in the Carnarvon Basin and the radials are sufficiently distinct to be identified when disarticulated.

The crown is crushed in situ as it retains the arms and considerable length of the stem. Erosion has removed, but left the impression of, the distal 30mm of the arms. Generic assignment remains tentative because the A ray is not exposed to determine if branching occurs on the first primibrachial or a higher primibrachial as in *Paracosmetocrinus*. Some species of *Paracosmetocrinus* have a strongly cirriferous proximal stem, which is not present in *C.*(?) *middalyaensis*. The number of infrabasals is also uncertain as only one complete and one partial infrabasal are exposed. Their size and position suggests there are only three infrabasals on this form.

Crinoids associated on the slab are a weathered crown of *Texacrinus granulosus* sp. nov., disarticulated columnals of a camptocrinid and at least five unidentified crinoids. In addition several specimens of the spiriferid brachiopod *Fusispirifer carnarvonensis* Archbold & Thomas, 1987 and fenestrate bryozoans are present.

Elevation of the right tube plate until it is nearly eliminated from the cup is an advanced condition, suggesting a younger age than the Early Carboniferous age of previously described species (Moore & Teichert, 1978). Aphele-crinids were previously known only from the Lower Carboniferous of North America and Europe (Moore &Teichert, 1978).

Superfamily AGASSIZOCRINOIDEA Miller, 1889

Spheniscocrinus Wanner, 1937

TYPE SPECIES

Spheniscocrinus spinosus Wanner, 1937 from the Permian of Timor; by original designation.

Spheniscocrinus australis sp. nov.
(Fig. 11A)

ETYMOLOGY

Latin *australis*, southern.

MATERIAL

Holotype crown CPC30682 from the Artinskian upper Bulgadoo Shale or lower Cundlego Formation, 7.5km on bearing 287° from Wandagee Homestead, Minilya 4 mile map sheet, Carnarvon Basin.

DIAGNOSIS

Ornament shagreen with small pits; sutures flush; spines on brachials without nodes.

DESCRIPTION

Crown small, low, outspreading laterally, estimated 60mm diameter; ornament of small depressions on very fine shagreen surface. Cup low bowl to discoid-shaped, 5.7mm wide, 2.2mm high (estimated), shallow apical pits. IBB 5, impressions small, probably subhorizontal. BB 5, small, convex transversely and longitudinally, unequal size; EA estimated 1.3mm long, 1.2mm wide; CD 2.1mm long (estimated), 2mm wide. RR 5, wider (1.8mm) than long (1.3mm), gently convex longitudinally, strongly convex transversely, thick, spreading laterally proximally resulting in wide gap between radials at summit. Radial facet plenary, slope steeply outward, thick, small gaps. Anals 3, in intermediate position. Radianal in oblique position intermediate in size. Anal X largest, strongly convex transversely, adjoins posterior basal. Right tube plate smallest, not in contact with

FIG. 15. *Minilyacrinus williamburyensis* sp. nov., posterior and B ray views of weathered holotype crown, WAM91.697, ×1. C, fragmentary set of arms, UWAF113504, ×1.5.

radianal, proximal end barely below radial summit, admedial to anal X, barely visible in lateral view. IBrr 2 per ray, rectilinear, wider than long, thick, straight longitudinally, strongly convex transversely; axillary $IBrr_2$ constricted slightly proximally. IIBrr and IIIBrr cuneate, wider than long, thick, strongly convex transversely. All branches isotomous on IBr_2 and $IIBr_8$, minimum 4 arms per ray. Pinnules moderately large but not ramules, one per brachial on alternate sides of arm. Stem and tegmen not known.

REMARKS

This crown is inverted with the arms splayed outward on the substrate. The stem, infrabasal circlet and parts of most basals are not preserved but impressions of the inner side of the infrabasals and basals are moderately clear. The anal series extending into the base of the anal tube or sac is large, nearly the size of the base of the arms.

Spheniscocrinus was defined by Wanner, 1937, as having only one anal in the cup, however, the holotype and only specimen appears to be slightly distorted in the base of the C ray and adjacent anal series. It may have an intermediate arrangement of the anals as described above.

This is only the second member of the genus and is distinguished from the type species by the fine shagreen ornament, flush sutures and lack of nodes or spines on the brachials. Generic distribution is extended to Western Australia strengthening the link between Timorese and Western Australian Permian faunas.

SuperfamilyDECADOCRINOIDEABather,1890Family DECADOCRINIDAE Bather, 1890

Trautscholdicrinus Yakovlev & Ivanov in Yakovlev, 1939

TYPE SPECIES

Trautscholdicrinus miloradowitschi Yakovlev & Ivanov in Yakovlev, 1939, Upper Carboniferous Moscow Basin; by original designation.

Trautscholdicrinus sp.
(Fig. 14B-D)

MATERIAL

Partial crown WAM67.529, from the Artinskian Fossil Cliffs Formation, north branch Irwin River, Perth Basin. Found by Mrs J. White.

DESCRIPTION

Cup medium bowl-shaped, shallow basal invagination, walls subvertical, fine granular ornament. IBB 5, small, equidimensional (2.0mm)

kite-shaped, slightly upflared, not visible in lateral view. BB 5, hexagonal, wider (5.8mm) than long (5.0mm), moderately convex transversely, strongly convex longitudinally, proximally form base of cup, distally subvertical forming nearly half cup height, slightly tumid. RR 5, wider (5.7mm) than long (3.4mm) slightly convex longitudinally, moderately convex transversely. Radial facet plenary, sloping gently outward, bearing transverse ridge, outer ligament pit and furrow, and wide shallow muscle areas adorally. Anals 3, in intermediate position. Radianal largest, pentagonal, adjoins C radial, BC and CD basals, anal X and right tube plates. Anal X pentagonal, truncated CD basal, adjoining one tube plate distally. Right tube plate not preserved, proximal end barely below radial summit. A ray IBr1 axillary, strongly convex transversely. Distal brachials slightly cuneate, strongly convex transversely, bearing one pinnule each distally. Stem impression round.

REMARKS

The cup is crushed from compaction but plates are well preserved. The infrabasal circlet is not visible in lateral view and sutures appear slightly impressed because the tumidity of the basals projects above them. This is the second crinoid reported from the Fossil Cliff Formation after *C. digitata* (Teichert, 1949). The specimen is of insufficient quality to serve as a type. Radials like these occur in the disarticulated ossicles at Callytharra Springs.

Superfamily CROMYOCRINOIDEA Bather, 1890

Family CROMYOCRINIDAE Bather, 1890

Minilyacrinus gen. nov.

TYPE SPECIES

Minilyacrinus williamburyensis sp. nov.

ETYMOLOGY

For the Minilya River.

DIAGNOSIS

Cup bowl-shaped, with single anal; arms uniserial, cuneate, numbering 20.

Minilyacrinus williamburyensis sp. nov.

(Fig. 15)

ETYMOLOGY

For Williambury Station.

MATERIAL

Holotype WAM91.697 from an undesignated locality on Williambury Station. The specimen was enclosed in a quartz and mica bearing grainstone of the Callytharra Formation. It probably came from the vicinity of Donnelly's Well or other exposures of the Callytharra Formation in the eastern line of the Gooch Range in the southwestern part of Williambury Station. One partial set of arms (UWA) from the eastern line of the Gooch Range along the Minilya-Williambury Station road.

DESCRIPTION

Crown moderately large, 42.8mm long incomplete, average 13.1mm wide, cylindrical. Anal sac small cylindrical, formed of eight rows of plates. Cup moderately large, 13.9mm high, 23.1mm wide at summit, bowl-shaped; walls gently outflared distally; moderately deep basal invagination (7.1mm diameter); unornamented; sutures flush. IBB small, covered by proximal columnals, confined to basal invagination, probably downflaring. BB 5, large, slightly wider (8.8mm) than long (7.8mm), strongly convex longitudinally, moderately convex transversely, proximal ends within basal invagination, forming basal plane of cup; CD basal symmetrical, truncated distally for adjoined radianal. RR 5, large, wider (14.7mm) than long (9.7mm), moderately convex transversely, mildly convex longitudinally. Radianal longer (8.6mm) than wide (6.5mm), slightly over half above radial summit, adjoined distally by one tube plate. Radial facets plenary, sloping gently outward, moderate gape between radials and primibrachials. IBrr one per ray, wider (14.5mm) than long (8.1mm), moderately convex transversely, mildly convex longitudinally, axillary. IIBrr 2 per ray, wider (8.4mm) than long (4.1mm), strongly convex tranversely. IIIBrr wider than long, slightly cuneate, strongly convex transversely, thick, pinnulate. Ambulacral groove narrow, deep. Branching isotomous, 20 arms. Stem heteromorphic; columnals circular transversely, lumen pentagonal, symplexy articulation.

REMARKS

The partial crown has been deeply weathered on exposed surfaces, the distal part of the arms and anal sac are lost, slight crushing occurred oblique to the A-CD symmetry plane, and arms adjacent to the anal series have been disarticulated in part. Weathering along the flush sutures of the cup plates and into cleavage planes in the calcite plates appear as deep impressions. A small portion of the B and C rays, including radials and adjacent basals were enclosed in matrix and unweathered.

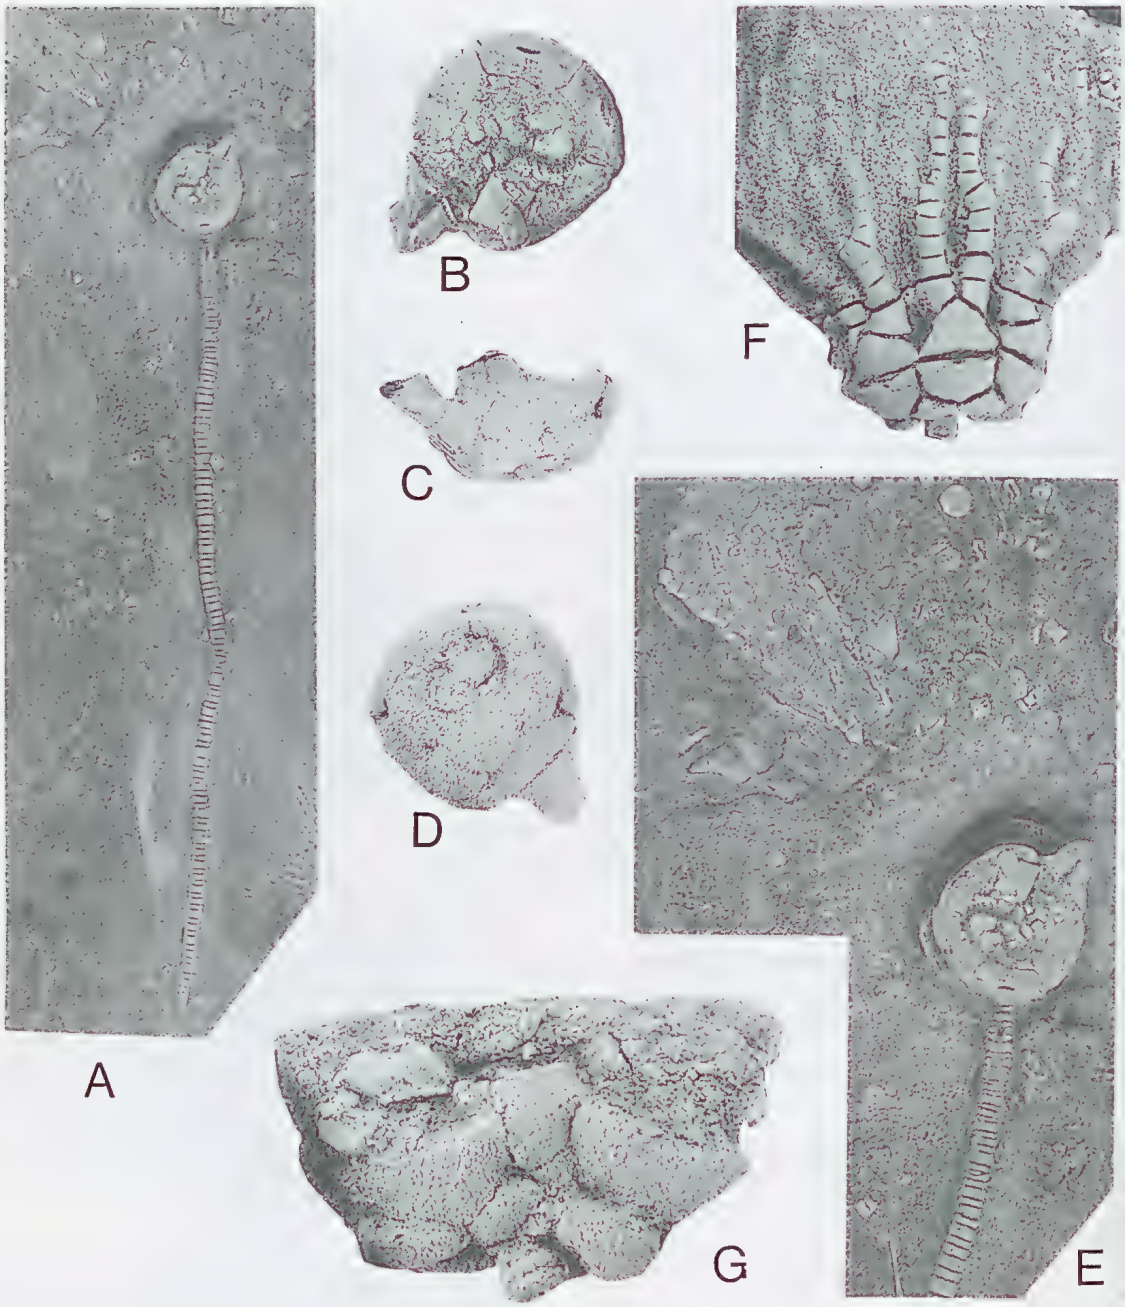

FIG. 16. *Texacrinus goochensis* sp. nov. A-E, paratype UWAF115099. A, weathered crown showing attached stem, ×1. B-D, oral, posterior and basal views of dorsal cup with attached primibrachial, ×3. E, enlargement of part of A showing parts of arms to upper left and directly above cup and change in heteromorphic patterns, proximally type II to distally Type I, ×2. F,G, lateral and posterior views of holotype crown UWAF 113387, F ×2; G ×3.5.

Removal of the matrix exposed the lack of ornamentation and flush sutures.

The partial set of arms show the tapering distal arm tips of slight cuneate shapes typical of the cromyocrinids. Thickness of the plates, narrow ambulacral grooves, strong external convexity and slight cuneate shape of the brachials is similar to that of uniserial brachials in the Cromyocrinidae. However, cup plates lack the impressed sutures typical of smooth plated cromyocrinids with uniserial arms (Webster, 1981).

The single anal and multiple arms reflect an advanced evolutionary condition. This is the first cromyocrinid bearing uniserial arms to be recognised with more than 10 arms, whereas many biserial armed cromyocriniods have 12 to 19 arms (Webster, 1981).

Evolution of *Minilyacrinus* is uncertain, perhaps through *Cromyocrinus*, *Goleocrinus* or *Mooreocrinus* by increase in arm number, reduction of the number of anals in the cup and increase in depth of the basal invagination. Evolution from *Moapacrinus* would only require increase in arm number.

The Cromyocrinidae is an Early Carboniferous to Early Permian family with greatest generic and specific diversity in the Late Carboniferous (Webster, 1981). They have been reported from North and South America and Eurasia. Webster (1981) considered all Permian forms from Timor, Russia and India previously referred to the cromyocrinids to belong to an unnamed genus or genera of non-cromyocrinid stock. Only two cromyocrinids, *Moapacrinus* and an unnamed genus, are of Permian age. Both are from the southwestern United States, have only one anal, and the 10 arms are uniserial on *Moapacrinus* but unknown on the unnamed genus (Webster, 1981).

Minilyacrinus is the first cromyocrinid from Western Australia. The partial set of 10 arms identified as Poteriocrinidae gen. ind. et. spec. nov. ind. (Wanner, 1949, pl. 3, fig. 31) from Timor probably belongs to a cromyocrinid.

Texacrinus goochensis sp. nov.
(Fig. 16)

ETYMOLOGY

For the Gooch Range.

MATERIAL

Holotype UWAF113387, a crown collected by Chris Hearne; paratype UWA115099 collected by John Williamson from QML770.

DIAGNOSIS

Ornament granulose.

DESCRIPTION

Crown small, weakly outflared, anal sac unknown, granulose ornament on cup plates and proximal brachials. Dorsal cup small, low bowl-shape, nearly three times wider than high, widest at radial summit, moderately deep basal invagination, sutures flush to gently impressed, moderate pits at apices of basals and radials. IBB small, confined to basal invagination, covered by proximal columnals, probably downflared. BB 5, wider than long, tumid, forming walls of invagination proximally, basal plane of cup medially, lower part of gently outflaring walls of cup distally, distal tip incurved; posterior basal may be

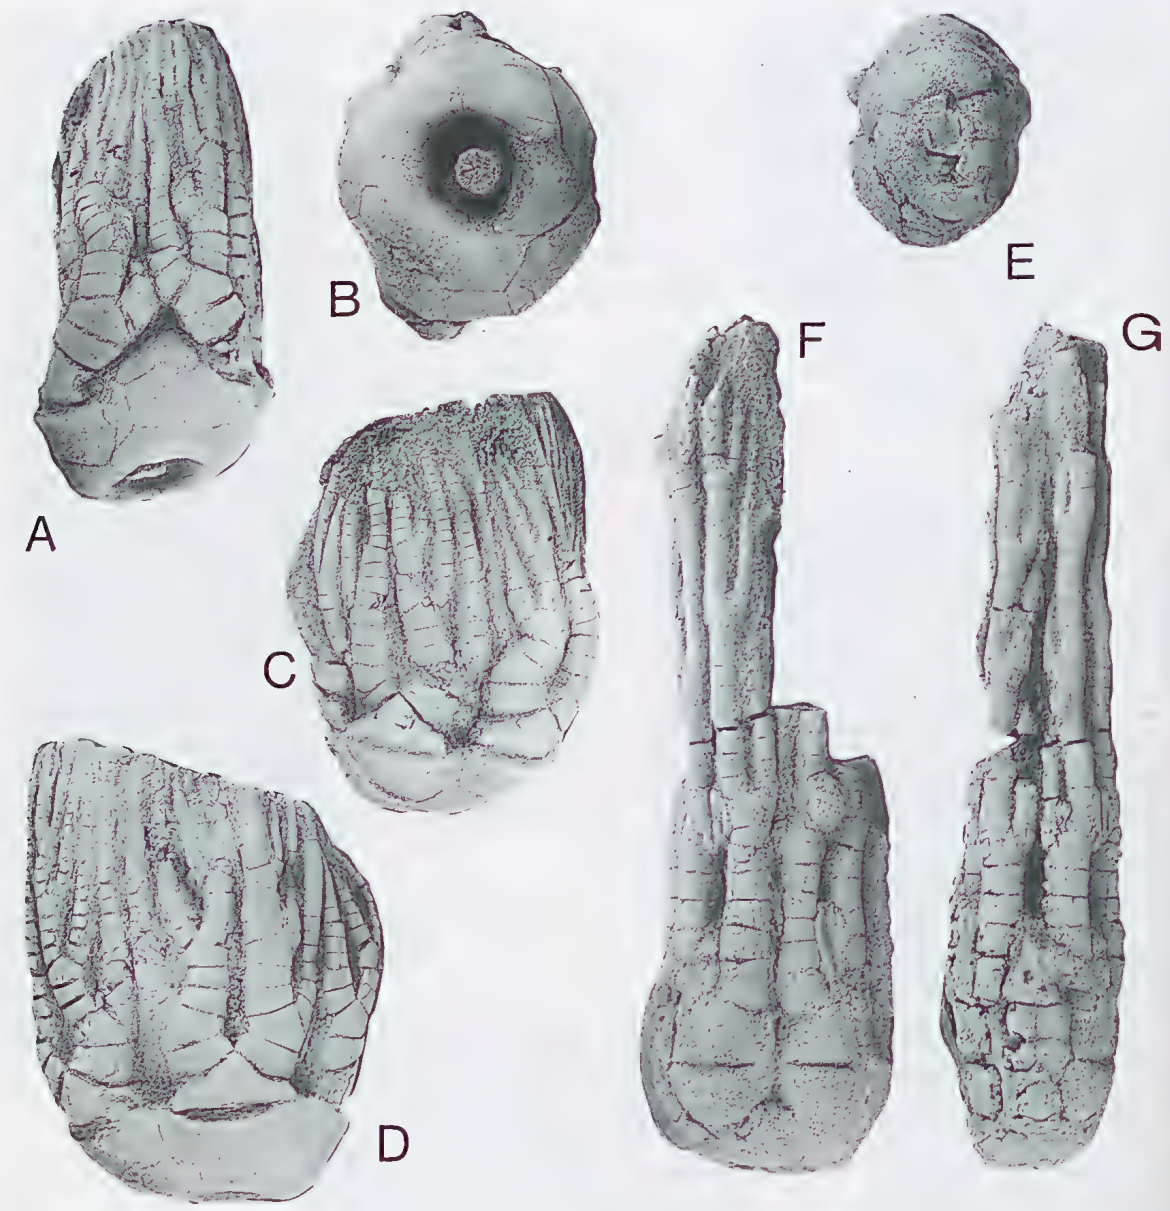

FIG. 17. A-D, *Texacrinus gascoynensis* sp. nov., posterior, basal, BC interray and B ray views of holotype WAM91.698, ×1. E-G, *Texacrinus hardmanensis* sp. nov., basal, BC interray and posterior views of holotype CPC30683, ×1.5.

truncated distally for anal X. RR 5, approximately twice as wide as long, mildly convex transversely and longitudinally, tumid, outflared. Radial facets plenary, sloping outward gently, with well developed transverse ridge, outer ligament pit and muscle fields. Anals 3 in primitive or modified primitive arrangement, variable in relative sizes. Radianal pentagonal or hexagonal, may or may not adjoin D radial, longer than wide. Anal X longer than wide, 0.5-0.67 below radial summit, adjoining one tube plate distally. Right tube plate small, proximal 1/3 below radial summit, adjoining one tube plate distally. IBrr one per ray, wider than long, constricted distally, strongly convex transversely, unequal in length (A ray longest), axillary. IIBrr to VIBrr slightly cuneate, equidimensional to wider than long, branching on 4th or 5th brachial in each series. First branch

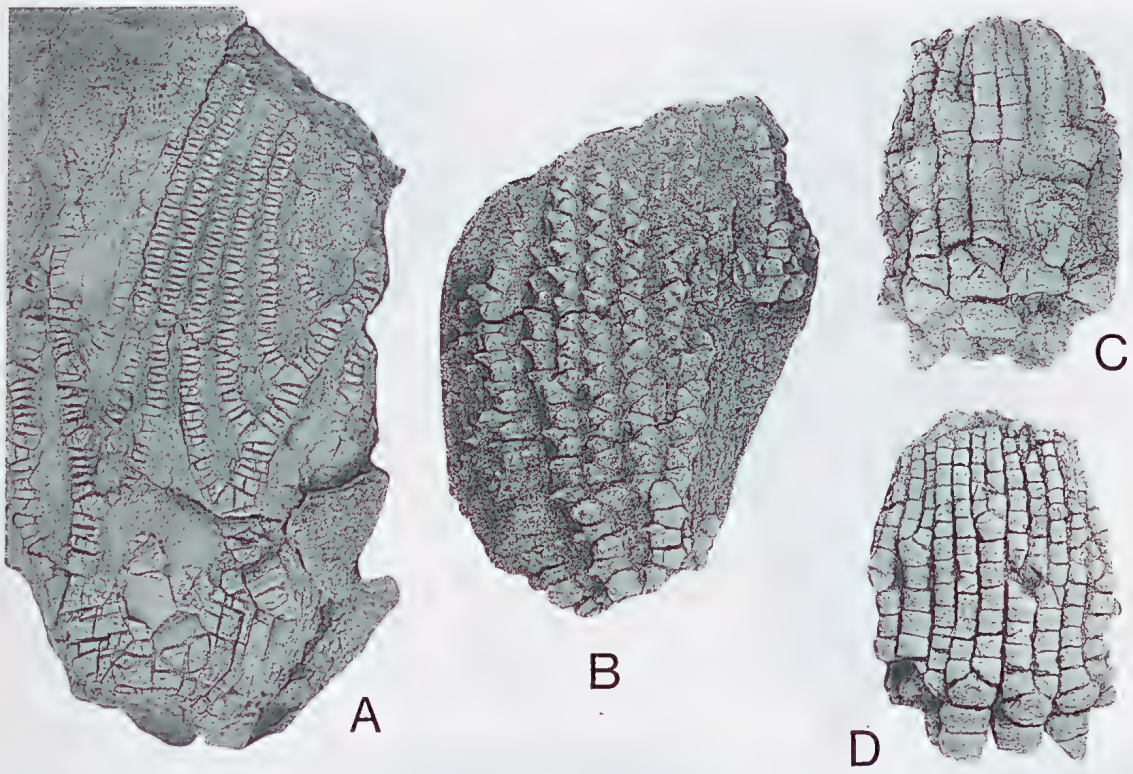

FIG. 18. A, *Galateacriuus australis* sp. nov., anal view of holotype UWAF113388, ×1. B, Family and genus indet., lateral view of set of arms QMF21469, ×1.6. C,D, Timorechinid indet., lateral views of set of arms, QMF21468, ×1.6.

isotomous, thereafter heterotomous bi-exotomous, 30 to 50 arms. Stem round, columnals thin heteromorphic type II pattern proximally, thicker heteromorphic type I pattern distally, latus convex, non-cirriferous, lumen pentagonal.

MEASUREMENTS (mm)

Cup width	11.8 (average)	9.9
Basal length	2.6	2.6
Basal width	3.6	3.6
Radial length	2.9	3.3
Radial width	6.0	5.9
IBr1 length	4.4	3.3
IBr1 width	6.0	4.5
Diam.proximal columnal	2.2	2.3

REMARKS

The holotype is a crushed crown lacking the distal parts of the arms with the anals in primitive arrangement; the radianal is in oblique position not in contact with the D radial. Weathering of the paratype has removed all except one primibrachial and distal parts of the arms of two rays. The paratype has anals in a slightly advanced arrangement; the radianal adjoins the D radial separating anal X from the CD basal. The slightly advanced arrangement of the anals has been reported in all species previously assigned to the genus suggesting that it has been a fairly stable genetic character since the middle Pennsylvanian.

Texacrinus has been reported from middle Pennsylvanian to Early Permian strata of the United States (Webster, 1973). Variables within the family are degree of suture impression (slight to moderate), depth of basal invagination (slight to deep), development of apical pits (not present to moderately deep), cup shape (slightly globose to weakly outflared low to medium bowl), and brachial form (nearly flat to strongly convex transversely; rectilinear to slightly cuneate, very

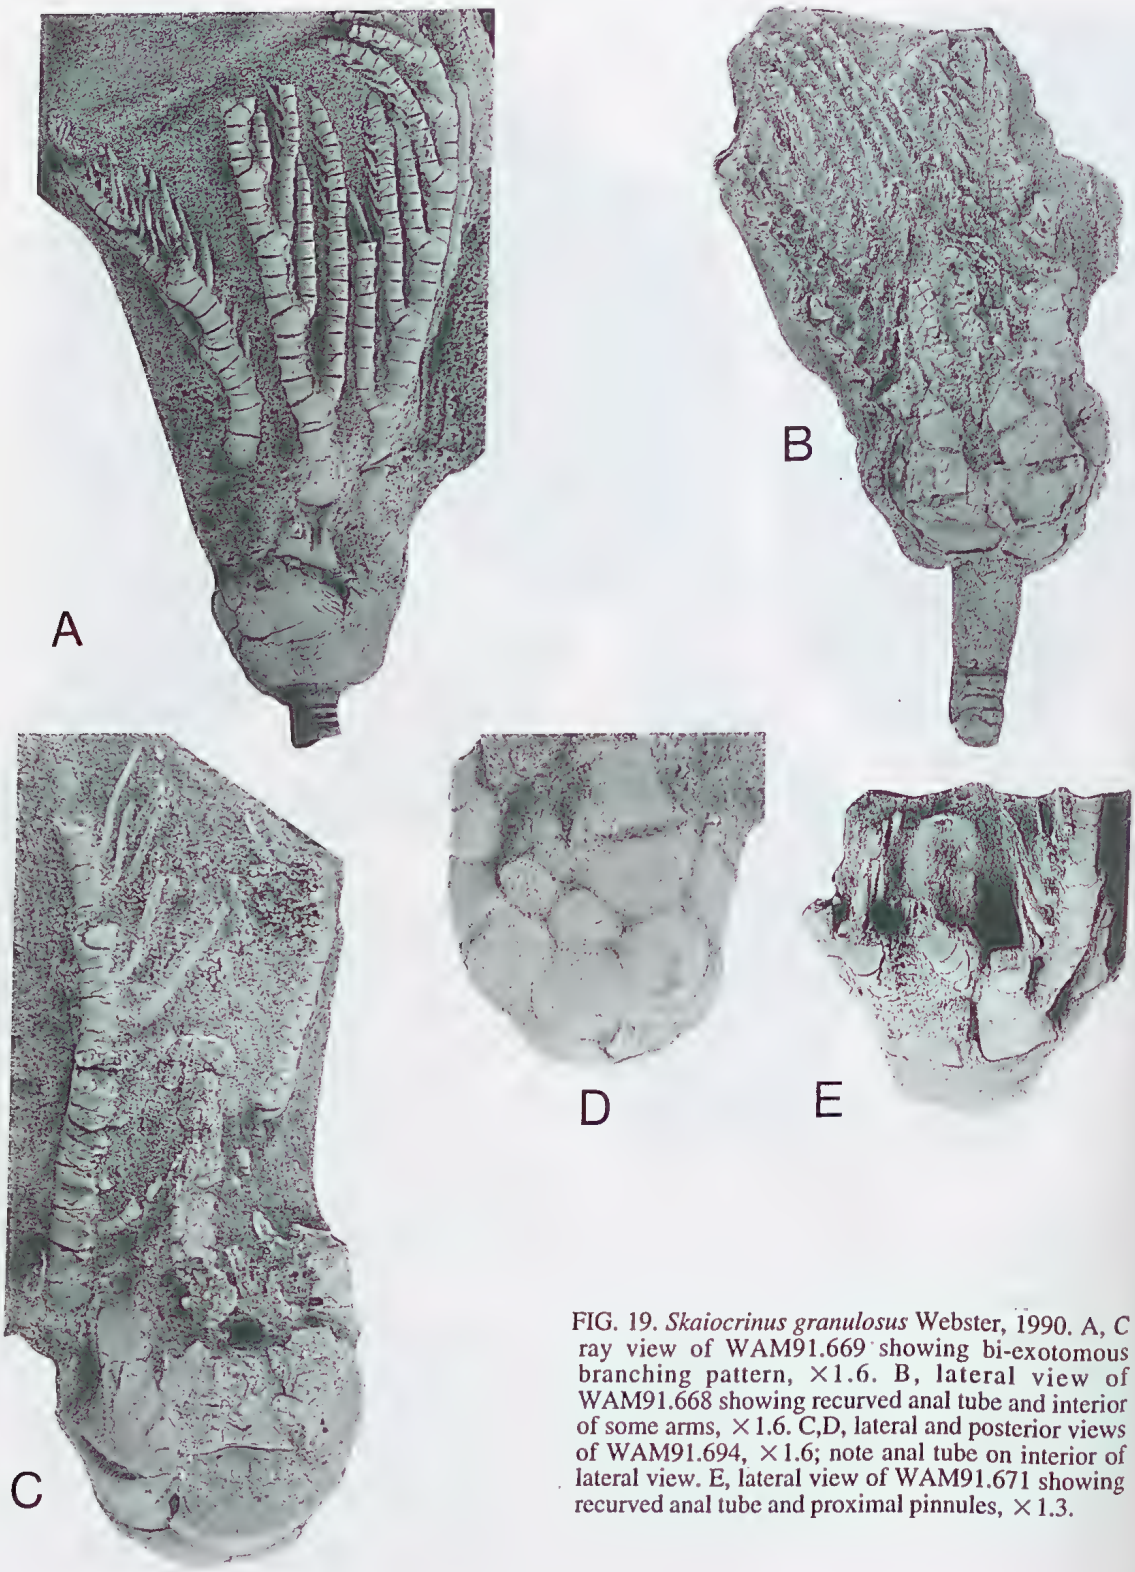

FIG. 19. *Skaiocrinus granulosus* Webster, 1990. A, C ray view of WAM91.669 showing bi-exotomous branching pattern, ×1.6. B, lateral view of WAM91.668 showing recurved anal tube and interior of some arms, ×1.6. C,D, lateral and posterior views of WAM91.694, ×1.6; note anal tube on interior of lateral view. E, lateral view of WAM91.671 showing recurved anal tube and proximal pinnules, ×1.3.

short to short). Where known, the arms branch bi-exotomous after an initial isotomous division. We consider *T. interruptus*, *T. irradiatus* and *T. compactus* named by Strimple (1952) and all from the Francis Shale of Oklahoma to be one species showing slight to moderate variation in many of the cup features listed above. We select *T. irradiatus* to be the senior synonym because the holotype is a more complete individual and intermediate in the range of variation.

Texacrinus goochensis extends the geographic range of the genus to Western Australia and is the first species named with granulose ornament.

Texacrinus hardmanensis sp. nov.
(Fig. 17E-G)

ETYMOLOGY
For Mount Hardman.

MATERIAL
Holotype CPC30683, a partial crown, from the Tatarian Cherrabun Member, Hardman Formation, at Mt. Hardman, Canning Basin. BMR localities KLB 11.

DIAGNOSIS
Anals in intermediate position with proximal tips of anal X and radianal below summit; arms elongate.

DESCRIPTION
Crown elongate (68.5mm, slightly incomplete), cylindrical, widest at radial summit, no arm girdle, fine vermiform to granular ornamentation on all plates, crushed slightly normal to plane of symmetry. Cup bowl-shaped, wider (16.3mm average) than high (9.7mm), base invaginated, sutures shallowly impressed, shallow apical pits. IBB 5?, covered, small, probably downflared, not visible in lateral view. BB 5, wider than long (C basal 6.4mm wide, 5.9mm long), gently convex transversely, moderately convex longitudinally, forming base of cup proximally; CD basal truncated distally for radianal. RR 5, wider (8.9mm) than long (6.3mm), gently convex. Radial facets plenary, subhorizontal, narrow gape. Anals 3, in intermediate position. Radianal large, 4.4mm long, 3.8mm wide, in line of radials. Anal X and right tube plate subequal, 2.5mm wide, 2.4mm long, proximal ends barely below radial summit, each adjoining one tube plate distally. IBrr one per ray, wider (9.7mm) than long (5.2mm), slightly convex longitudinally, moderately convex transversely, axillary. IIBrr, IIIBrr, IVBrr and VBrr rectilinear, wider than long, strongly convex transversely, branch on 5th to 8th brachial in each series. First branching isotomous, thereafter heterotomous bi-exotomous, minimum of 10 arms per ray. Pinnules slender, borne by alternating branchials. Stem pentagonal.

REMARKS
The crown was enclosed in a quartz wackestone. It had been crushed slightly by compaction. Irregular calcite cementation of the matrix and hydrous iron oxide cementation and replacement of plate edges along some sutures made preparation difficult.

The specimen is an advanced member of *Texacrinus* with the most elongate slender arms known within the genus. It probably evolved from *T. goochensis* by elongation of the brachials and modification of the anals. It is one of the three youngest known Palaeozoic crinoids.

Texacrinus gascoynensis sp. nov.
(Fig. 17A-D)

ETYMOLOGY
For the Gascoyne River.

MATERIAL
Holotype WAM91.698, from the Artinskian Cundlego or Wandagee Formation on Jimba Jimba Station, Carnarvon Basin. Exact horizon and locality unknown.

DIAGNOSIS
Radial facets peneplenary; anals in a near advanced position with only proximal most tips of anal X and right tube plate below radial summit.

DESCRIPTION
Crown, robust, moderately short, 56.9mm long, average 37.4mm wide, cylindrical. Cup moderate bowl-shaped, large, 10.0mm high, average 33.7mm wide; basal invagination 12.4mm diameter, 4.0mm deep; sutures flush; shagreen ornamentation. IBB 5?, covered, small, confined to basal invagination, probably downflared. BB 5, large, wider (12.9mm) than long (10.0mm), strongly convex longitudinally, mildly convex transversely, forming basal plane of cup; CD basal truncated distally for radianal. RR 5, large, nearly twice as wide (17.6mm) as long (9.0mm), gently convex longitudinally and transversely, mildly outflaring. Radial facets peneplenary with narrow notch, sloping gently outward. Radianal large, slightly wider (8.1mm) than long (7.8mm), adjoined distally by anal x and right tube plate proximal most tips of which are below radial summit. IBrr one per ray, pentagonal, wider

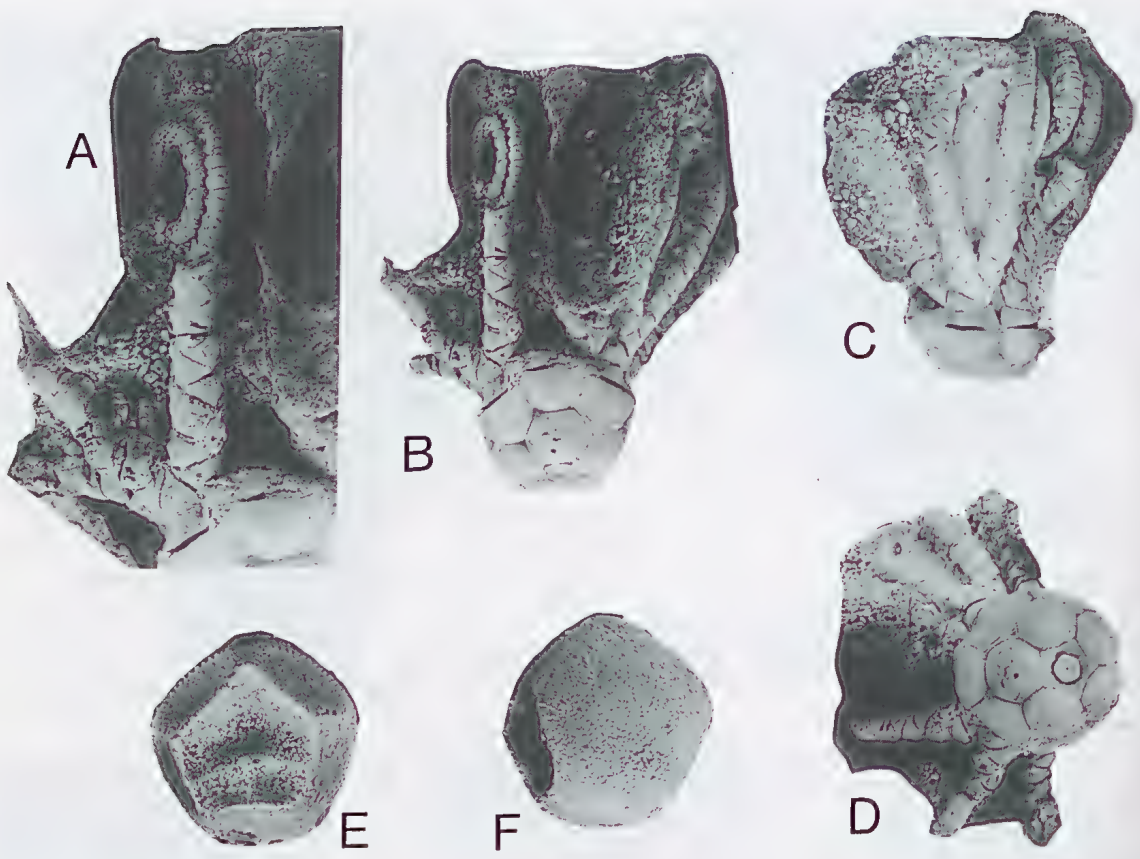

FIG. 20. *Cymbiocrinus cherrabunensis* sp. nov. A, D ray arm showing cuneate brachials, ×1. B-D, posterior, C ray and basal views of holotype CPC30684, ×0.75. E,F, internal and external views of paratype basal QMF21480, ×2.

(14.5mm) than long (6.7mm), constricted distally, strongly convex transversely, gently convex longitudinally, axillary. IIBrr to VIIBrr rectilinear, wider than long, moderately convex transversely, straight to gently convex longitudinally; brachials number 2 IIBr; 3 IIIBr, 4 IVBr, 4 or 5 VBr, 5 VIBr, 3 or 4 VII Br, unknown number of VIII Br. First branching isotomous, all others heterotomous biexotomous; minimum 14 arm per ray. Anal sac unknown, probably short. Stem round transversely, heteromorphic. Latus strongly convex; axial canal round.

REMARKS

This nearly complete crown is replaced with hydrous iron oxides and weathered a deep ferruginus red. It was embedded in a medium-grained quartz wackestone and slightly compressed normal to the A-CD axis. The radial facets are peneplenary and distinguish it within the genus. If the base of the anal X and right tube plate were any higher they would be out of the cup and the form would be considered to have a single anal.

Consideration was given to designating a new genus based on the combination of the peneplenary facets and near single anal condition. Until the single anal condition is established we prefer to retain this form in *Texacrinus*.

MATERIAL
Holotype UWAF113388 from QML770.

DIAGNOSIS
Cup low bowl-shaped, lacking radial notches; brachials very short, locally becoming biserial within the uniserial arms.

DESCRIPTION
Crown tall (85.9mm incomplete) moderately outflaring (55.3mm wide at IBr1), anal sac stout. Dorsal cup low bowl-shape, nearly discoid, twice as wide (33.3mm maximum) as high (16mm diameter); sides widely outflaring; wide deep basal invagination (9.9mm); coarse vermiform(?) ornamentation; sutures weakly impressed. IBB restricted to invagination, probably downflared, not exposed if preserved. BB 5, large, CD 8.8mm long, 10.2mm wide, moderately convex longitudinally, gently convex transversely, proximal ends in basal invagination, widely outflared distally, forming basal plane of cup; CD basal truncated distally for adjoining anal X. RR 5, large, wider (15.5mm) than long (9.6mm), outflared widely; radial facets plenary, sloping strongly outward. Anals 3, primitive arrangement, distal 1/3 of anal X and right tube plate above radial summit. Radianal pentagonal, in oblique position, slightly longer (7.9mm) than wide (6.7mm); adjoining C radial, BC and CD basals, anal X and right tube plate. Anal X hexagonal, longer than wide (8.5x6.2mm), adjoins one tube plate distally. Right tube plate hexagonal(5.5x5.5mm). IBrr 1/ray, wider than long (15.5x6.2mm), moderately convex transversely and longitudinally, axillary. IIBrr to VIBrr strongly convex transversely, wider than long, cuneate with local biserial brachials. First branch isotomous, thereafter heterotomous bi-exotomous. Second branching on IIBrr4 or 5, third through sixth branch on 6th to 8th brachial in the series; 12 arms per ray. Pinnules, anal sac and column not preserved.

REMARKS
Only the C and D rays and adjoining parts of the dorsal cup are exposed and perhaps the only parts preserved. Its lack of radial notches and possession of cuneate brachials leave it transitional between the Texacrinidae (lacking radial notches with rectilinear to cuneate brachials), and the Galateacrinidae (with radial notches and cuneate brachials). The radial notches of the Galateacrinidae are formed by the very bulbous nature of the radials as the facets are actually plenary but adoral of the aboreal tumidity. Thus the Galateacrinidae are separated from the Texacrinidae on the shape of the cup, discoid vs low bowl respectively, not the length of the radial facet as the presence of radial notches tends to imply. We question if this is of sufficient difference to justify family separation.

This is the first record of a *Galateacrinus* in Australia. The genus has previously been reported only from the middle Pennsylvanian to Early Permian of the United States (Webster, 1973, 1977, 1986). The low bowl shaped cup, lack of radial notches and short brachials which locally become biserial readily distinguish *G. australis* from all other species of the genus.

Skaiocrinus Webster, 1990

TYPE SPECIES
Skaiocrinus granulosus Webster, 1990 from the Artinskian Wandagee Formation, Minilya River; by original designation.

Skaiocrinus granulosus Webster, 1990
(Fig. 19)

Skaiocrinus granulosus Webster, 1990:66, pl.2, figs 15-17.

MATERIAL
Cup WAM91.684; 6 partial crowns, WAM91.668, 91.669, 91.671, 91.692, 91.694, 91.696 and 3 sets of arms WAM91.670, 91.691, 91.693 from the Artinskian Wandagee Fmn, Minilya River, collected by H. Coley.

REMARKS
Several morphological features not visible or showing variation not recognisable on the original study material (Webster, 1990) are shown on the new specimens. Cup morphology is quite consistent with the exception of the width of the radial facets. On the holotype they are nearly plenary but must be considered peneplenary, whereas they are plenary or very nearly plenary with slight variation on all new specimens. Arms may branch up to 8 times (WAM91.692), resulting in 9 arms in one half ray and 90 arms for the crown if branching is uniform and maximum in all rays. Pinnules are very slender, taper slightly until the distal termination, have a medial longitudinal ridge, begin on the first secundibrach, and contain 9 plates in proximal pinnules. The slender tegmen is formed of small polygonal plates with flush sutures, no appearant transverse or longitudinal alignment of plates and is recurved. The column is heteromoprhic Type II pattern.

Based on the peneplenary radial facets, Webster (1990) assigned *Skaiocrinus* to the

Pachylocrinidae noting exotomous arm braching and similarity to the Texacrinidae. The genus is here transferred to the Texacrinidae because most of the new specimens show plenary facets.

No formation was known for the original study material. New specimens are from the Wand/agee Formation, in a calcareous siltstone to medium-grained quartz wackestone. Cementation is generally weak but may include hydrous iron oxides which are difficult to remove when preparing specimens. Natural weathering exposed most of the features described above.

Family CYMBIOCRINIDAE Strimple & Watkins, 1969

Cymbiocrinus Kirk, 1944

TYPE SPECIES

Cymbiocrinus romingeri Kirk, 1944 from the early Chesterian St. Genevieve Limestone of Alabama; by original designation.

REMARKS

The Cymbiocrinidae may be divided into 2 groups with differing arm structures *Cymbiocrinus, Aenigmocrinus, Oklahomacrinus* and *Allosocrinus*, have cuneate brachials. *Lecobasicrinus, Aesiocrinus, Paracymbiocrinus* and *Proallosocrinus* have rectilinear brachials. Both groups appear in the Chesterian and range into the Virgilian in the United States. They probably had differing ancestral lineages and may represent different families. Additional investigation of the Cymbiocrinidae is required to properly resolve these problems.

Cymbiocrinus cherrabunensis sp. nov. (Fig. 20)

ETYMOLOGY

For the Cherrabun Member.

MATERIAL

Holotype, CPC30684, a crown from the Tatar-ian Cherrabun Member, Hardman Formation, east side of Mt Hardman, Canning Basin. Coll. J.M.Dickins. Paratype QMF21480 from QML 772.

DIAGNOSIS

Primanal large; 11 arms incurled distally.

DESCRIPTION

Crown 72mm long (arms curled distally), 75mm wide, inflated pear-shaped with incurled distal arms, no surface ornament. Cup medium bowl-shaped, wider (27.3mm) than high (11.8mm), walls outflared, base shallowly invaginated, sutures impressed, moderately deep apical pits. IBB 5, small, kite-shaped, 4.8mm long, 4.7mm wide, downflared, not visible in lateral view of cup. BB 5, large, 10.0mm long, 10.8mm wide, inflated, moderately convex transversely and longitudinally. RR 5, wider (14.3mm) than long (8.8mm), outflared, gently convex transversely and longitudinally. Radial facet plenary, bearing transverse ridge and outer ligament pit, slightly gaped. IBrr two per ray, moderately convex transversely, constricted distally. IBr_1, trapezoidal, wider (14.3mm) than long (3.7mm). IBr_2 triangular, 6.6mm wide 5.3mm long, axillary. All other brachials, unless axillary, strongly cuneate, bearing one slender pinnule each on alternate sides of arm. Arms 11? all branching isotomous. Proximal columnal pentagonal, 4.5mm diameter; latus convex. Crenularium narrow, culmina short, coarse. Areola wide, flat. Axial canal subpentagonal.

REMARKS

Assignment to *Cymbiocrinus* is based on cup shape, single anal, cuneate brachials, and branching on the second primibrachial. A third arm on the C ray (branching on the first secundibrachial abanally) is not typical of the genus. It is uncertain if this represents an evolutionary development or a variant. The bulbous basals show affinity to the calceolispongiid, *Jimbacrinus*, however the calceolispongiids have inflated basals, 5 atomous arms and most commonly a vestigal stem.

Hydrous iron oxides have replaced all plates and the crown is embedded in a coarse-grained quartz wackestone. The delicate arms are incurl-ed distally but visible in the natural weathered specimen. It is interpreted to have lived in or near the burial site on a sandy substrate.

Family TIMORECHINIDAE Jaekel, 1918

Timorechinid gen. indet. (Fig. 18C,D)

MATERIAL

QMF21468 a partial set of arms, QML770.

REMARKS

A small incomplete set of arms (25.0mm long) with 3 series of brachials shows 2 isotomous branchings. Brachials are wider than long proximally, equidimensional medially, longer than wide distally, strongly convex externally, and slightly cuneate. Axillary brachials (5-7 in middle series) have a central upward and outward directed short spine. Most spines are broken off

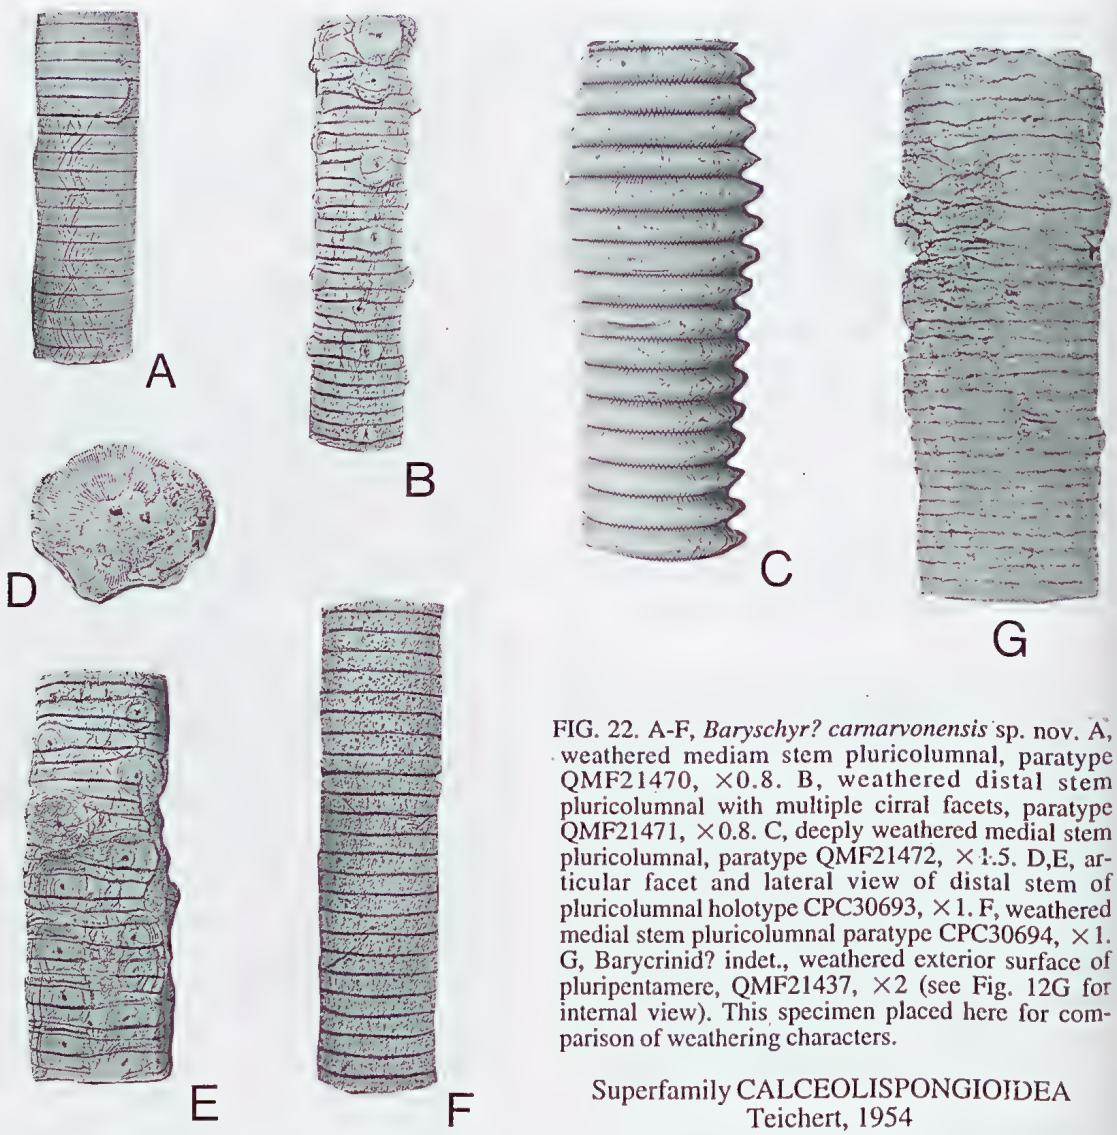

FIG. 22. A-F, *Baryschyr? carnarvonensis* sp. nov. A, weathered mediam stem pluricolumnal, paratype QMF21470, ×0.8. B, weathered distal stem pluricolumnal with multiple cirral facets, paratype QMF21471, ×0.8. C, deeply weathered medial stem pluricolumnal, paratype QMF21472, ×1.5. D,E, articular facet and lateral view of distal stem of pluricolumnal holotype CPC30693, ×1. F, weathered medial stem pluricolumnal paratype CPC30694, ×1. G, Barycrinid? indet., weathered exterior surface of pluripentamere, QMF21437, ×2 (see Fig. 12G for internal view). This specimen placed here for comparison of weathering characters.

and the weathered fracture is sometimes difficult to detect. Isolated spinose axillary brachials probably belonging to this specimen are moderately common at Callytharra Springs. Proximal series of brachials twice width (3.9 mm) of middle series (1.9mm); distal series (1.1 mm wide) >1/2 width of middle series. Except for spines on axils and smaller size, this set of arms is similar to *Notiocrinus timoricus* Wanner (1924a, pl.12, figs 18,19) from Basleo, Timor.

Because the branching pattern cannot be determined and the cup is lacking, the arms are questionably referred to Timorechinidae, with isotomous and heterotomous biendotomous arms.

Superfamily CALCEOLISPONGIOIDEA Teichert, 1954

FamilyCALCEOLISPONGIIDAETeichert,1954

Jimbacrinus Teichert, 1954

TYPE SPECIES

Jimbacrinus bostocki Teichert, 1954 from the Artinskian Cundlego Formation, Western Australia; by original designation.

Jimbacrinus donnellyensis sp. nov.
(Fig. 21)

ETYMOLOGY

For Donnelly's Well.

MATERIAL

Holotype CPC30685, paratypes CPC30686-30691

from the upper part of the Artinskian Bulgadoo Formation in the type section near Donnelly's Well.

DESCRIPTION

Crown small, pear-shaped, arms incurled distally. Cup bowl-shaped, walls subvertical, base slightly invaginated, moderately deep apical pits. IBB 5, kite-shaped, longer than wide, proximally downflared, distally upflared, visible in lateral view of cup. BB 5, hexagonal, subequal to wider than long, proximally subhorizontal, distally upflared becoming subvertical at distal tip; CD basal heptagonal, truncated distally for primanal. RR 5, pentagonal, wider than long, subvertical, bear shallow medial longitudinal depression. Radial facet plenary, bearing transverse ridge, outer ligament pit and marginal shelf. Primanal large, longer than wide, proximal 2/3 in radial circlet, adjoins 2 tegmen plates distally. Arms 5, atomous. Brachials rectilinear proximally, cuneate distally, strongly convex transversely, concave longitudinally, bearing faint longitudinal ridges after 3rd or 4th brachial; IBr_2 bearing two coarse slightly diverging laterally projecting blunt nodes. Pinnules large, elongate, one per brachial on alternate sides of arm. Stem pentagonal in section proximally; latus convex; heteromorphic type 1 pattern; distally round, homeomorphic, bearing few short cirri. Axial canal round.

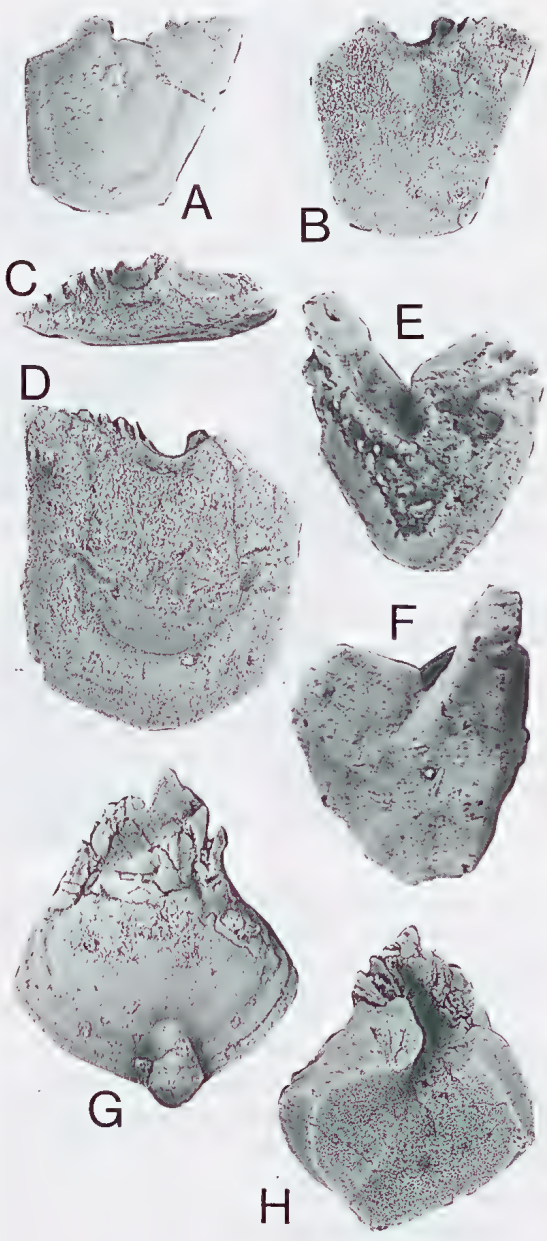

FIG. 23. *Neoschisma verrucosum* Wanner, 1924b. A,B, C radials QMF21481 and 21482, ×10 and ×6, respectively. C,D, oral and lateral views of D radial QMF21483, ×5 and ×6, respectively. E,F, external and internal views of epideltoid QMF21484, ×7. G,H, external and internal views of hypodeltoid QMF21485, ×4.

REMARKS

This description is a composite based on the 7 specimens. The holotype has a well preserved cup, proximal most column and C ray arm but exposed basals have been rounded by solution. One paratype (Fig. 21C) shows the infrabasal circlet and prominent protrusion on the basals. Two specimens (Fig. 21A,B) have well preserved brachials one and two, and two other specimens (Fig.21D) have well preserved columnals showing the gradation from the pentagonal to round sections within approximately one centimeter of the cup. Weathering has etched the surface of most specimens producing nodes and grooves which could be mistaken for ornamentation unless all specimens are considered.

Unlike most species of *Calceolospongia* that rested on the substrate with extended basals (Teichert, 1949), *Jimbacrinus* lived above the substrate supported by the stem (Teichert, 1954). All plates except the basals of *J. donnellyensis* are relatively thin and the crown is small relative to the stem; these features suggest an elevated life habit.

This is the third species of *Jimbacrinus* recognised and it is the oldest. It is easily distinguished from *J. bostocki* and *J. minilyaensis* by the wider basal plane and subhorizontally directed basal protuberances. *J. bostocki* probably evolved from *J. donnellyensis* by development of the central spine on the basals.

Family and genus indet.
(Fig. 18B)

MATERIAL

QMF21469 a partial set of arms from QML770.

REMARKS

This set of arms includes parts of 4 half(?) rays which could be a part or parts of one to three rays. The brachials are: moderately (proximally) to slightly (distally) wider than long; externally strongly convex transversely; bearing a medial longitudinal ridge terminating distally in a very short spine directed upward and outward; and moderately (proximally) to strongly (distally) cuneate. Brachials are slightly offset giving arms a slightly zigzag appearance, which is enhanced by the alternating direction of the medial ridge/spine. Isotomous endotomous or exotomous branching occurs twice on two of the partial rays and possibly a third time on one. A slender pinnule articulates with the branchial at the distal end of the medial ridge aboreal to the spine.

Classification of this specimen is uncertain. The zigzag brachials resemble some genera of the Decadocrinoidea, but they only have 10 arms, isotomously branching on the first or second primibrachial. Four superfamilies of the poteriocrininids include genera with endotomous or exotomous branching. The Hydreionocrinoidea have biserial arms and given no further consideration. The Pirasocrinoidea typically have spine rings capping the anal sac, brachials are rectilinear to faintly cuneate, and few genera are actually known to have endotomous or exotomous branching. *Linocrinus*, *Tholocrinus* and *Exocrinus*, of the Zeacrinitoidea have ray ridges or cuneate brachials but all lack the zigzag offset of the brachials. Only *Linocrinus*, has both ray ridges and cuneate brachials. Cuneate brachials are characteristic to several genera of the Texacrinoidea. *Galateacrinus ornatus* Moore, 1940 has medial ridges terminated in short spines on cuneate brachials, but the brachials are not offset.

Lacking proximal parts of the arms and the cup the specimen is left in open nomenclature. It is illustrated to show recognised diversity in the advanced poteriocrinid faunas from the Callytharra Formation. The branchials and branching pattern are sufficiently distinct to offer correlation potential if similar specimens are found elsewhere.

DESCRIPTION

Proximal columnals unknown; medial columnals homeomorphic to heteromorphic type I; cirriferous distal columnals heteromorphic type I. Columnals circular in transverse section, axial canal pentagonal. Articulum wide, full facet width with no areola to nearly full facet width with narrow areola sloping into axial canal. Culmen fine, branching isotomously at midwidth to distal 1/4 of articulum, 40 per cm at mid width of articulum. Symplexy articulation. Latus smooth, straight. Axial canal narrows at moderately convex claustrum on each columnal. Cirri circular in transverse section, articulum like columnal articulum. Cirral scars aligned in part, may give columnal a rough pentagonal section, overlap 1 then 2 adjacent columnals as growth increases; cirri scars increase in size distally.

REMARKS

Large pluricolumnals, 5.0-9.4cm long and 1.7-2.4cm diameter are especially common in exposures of the basal part of the Callytharra Formation throughout the Carnarvon Basin. They have been collected for many years and are present in most major museum collections throughout Australia. The first illustrations of these columnals was by Foord (1890) followed by Etheridge (1903) who reported infestations of endophytic fungus on some stem segments. More recently Welsh (1976) has demonstrated that these infestations and others referred to myzostomids by Warn

R

(1974), among others, are caused by *Phosphannulus*.

Considerable morphologic and diagenetic variation occurs in the pluricolumnals of *B.? carnarvonensis*. Many pluricolumnals lack cirri whereas others have a few and others many. Those with cirri show a progradation of increasing size of the facet distally and a corresponding alignment of the facet and more pentagonal transverse section of the columnals with the larger facet sizes. Heteromorphic noditaxial patterns change distally. Proximal patterns are 2 or 3 internodals between nodals in fairly regular repetitions. Distally internodals are fewer and occur infrequently, one every 3 to 7 nodals. The distal irregular noditaxis patterns correspond to the most cirriferous pluricolumnals.

Weathering of the pluricolumnals is greatest along articular facets resulting in pluricolumnals with a V-shaped or cog-shaped latus and what appears to be impressed sutures. Weathering on some specimens has been deep and results in irregularly shaped transverse cross-sections. The large axial canal collapsed under compaction after burial and many pluricolumnals appear elliptical in transverse section.

Class BLASTOIDEA

The only descriptions of Western Australian Permian blastoids have been those of Breimer & Macurda (1972) who named the fissiculates *Neoschisma australe* and *Notoblastus stellaris* and identified the Timorese species *Thaumatoblastus lonigramus* Wanner, 1924b in Western Australia and Breimer (1983) where the detailed species descriptions were provided. Apart from providing further information on each of these a new spiraculate species is described and the Timorese species *Neoschisma verruscosum* is recorded in W.A. Apart from this specific match all have generic links to Timor suggesting a close biogeographical link between the two areas.

Order FISSICULATA Jaekel, 1921
Family NEOSCHISMATIDAE Wanner, 1940

Breimer & Macurda (1972) discussed fissiculate phylogeny in great detail having established their classification apparently phenetically. All the fissiculates described herein are assigned to the Neoschismatidae following Breimer & Macurda. The only comment regarding intergeneric relationships concerns the placement of *Pterotoblastus*. Although placed in the Codasteridae by Wanner (1940) and by Breimer & Macurda (1972) *Pterotoblastus* appears to have quite a deal in common with various neoschismatids, in particular *Notoblastus*. The major distinguishing feature appears to be the reduction in the number of slits per hydrospire field and loss of slits on the anal deltoid in *Pterotoblastus*. Breimer & Macurda (1972) made an emphatic point that "Hydrospire structures of neoschismatids are essentially unchanged; ... There is no trend towards reduction in the number of hydrospire slits, neither in regular, nor in anal hydrospire groups". However, their further discussion of hydrospires in the Family reveals an abundance of slits in the earliest representative, *Hadroblastus*, and several of the Permian genera but in several species, effective reductions are recorded. According to Breimer & Macurada (1972, p. 346) these reductions are effected through filling of the slits by secondary calcite deposits. They regard *Timoroblastus* as a form with most of its slits completely closed off by secondary calcite. *Pterotoblastus* has more slits than *Timoroblastus* and the small number in each genus could be due to the same process, calcite infilling of most slits. In the anal interray groups of slits, *Neoschisma* contains one species with approximately the same number of slits as non-anal groups because the hypodeltoid bears numerous slits; a second species has a greatly reduced number where the hypodeltoid does not bear slits. In *Notoblastus* there are 1-5 slits in each anal hydrospire field. This is significantly fewer than in anal fields of certain species in other genera where slits are present on both epi- and hypodeltoids. Even in *Notoblastus*, *N. cornutus* (McKellar, 1969) has 5 slits per group in the D interray, *N. oyensi* (Wanner, 1940) and *N. stellaris* have 3 and *N. brevispinus* has 2. Therefore, we consider that the difference between 2 and 0 slits in the anal group no more significant than that between 5 and 3. We suggest that *Pterotoblastus*

Neoschisma australe Breimer & Macurda; Macurda, 1983: pl.27, fig. 2 (only); pl.28, figs 7-9, 12.

MATERIAL

Western Australia – UMMP58682 (holotype of *N. australe*) from the type section of the Callytharra Formation, 0.88 km west of Callytharra Springs, WA. QMF21485 an hypodeltoid, QMF21484 an epideltoid and QMF21481-21483 radials from QML757.

DISCUSSION

Breimer & Macurda (1972) diagnosed *N. australe* as having a flat rather than scalloped vault and as having hydrospire slits developed on both the epi- and hypodeltoids. The surface of the vault was a variable feature in the Callytharra collections with the depth of the V in the top of the radials and the convexity of the deltoids varying with growth and among individuals of similar size. With the relatively few specimens available this feature would seem unsuitable for species separation. However, development of hydrospire slits on both epi- and hypodeltoids should be clear cut. In the type species, the hypodeltoid does not bear any hydrospire slits (Wanner, 1924b, pl. 199, fig. 10; Breimer & Macurda, 1972, pl. 19, fig. 5). In the holotype of *N. australe* (Breimer & Macurda, 1972, pl. 19, figs 6, 7) the hypodeltoid is a flat, fairly upright plate, tapering adorally but not pointed, with the anal aperture an indistinct invagination into the adoral side and with a distinct double tubercle medially on the aboral RD margin.

Another such plate (Fig.23G,H) is now available with the same shape, distinctive aboral tubercle and ragged adoral margin. In this specimen the protruding ragged adoral edge conceals the anal aperture which is obvious on the internal side. The anal opening cuts through a prominent curving ridge that runs across the plate. A low but distinct ridge runs from near the centre of this gap to the RD margin towards the C side. Moreover this specimen bears no hydrospire slits. On this basis we assign the holotype of *N. australe* and the isolated hypodeltoid mentioned above to *N. verrucosum* based on the lack of hydrospire slits on the hypodeltoid. Radials (2 C and 1 D radials; Fig.23A-D) with truncated upper corners are referable to this species also; the truncation corresponds to the RD margin along the hypodeltoid.

On the other hand, the hypodeltoid figured by Breimer & Macurda (1972, pl. 19, fig. 1) and two others (Fig. 25C,D,H,I) do bear numerous hydrospire slits. These plates represent a separate species and are described below. To that species are also assigned several radials which may be identified as having the "broad convex humped area" described by Breimer & Macurda (1972, p.32) in the hydrospire field adjacent to the hypodeltoid near its widest point. However, many radials, basals and deltoids, from other than the anal part of the theca are not able to be assigned with certainty. They are here assigned to *N. extensum* for convenience only.

The epideltoid (Fig.23E,F) is assigned to this species because the anal opening is irregular, anal collar very low and there are hydrospire slits on both its aboral extremities. Despite the considerable size difference between this epideltoid and available hypodeltoids it seems to fit with the hypodeltoid described above in that the low collar

Neoschisma australe Breimer & Macurda; Breimer, 1983:122, pl.27, figs 1, 3-12; pl.28, figs 1-6, ?10, 11, 13-16; pl.30, fig.3.

ETYMOLOGY
Latin *extensus*, stretched out; referring to the anal collar.

MATERIAL
Holotype QMF21494, an hypodeltoid from QML760. Paratypes hypodeltoid and D radial (Breimer & Macurda, 1972, pl. 19, fig. 1), C radial (Breimer & Macurda, 1972, p. 19, fig. 3, 4; BMR GW137), D radial (Breimer & Macruda, 1972, pl. 19, fig. 8) NMVP127198 an articulated but crushed and incomplete theca from 20.3m in the type section of the Callytharra Formation, 0.88km west of Callytharra Springs. QMF21490 fragmentary basal, QMF21486-21489, 21491, 21492 almost complete radials, QMF21493, 21495, 21498-21501 deltoids, hypodeltoid QMF21497 from QML757. One deltoid, QMF21496 from QML760.

DISCUSSION
The problem of assigning non-anal plates to *N. verrucosum* or this new species has been discussed above as has the hypodeltoid with hydrospire slits belonging to the new species. One hypodeltoid (Fig.25C,D) is of the same maximum width as the isolated hypodeltoid of *N. verrucosum* (Fig.23G,H) so the different hypodeltoids may not be attributed to different growth stages of the same species. Any isolated plates of *Neoschisma* that cannot be definitely referred to one or other of the species is tentatively referred to this new species.

The description of *N. australe* as given by Breimer & Macurda (1972, p. 32) and Macurda (1983, p.122) should be applied to this new species except as varied in the following. The fragmentary basals suggest that the BB sides of the plates diverged strongly adorally to give the theca a strongly flared base. In large radials, lateral edges are not always straight; often having a gently sigmoidal curve over adoral half (Fig.24H). In C and D radials hydrospire slits are absent in a zone near to and on the anal interarea side of the central and ambulacral notch. This zone was described by Breimer & Macurda (1972) as that where a "broad convex humped area formed". In specimens available to us (Fig.24A,C,D) the convexity is at right angles to the hydrospire slits and parallel to the RD margin with sharp furrows crossing the humped area also parallel to RD margin (Breimer & Macurda, 1972, pl.19, fig.4; Fig.24A). The upper margin of this convex zone is in contact with a convex face on the hypodeltoid just adoral to the hydrospire slits. On the interior side of this convex area on the radial is a shallow concave channel that leads across the RD suture along the deltoid to the anal opening. Lateral to this convex zone on the radial, the projection of the radial limb is greatly reduced and in one specimen the hydrospire field is declined aborally (Fig.24D). In this same CD interarea position there appears to be a greater than normal development of secondary calcite in front of the slits and one specimen (Fig.24D) a shield has grown almost completely hiding the slits from lateral view.

One available deltoid (Fig.25O,P) is much shorter, in interradial direction, than other deltoids. This specimen has the aboral tip slightly downturned forming a shallow aboral pocket on the internal surface. It has 8 hydrospire slits on one

side and only 3 or 4 on the other, whereas elongate deltoids of comparable width may have 15 or 16 slits. The side with only 3 or 4 slits has a long aboral zone without slits. Whether this is from an aberrant specimen or there is some other explanation is not known at present. We have no epideltoid to assign to this species. The two hypodeltoids appear dissimilar principally because one has a very high anal collar, subdued comarginal ornament and prominent distal blade-like projection whereas the other has no raised anal collar, prominent sharp comarginal ridges and no distal projection. On the latter specimen the anal collar and distal projection may have bene removed by postmortem abrasion. Internally (Fig.25D,H) the two plates are identical with a ridge across the plate at the adoral end of the hydrospire slits. On the surface of the anal groove, adoral to the transverse ridge, are low irregularly placed tubercles. Adorally on the plate are a pair of flat facets presumably for junction with the epideltoid.

One deltoid retains a lancet on one side (Fig.25J-L) and one radial retains the short aboral tip of the lancet in the ambulacral notch (Fig.24G,H). The DD margin of the deltoid is straight adorally, then slightly concave and convex dipping down aborally. This shape is well illustrated in the assembly of Breimer & Macurda (1972, pl.19, fig.1) but the dorsal half of deltoids should be in contact. In oral view the lancet corresponds to this shape being narrow and depressed adorally beneath the abutting deltoids, but wider and flush, with the sides of the deltoids in the main body area where deltoids do not touch. In Breimer & Macurda's (1972, p.33) description it is not clear which part of the lancet is being referred to as adoral and which is aboral; in this work the adoral section is where the ambulacral groove is supported entirely by the deltoids, the main body is where the ambulacral groove is supported by the lancet and adoral section is on the radial. The lancet is widest at aboral end of main body, tapering very slowly adorally it disappears internally at adoral end of the main body. Small transverse grooves are evident within the ambulacral tract but the arrangement of side plates or even their presence is not confirmed by available material.

Notoblatus Brown, 1942

TYPE SPECIES

Notoblastus brevispinus Brown, 1942 from the Early Permian of New South Wales; by original designation.

Notoblastus stellaris Breimer &Macurda, 1972 (Fig. 26)

Notoblastus stellaris Breimer & Macurda, 1972:34, pl.20, fig. 1; pl.21, figs 1,2,7,8.

Notoblastus stellaris Breimer & Macurda; Breimer, 1983:132, pl.29, figs 5-7,11,12; pl.30, figs 1,2,4-10,15-17.

MATERIAL

Holotype UMMP58683 from the type section of the Callytharra Limestone on the Wooramel River, WA. NMVP127199 an articulated but weathered specimen from locality BB929 which is 20.2m above the base of Section 7 on Mt. Sandiman Station, 1.9km at 15° from Mt Sandiman Woolshed, from the collection of Dr G.A. Thomas, now housed in the Museum of Victoria. Radials QMF21506-21510, 21517, 21518, CPC30965, 30967, deltoids QMF21502-21505, epideltoids QMF21511-21513, and lancets QMF21514-21516 from QML757.

DISCUSSION

This species was described in detail by Breimer and Macurda (1972:34) and Macurda (1983:132); only where new information is available are comments added here. However, an attempt is made to illustrate several features and plates not obvious in earlier papers.

The theca described here is taller than that of Breimer & Macurda (1972) with the basals accounting for some 25-30% of total height; the height is 17mm and maximum width 16mm but this theca is compressed laterally so the width is overstated. In life the theca must have been considerably higher than wide.

On the radials, the ambulacral sinus extends along the radial projection to the point where the projection turns upwards; in the smaller specimens this means the sinus does not extend onto the projection at all but in the largest radial (Fig.26Y,Z) the sinus extends well out onto the projection to the point where the upper surface of the projection is about to turn upwards. There

appears to be some variation in the shape of radials through growth but the small sample size and degree of postmortem deformation make it impossible to identify how much. In the CD interray, hydrospire slits are reduced to one or two per field and these situated close to the ambulacrum. In the smaller radials described here, both in the articulated specimen and as disassociated plates, the hydrospire fields are not evident in lateral view; although the individual plates all appear to have undergone a degree of distortion this is unlikely to have accounted for the attitude of the hydrospire fields in every case. In large radials (Fig.26S,U,Y,Z) the hydrospire fields are more upright and evident in lateral view.

Epideltoid same as a deltoid except that hydrospire fields are reduced to 1 or 2 slits on each margin projection at lateral extremes; these projections were sutured to radials. On inner sides of these projections are elongate facets that presumably sutured to the hypodeltoid. In the centre of the plate was a large circular anal opening. The adorally chevron-shaped ridge of the deltoid is greatly accentuated. No plate in our collections may be certainly identified as the hypodeltoid but its shape is inferred from the epideltoid and radial that would have bounded it. The hypodeltoid must have been wide and rhomboidal with the adoral corner excavated by the anal opening so that a shape approaching broadly arcuate is possible.

Since isolated lancets and those still in the ambulacra of weathered radials (Fig.26S,U) show the lancet to be elongate rhomboidal in plan view. The adoral part (i.e. from widest point to adoral tip) is shorter than aboral part which tapers very gently and extends to tip of ambulacrum. Laterally on adoral part are the slightly protruding faces that abut the excavation into the sides of the deltoids. On internal surface is an adoral diamond shaped area bounded by a distinct ridge and with concave surface. The aboral tip of the diamond fills the V-shaped gap in the radial and the aboral extension with rounded inner surface lies in the ambulacral groove on the radial.

Thaumatoblastus Wanner,1924b

TYPE SPECIES

Thaumatoblastus longiramus Wanner,1924b from the Permian of Timor; by original designation.

Thaumatoblastus longiramus Wanner,1924b (Fig.30H,I)

Thaumatoblastus longiramus Wanner:Breimer & Macurda, 1972:36, pl.24, fig.2; pl.25, figs 1-8; pl.28, fig.5.

Thaumatoblastus longiramus Wanner: Macurda, 1983:135, pl. 31, figs 7-10; pl.32, figs 1-10.

MATERIAL
Radial plates CPC30703, 30704 from ML87.

REMARKS
One of these radials (Fig.27H) was figured by Breimer & Macurda (1972, pl.25, fig.5) and agrees with the other in size of the side plates relative to the width of the ambulacrum. These side plates appear to be the same size and shape as figured by Wanner (1924b) and their assignment to the type species is accepted.

Thaumatoblastus sp. nov.
(Fig.27A,G)

MATERIAL
Radial plates CPC30698,30702 from KNF73 and QMF30705-30709 from ML89.

REMARKS
The two specimens with lancet and side plates preserved (Fig.27A,F,G) show a greater number of side plates per centimetre of ambulacrum when compared with the 2 radials described above as *Thaumatoblastus longiramus*. These two specimens are considered specifically separate but because they are so incomplete no new specific name is introduced.

Thaumatoblastus sp. indet.
(Fig.27B-F,J-O)

MATERIAL
Radial plates CPC30699-30701 from KNF73 and QMF30705-30709 from ML89.

REMARKS
Assignment of these radials, that have lost their lancet and side plates, to either of the species mentioned above is not possible with the present state of knowledge. However, it is likely that they belong to one or other of the species occurring in Western Australia. All those radials figured by Breimer & Macurda (1972, pl.24, fig.2; pl.25, figs 1-4, 6,8; pl.28, fig.5) which do not retain a lancet or side plates are in the same situation and definite specific assignment will depend on more detailed study of this and better material from Western Australia and Timor if and when it becomes available.

Family UNCERTAIN
Deltoid indet
(Fig. 28)

MATERIAL
Two plates QMF21553 from QML757 and CPC30710 from 20m above base of the type section of the Callytharra Formation.

DESCRIPTION
These two plates are hexagonal with the six sides virtually of equal length. Two adjacent sides have 7 or 8 slits normal to the margin; interpreted as hydrospire slits. Comarginal growth lines are evident parallel to the other sides; a group of 6-9 low rounded tubercles are situated centrally with the central tubercle highest and most prominent.

REMARKS
Although these plates are abraded and only one is preserved so as to be confident of its features they are interpreted as the deltoid plates of some blastoid because of the hydrospire slits and general resemblance to the deltoids of *Notoblastus* described above. However, the six even sides to these plates and apparently unspecialised edges (ie. other than those with slits) are features unknown among the blastoids. Their identity even as blastoid plates, remains a mystery at present but they are recorded to show the diversity.

Order SPIRACULATA Jackel, 1921
Family PENTREMITIDAE d'Orbigny, 1851

Rhopaloblastus Wanner, 1924b

TYPE SPECIES
R. timoricus Wanner, 1924b from the Permian of Timor; by orginal designation.

DIAGNOSIS
See Breimer & Macurda,1965:216.

REMARKS
Breimer & Macurda (1965) considered *Rhopaloblastus* to differ from other genera in the Pentremitidae by its petaloid ambulacra and exposed cryptodeltoids. The species described below has exposed cryptodeltoids but ambulacra,

FIG. 32. *Monaster coleyi* sp. nov. A,E, adoral end and oral view of arm fragment (could be part of holotype but not certain) NMVP127201, ×7 and ×8, respectively. B-D, F-H, holotype NMVP127200. B, lateral view of A ray, ×5. C,D, oral view, ×4 and ×7. F,E, aboral view, ×4 and ×6. G, enlargement of madreporite area, ×10.

in the largest available specimen, are not petaloid but rather elongate, much more in the style of *Calycoblastus*. We have assigned the species with the emphasis on the anal deltoid arrangement because that feature seems generically more consistent through the blastoids. The smaller theca (Fig.29D,E) exhibits more petaloid ambulacra but in all other respects this species coincides better with the type of *Calycoblastus* than *Rhopaloblastus*. *Calycoblastus* was originally protrayed (Wanner,1924b) as having eight spiracles and an anispiracle. Brown (1942) credited *C. casei* from New South Wales with 10 spiracles. However, Breimer & Macurda (1965) re-examined the holotype of the type species arguing from the weathered surface that it possessed four spiracles and an anispiracle. This is in accord with the diagnosis of *Rhopaloblastus* and with the species described below but *C. casei* Brown, 1942 has yet to be re-examined to verify this feature and determine whether it should remain in that genus. Radials of this new species closely resemble radials ascribed to *Rhopaloblastus* (?) *belfordi* (Crockford & Brown) (Brown,1942:102) from the Permian of the Hunter Valley and to *Rhopaloblastus*? cf. *belfordi* (McKellar,1969:25) from the Berserker Beds near Rockhampton. Without knowledge of the anal deltoids it is impossible to assign these isolated radials generically; their elongate ambulacra indicate *Calycoblastus* but the similarity to those assigned to *Rhopaloblastus* below suggest the earlier assignments may be correct. It is surprising that no reference was made to *Calycoblastus* in discussions of these eastern Australian radials by either author.

Rhopaloblastus cuspidus sp. nov.
(Figs 29,30)

ETYMOLOGY

Latin *cuspis*, point; refers to adoral projection of radial at centre of ambulacra.

MATERIAL

Holotype QMF21519; paratypes articulated specimens QMF21519, 21521, and NMVP94182, basals QMF21523, 21525-21527, radials QMF21524, 21528-21530, 21532-21537, and lancets QMF21520, 21522, 21531 from QML757.

DESCRIPTION

Calyx tall, with height to width ratio 2, maximum width at aboral extremities of ambulacra which are 0.3 of height from oral pole; vault dome-shaped. Pelvis conical, with relatively broad base (2mm), at least at calical height of about 20mm. Stem unknown.

Basals three, approximately half pelvic height, each occupying 120° of circumference, slightly waisted just above stem attachment, with straight flaring sides; upper margin concave to chevron-shaped centrally, descending on both sides. Stem attachment area terminal, flat to gently concave, with narrow marginal crenullarium. Radials tall, occupying about half calical height, with well developed comarginal growth ridges in each growth sector, externally convex in both transverse and vertical section, with broad low tubercle at origin a short distance below the aboral end of ambulacral sinus, with a low ridge extending over that short distance and the ridge waisted at its midlength. As the ridge widens towards the ambulacrum it merges with a narrow smooth area of secondary calcite deposition bordering the ambulacral sinus under which growth lines of the RR sector simply disappear. At the aboral end of the ambulacral sinus a short broad cusp projects orally (often broken off on available material but if not evident, the broken base is evident). Ambulacral sinus of variable length but usually occupying about half length of radial (almost all dissociated radials are broken in the RD sector, making it impossible to be certain of this proportion but in some radials the length of the RB sector relative to its width suggests that the ambulacral sinus may occupy less than 20% of radial length). Ambulacra narrow, widening only gently adorally, depressed beneath outer surface of radial; lateral walls of ambulacral sinus becoming higher towards RD front, gently convex, crossed at low angle to lateral margins by growth ridges that are coarser than on the exterior, sigmoidal in section with variable attitude from almost vertical and then the sigmoidal section only weakly evident to much lower angle exposing a stronger sigmoidal section and producing a much wider ambulacral sinus; in the latter case the groove formed by the sigmoidal wall of the sinus is closer to the external surface than the convex roll and the groove does not reach the aboral end of the sinus. On the floor of the ridges is a further groove to accommodate the lancet plate; lancet extremely long, subquadrate in section, covered by side plates. Side plates each with single large prominent brachiolar facet and hydrospire pore abradially between successive side plates; side plates in contact along radial line throughout ambulacrum. RD margin variably transverse to chevron-shaped orally, and either straight or slightly sigmoidal, overlying part of deltoid; some isolated radials appear to have

pointed limbs suggesting the RD margin could, in that case, be rather short but articulated specimens of that type are unknown. On the radial interior secondary calcite near the aboral end of the ambulacrum has weathered away in some specimens exposing the hydrospires in groups of 5.

Deltoid with tall triangular aboral part bearing a median radial crest and prominent transverse coarse growth ridges that run aborally down the wall of the ambulacral sinus; oral end expanded into large deltoid lip around the spiracle opening which descends at a low angle beneath the triangular part of the deltoid. Around the spiracle and extending down the deltoid-ambulacrum boundary are small upright spiracle cover plates. Anal deltoid area destroyed by compaction in holotype but a superdeltoid is evident with low ridged radial ornament on it in a dislocated situation. On paratype theca (Fig.29E,F) the exposed cryptodeltoids are evident with weathered remnants of the hypodeltoid also apparent. Oral opening pentagonal.

REMARKS

The complete holotype and paratype (Fig.29D-F) provide most of the critical information on arrangement of plates in the theca. In the holotype, features may not be directly interpreted because of compaction after death which has apparently shortened the polar axis and probably increased its diameter. Most isolated plates available are incomplete or crushed but all in all a fairly good idea of the species is available.

This species is distinguished by its thecal and ambulacral shapes and has the unique feature of the cusp in the aboral end of the ambulacral sinus. The prominent growth lines across the deltoid also appear to be distinctive.

Class ECHINOIDEA
Subclass REGULARIA Latreille, 1825
Order CIDAROIDA Claus, 1880

Cidaroid indet.
(Fig.31)

MATERIAL

Spine bases QMF21541-21543 and fragmentary interambulacral plates QMF21544-21552 all from the type section of the Callythara Formation (QML761).

REMARKS

Teichert (1951:80) reported that echinoids are quite unknown in the Permian of Western Australia and none have been described since then. In washed samples from the type locality of the Callytharra Formation fragments of echinoids have been found and are reported here to make the faunal list more comprehensive.

The primary tubercles on these interambulacral plates are typically cidaroid with their prominent boss, platform, and tubercle.The noncrenulate tubercles along with the long, solid spines with longitudinal ridges suggest the Archaeocidaridae but the Miocidariidae cannot be excluded so family assignment is not attempted. Although different stages of weathering could be inducing different appearances of the plate ornament away from the tubercles it seems highly likely that at least 2 different types are present. Therefore, the possibility should be kept in mind that more than one species is present.

Archaeocidaris selwyni Etheridge,1892 from the Permian of NSW so the group is known from Australia but that species had much larger interambulacral plates than are available from the Western Australian sample. Although these species are probably closely related useful comparison is not possible at present.

Class STELLAROIDEA Lamarck, 1801
Family MONASTERIDAE Schuchert,

Monaster Etheridge,1892

TYPE SPECIES

Palaeaster clarki deKoninck, 1877 from the Permian of New South Wales; designated Schuchert,1914.

Monaster coleyi sp. nov.
(Fig.32)

ETYMOLOGY

For the collector Mr J. Coley who was bookkeeper at Wandagee Station for many years.

MATERIAL

Holotype NMVP127200 and paratype NMVP127201 from the Wandagee Beds (horizon q-r), on the north bank of the Minilya River in the eastern limb of the syncline near Coolkilya Pool. Collected by J. Coley. From the collections of C. Teichert deposited in the University of Melbourne and transferred to the Museum of Victoria in the early 1980s.

DESCRIPTION

This species is described by comparison with *Monaster wandageensis* Kesling,1969.

Stellate; arms tapering gradually to nearly parallel-sided; widened adorally to produce smooth curve on the interbrachial margin. Disc with prominent coronet on aboral surface; R1 subrec-

tangular, smooth, lying over Sm2 plates and abutting Sm1 plates on adpolar corners. Plating inside Sm1 circlet unknown. Interradially and distally between Sm2 plates is a deep cleft. M large, overlapping two Sm2 and abutting two R1 plates, with subradial striae.

Oral surface flat, mouth small; Adm1 and Ax not clear.

Arms strongly plated. Amb plates small, set deep in ambulacral groove. Admm wider than long, with transversely oblique row of 3 or 4 short stout spines, with obtusely pointed margin on ambulacral groove, with abradial margin in zone of tiny plates apparently part of a shagreenate skin covering the aboral surface and terminating at the junction between Imm and Admm.

Imm longer than Admm, approximately subquadrate, with obtusely pointed adradial margin, with series of transverse flutings along abradial edge. Radials small, subquadrate proximally, becoming more rounded distally, not in contact with each other, in contact with Imm at certain points only leaving gaps at sutures between Admm. All covered by finely shagreenate skin with small plates embedded in it.

REMARKS

This species is separated from the closely related *M. wandageensis* Kesling,1969 from the same locality by its nontuberculate R1, smaller Sm1, interradial clefts between Sm2 plates, and finely shagreenate aboral skin. It differs from *M. carnarvonensis* Kesling, 1969 also from the same locality, by the subrectangular R1, larger M, less tapering arms and finely shagreenate skin. It differs from the type species in the narrower, and straighter arms and more numerous arm plates.

ACKNOWLEDGEMENTS

We thank Dr J. Mac Dickins, Bureau of Mineral Resources, Canberra and Dr Ken J. McNamara, Western Australian Museum, Perth for their hospitality and for arranging for the loan of specimens from their respective institutions. Dr Des Strusz, Bureau of Mineral Resources, Canberra, Dr David Haig, Department of Geology, University of Western Australia, and Dr David Hollaway, Museum of Victoria are also thanked for organising loan of material in their care. We are grateful to the managers of Williambury, Wandagee, and Cherrabun Stations for access to collecting localities on their properties. We are grateful to Margaret Eva, Librarian at the Geology Department, University of Queensland for considerable help with provision of necessary references. GDW extends his appreciation to the Director of the Queensland Museum for facilities and office space during prosecution of this project.

LOCALITY REGISTER

QML localities are in the Callytharra Formation. Map sheets referred to are in the 1:250 000 Geological Series.

QML757 – North side of bladed track from Callytharra Homestead to Byro Homestead in western most exposures 1.5km west of type section south of Wooramel River. 25°52'30"S, 115°29'E Wooramel Sheet SG50-5, 1966.

QML758 – North side of bladed track from Callytharra Homestead to Byro Homestead as track enters dry wash tributary to Wooramel River; lowermost fossiliferous shale and marl capped by limestone in lower fossiliferous unit in Callytharra Formation. type section. 25° 52'30"S, 115° 30'05"E, Glen burgh Sheet SG50-6, 1963.

QML759 – Second fossiliferous shale and marl capped by limestone in type section. South side of track and stratigraphically higher than QML758.

QML760 – Third fossiliferous shale and marl capped by limestone in type section. Immediately south of and stratigraphically higher than QML759.

QML761 – Fourth and fifth fossiliferous shale and marl capped by limestone in type section. Immediately south and stratigraphically higher than QML760.

QML767 – Flats south of low hill approximately 100-150m northeast of turnoff to Merlinleigh Homestead, 6.5km west northwest of Mt Sandiman Homestead. 24° 23'S, 115° 20'E, Kennedy Range Sheet SG50-1, 1963.

QML768 – Flats with low limestone exposures 50-100m east of new road to Moogoorie on both sides of northeast-southwest fenceline, 24° 18'57"S, 115° 18'40"E, Kennedy Range Sheet SG50-1, 1963.

QML770 – 2-3km east of Mundarrie Well in limestones of west dipping hogbacks north and south of Carnarvon-Lyndon road; GR292356, Winning Pool - Minilya Sheet SF50-13, 49-16, 1984.

QML771 – Third massive sandstone above base of Wandagee Formation, 50-150m north of Minilya River in east limb of syncline; GR257375, Winning Pool-Minilya Sheet SF50-13, 49-16, 1984.

QML772 – Bench in lower slope below cliff 0.5-1.0km NNW of type section in Cherrabun Member of

Hardman Formation, Millyit Range; GR767877 Crossland Sheet SE51-16, 1977.

BMRloc. KNF73 – Noonkanbah Formation (type section) at Brutens Yard.

BMR loc. ML87 and ML89 – Bulgadoo Shale, lowermost fossiliferous horizon; campsite east of Mia Mia Homestead. 23° 21'S, 114°34'E.

A NESTING COMMUNITY OF FALSE WATER RATS *XEROMYS MYOIDES* ON THE MYORA SEDGELANDS, NORTH STRADBROKE ISLAND.

Memoirs of the Queensland Museum 32(1): 374. 1992:- The False Water Rat *Xeromys myoides* Thomas, 1889 was described from Mackay. There are 14 in museums: 8 Northern Territory (1, from Sth Alligator R. [Parker, 1973]; 2, Daly R. [Redhead & McKean, 1975]; 2, Tomkinson R. [Magnusson et al., 1976]; 3 Melville Is. [Magnusson et al. 1976]): 6 Queensland (3, from Mackay [Thomas, 1889 (holotype), McDougall, 1944 (5, 3 have been lost)]; 1, Beerwah [Dwyer et al., 1979]; 1, Bribie Is. [Qld Museum JM2381]; 1, Nth Stradbroke Is. [Van Dyck, 1979]). In addition, specimens have been sighted or trapped-and-released: N.T. - Tomkinson R., 4, and Melville Is. where 3 were captured from an extraordinary mud nest (Magnusson *et al.*, 1976); Qld - Proserpine, 2 (P. Campbell, pers. comm. 1981), Kinaba Is., 1, Cooloola, 1, and Beerwah, 1 (Dwyer et al., 1979).

This small species has been seen and collected in or near shallow coastal wetlands such as mangrove forests, freshwater lagoons, swamps and sedged lakes close to foredunes. Little is known of its ecology or social behaviour. Curiously, it is not even known if the False Water Rat is aquatic.

This note reports the recent discovery of a number of active nests of *X. myoides* in the Myora sedgelands, North Stradbroke Is., (see Van Dyck, 1992). On 2 November, 1991, a large, reed-covered mound similar to that described by Magnusson et al. (1976) was found 13m inland from the upper mangrove limit on the Myora sedgelands, between Capembah and Cooroonpah Cks (27°27'58"S,153°25'47"E). Overnight trapping at the mound was unsuccessful. The following day a two hour survey along this narrow sedge strip revealed 3 more nests at intervals of 80-410m. Overnight trapping at one of these nests yielded an adult female (HB:120mm, TV:87mm, HF(su):24, E(n):14.4mm, W:49g) which was photographed, fitted with a radio transmitter and released at the capture site. This individual had small white spots over the dorsum, posterior of the shoulder blades. Similar spots were evident in JM2381 collected at Myora Springs in 1978. On 15 November, 1991, a 6hr survey of coastal sedgeland between Myora Springs and Chiggil Chiggil found another 8 possible nests that varied from relatively simple tunnels built into the supralittoral bank to more complex mounds. A recently constructed mound was found near Myora Springs on 4 February, 1992.

All mounds were located within the narrow ribbon of reed and sedgeland (1.2m high) where salinity is reduced by freshwater drainage. This zone, comprised almost exclusively of *Juncus kraussii*, *Baumea juncea*, *B. rubiginosa* and *Fimbristilis ferruginea* was up to 30m wide and was sharply delineated from the upper mangrove woodland tract (*Avicennia marina*, *Rhizophora stylosa* and *Bruguiera gymnorrhiza*) and the lowest extent of the wallum (dominated by *Melaleuca quinquenervia*, *Eucalyptus intermedia*, *E. robusta*, *Leptospermum liversidgei*, *Gahnia sieberiana* and *Caustis blakei*). Mounds were built on slightly elevated 'islands', some being found among small patches of stunted *Melaleuca quinquenervia* and *Casuarina glauca*, others on raised sedge hummocks. One nest was incorporated around the stem of a living *Vitex trifolia* var. *bicolor*.

Mounds were from 20cm to 60cm high with basal circumferences from 1.6m to 4.8m. From 1 to 3 entrance holes were found at each mound but others may have been hidden under the labyrinth of exposed tree roots into which mounds were often incorporated. These holes were oval in shape (approximately 60mm by 40mm) and were positioned either at the top or the bottom of mounds; they were from 30cm to 2m apart. Although lower holes were flooded at high tide, the mounds themselves were never entirely inundated.

Evidence of external mound 'workings' consisted of fresh roof plasterings in which a thin paste of black mud mixed with peat, dried leaves, sedges, or crab shell had been daubed over the top of the mound and worked between sedges (usually *Juncus kraussii*). Areas 'plastered' in this way measured as much as 1200cm^2 and fresh 'plastering' seemed to indicate that the nest was occupied.

X. myoides has been variously described as 'one of the rarest of our native mammals', 'vulnerable to changes caused by man', 'rare, scattered (probably at risk in some habitats and extinct in others)' and I designated it as 'vulnerable' (Van Dyck, 1991). It is not known whether the few records of the species reflect genuine rarity or a lack of searching effort in appropriate habitats. However, an occupied band of mud nests of *X. myoides* in the Myora sedgeland provides an excellent opportunity for future conservation research.

The commitment of the Endangered Species Program (ANPWS) to funding such research is gratefully acknowledged. Dr Peter Bostock (Queensland Herbarium) provided plant identifications.

THE AUSTRALIAN ASCIDIACEA PART 3, APLOUSOBRANCHIA (2)

PATRICIA KOTT

Kott, P. 1992 10 01: The Australian Ascidiacea Part 3, Aplousobranchia (2). *Memoirs of the Queensland Museum* **32**(2): 375–620. Brisbane. ISSN 0079-8835.

In this continuing systematic revision of the taxonomy of the class Ascidiacea (subphylum Tunicata) taxa in the formerly polyphyletic family Polyclinidae Milne Edwards are treated. Included are all species recorded from Australian waters with a posterior abdomen containing the gonads, and usually the heart. New families are erected to accommodate the genera formerly grouped in the polyphyletic Euherdmaniinae, viz. Placentelidae (*Placentela*), Protopolyclinidae (*Protopolyclinum*, *Monniotus*, *Condominium* n.gen.), Ritterellidae (*Ritterella*, *Dumus*, *Pharyngodicyton*), Euherdmaniidae (*Euherdmania*) and Pseudodistomidae (*Pseudodistoma*, *Anadistoma* n.gen., *Citorclinum*). The family Polyclinidae is redefined and restricted to the genera formerly comprising the nominal subfamily Polyclininae, viz. *Polyclinum*, *Aplidiopsis*, *Sidneioides*, *Synoicum*, *Morchellium* and *Aplidium*.

Larvae, observed for the majority of species, have characters significant at species, genus and family levels, and constitute valuable evidence of phylogenetic affinities. Embryos are incubated to tailed larvae internally in all taxa, usually being fertilised and beginning their development in the distal part of the oviduct, sometimes in a brood pouch constricted off from the zooid and sometimes at the base of the oviduct.

Colony development is significant in this group of aplousobranch taxa in which replication is prolific. Zooids are arranged in various colonial, including cloacal, systems. In taxa with extensive cloacal spaces (*Aplidium*), and in those with a soft test (e.g. *Polyclinum*), intracolonial hydrostatic pressure appears to contribute to colony turgidity. Sand and other inclusions in the test add strength and contribute to diversity in colony size and shape.

Parallel reduction in the size of zooids often results in convergent evolution, especially in size (number of rows of stigmata and number per row) of the branchial sac and size of larvae. Some taxa (*Pseudodistoma*, *Polyclinum*) have zooids and larvae with conservative morphology, and differences in colonial systems and colony shape and texture often determine species-level taxa. Zooid and larval morphology are more diverse in *Ritterella*, *Synoicum*, *Aplidiopsis* and *Aplidium*, with differences in the atrial aperture, stigmata, stomach wall and arrangement of larval ampullae and vesicles, as well as features of the colony and its systems, providing characters for species determination. Other characters, such as the nature of the larval adhesive apparatus, presence of branchial papillae, length of the oesophagus, nature of the stomach wall, and shape of the posterior abdomen and arrangement of male follicles in it, are significant indicators of relationships at higher (genus or family) taxon levels.

Sixty-two of the total of 110 species treated in this work are new. Many may be indigenous, but these families are not always well sampled, not often being found intertidally. Collection by SCUBA diving enables a diversity of habitats to be sampled and the range of forms treated in this work is largely the result of efforts of these divers. Other difficulties in studying this group, which have resulted in synonymy and misidentification, are colour variation and its post mortem change and loss, loss of colony and zooid turgor obscuring their shape and arrangement, and contractibility of zooids obscuring their morphology.

The most diverse genera in these waters are in the Polyclinidae, in which zooids are organised around well developed cloacal cavities. *Aplidium* is the most diverse genus, and is well represented in both tropical and temperate waters by species with large and conspicuous colonies. Of the families with independently opening zooids without cloacal systems, Pseudodistomidae and Ritterellidae are well represented, especially in certain temperate locations. Euherdmaniidae and Protopolyclinidae are less diverse although each contains some species with wide temperate geographic ranges common in certain locations.

☐ *Indo-West Pacific, Ascidiacea, Aplousobranchia, Placentelidae, Protopolyclinidae, Ritterellidae, Euherdmaniidae, Pseudodistomidae, Polyclinidae.*

INTRODUCTION

Ascidians of the suborders Phlebobranchia (one of the 2 suborders of the order Enterogona) and Stolidobranchia (the only suborder of the order Pleurogona) were reported on in part 1 of the present work (Kott 1985); and 7 families of Aplousobranchia (the other suborder of the Enterogona) were dealt with in part 2 (Kott 1990). The following account (part 3) continues the review of the Aplousobranchia, dealing with genera formerly contained in the family Polyclinidae Milne Edwards, 1842. These genera are here assigned to 6 different families, 5 of them new (Table 1).

Didemnidae (Aplousobranchia), the only family not yet treated, will comprise part 4 of this monographic treatment of the Ascidiacea in Australia.

The collections on which the work is based are those set out in parts 1 and 2 (Kott 1985, 1990). Museums housing the material examined are referred to by the following abbreviations: AM, Australian Museum, Sydney, New South Wales; BM, British Museum (Natural History), London, UK; QM, Queensland Museum, Brisbane, Queensland; SAM, South Australian Museum, Adelaide, South Australia; TM, Tasmanian Museum, Hobart, Tasmania; MV, Museum of Victoria, Melbourne, Victoria; NTM, Northern Territory Museum, Darwin, Northern Territory; WAM, Western Australian Museum, Perth, Western Australia; USNM, US National Museum of Natural History, Smithsonian Institution, Washington DC, USA; ZMA, Zoological Museum of Amsterdam, Amsterdam, Netherlands; ZMC, Zoological Museum, University of Copenhagen, Copenhagen, Denmark. AMPI refers to the Australian Marine Photographic Index (Neville Coleman).

All specimens referred to by a museum registration number have been examined in the course of the present study. A registration number in italics refers to a sampled portion of the preceding colony.

Throughout this work, the characters of species are summarised to provide a general overview of the diversity of each genus. Dichotomous keys are presented as aids to the identification of taxa at all levels. They have been prepared, as far as possible, to reflect phylogeny. This type of key is generally used for biological material in preference to tabular keys such as those in Monniot (1987). The latter provide too rigid a framework for the analysis of diverse biological material, communicate only a limited amount of information, lack the flexibility to distinguish between convergent and phylogenetic relationships, are open to subjective interpretation, and are unnecessarily unwieldly and ambiguous to use.

Procedures for collection and examination of species are set out in Kott (1990). Examination of specimens is by stereoscopic and compound light microscopy. All larvae are described from stained and mounted specimens taken from adult colonies as indicated.

ACKNOWLEDGEMENTS

I am grateful to those of my collegues, as set out in parts 1 and 2, who, in various material ways, have contributed to the preparation and presentation of these volumes; and to those who have made less tangible, but equally significant contributions by their support and encouragement.

The black and white figures were prepared from camera lucida and other sketches of the specimens by Stephen Cook (Figs 1a–d, 2–6, 7b–d, 8a, 9a–f, 11a–f, 13a–e, 14, 17b–3, 18a–c, 19, 21a, 24, 27, 28a, 35a,b–e); Lucille Crevola Gillespie (Figs. 7a, 17a, 22a); and John Kennedy (all other figures including the larvae of all taxa). Peta Woodgate typed the manuscript. I am grateful to them all. Sue Boyd with Christine Mateira in the Museum of Victoria; Penny Berents in the Australian Museum, Loisette Marsh with Jean Thipthorp in the Western Australian Museum, and Wolfgang Zeidler with Karen Gowlett Holmes in the South Australian Museum have been co-op-

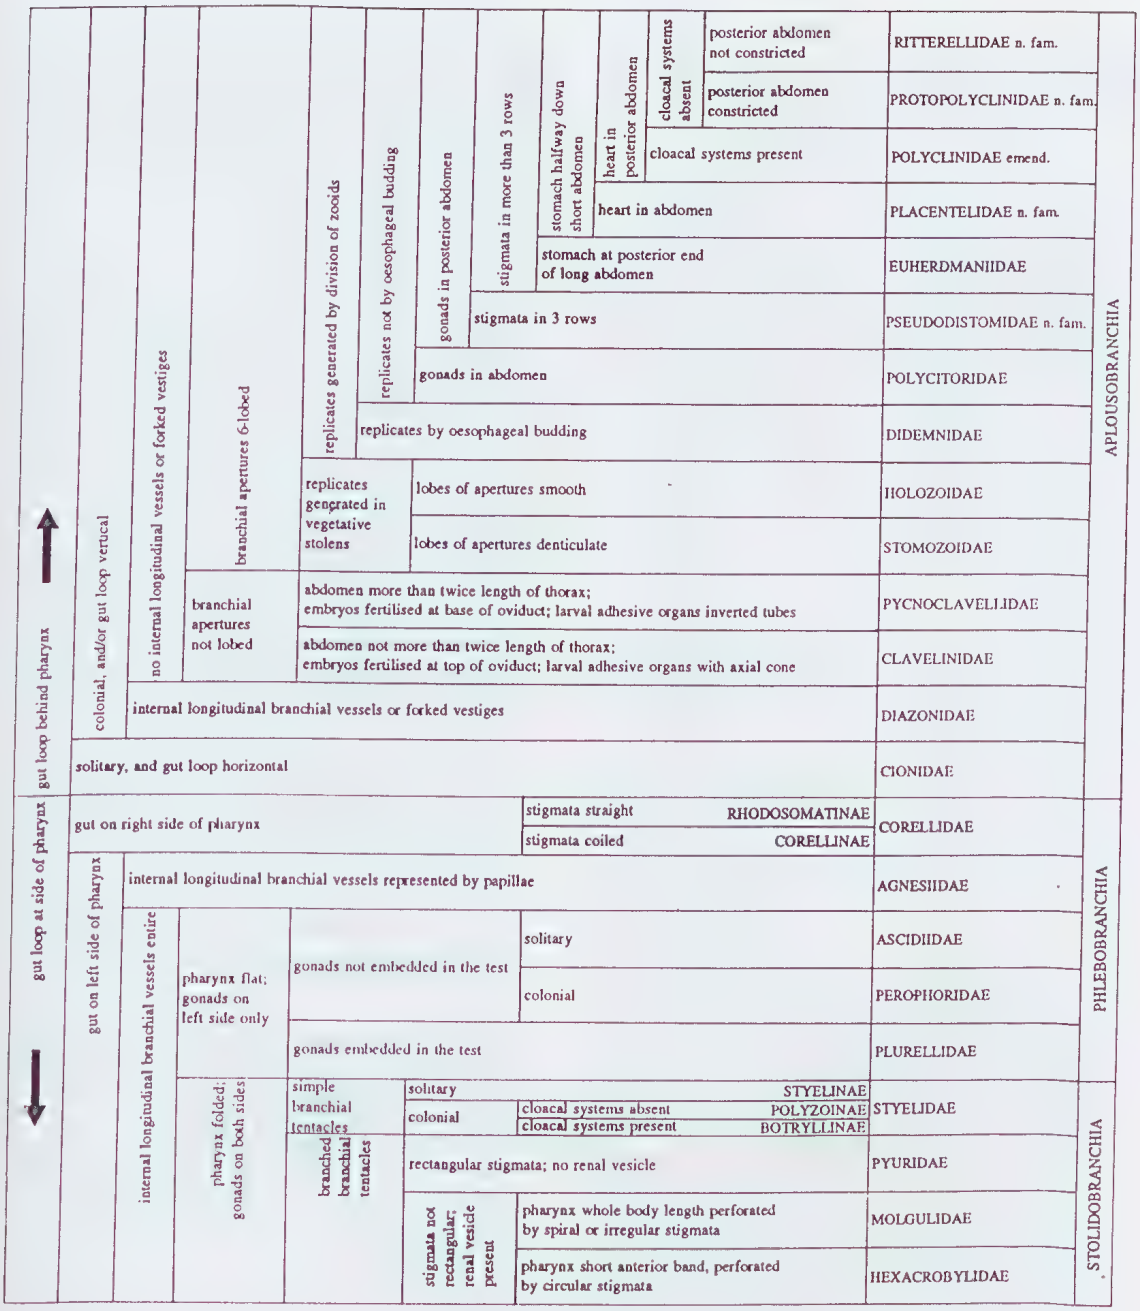

TABLE 1. Ascidiacea – Graphic Key to families

erative and prompt in response to my many requests for large specimen loans.

During 1991 large collections from all around Australia also became available to me from the Australian Institute of Marine Science (AIMS), Townsville, through Dr Peter Murphy. This important collection was made by Rob McCauley and his colleagues (AIMS Bioactivity Group), by SCUBA, as part of their Shallow Water Marine Organism Collection Program for the National Cancer Institute (1992-1996). This collection includes photographs of the living colonies *in situ*. The voucher specimens are now registered in the collection of the Queensland Museum.

Grants from ABRS (1980–82) and MST (83/1320) supported the author's field programme. The work was also supported by the ARC (A19031140).

ANNOTATED GLOSSARY

A discussion of the morphology of aplousobranch ascidians and their larvae in the Australian Ascidiacea Part 2 (Kott 1990) refers particularly, although not exclusively, to families reviewed therein. Morphological features, and their variations and functional implications that have not been discussed previously, are reviewed in the glossary that follows. It should be used in conjunction with the glossaries in parts 1 and 2 (Kott 1985, 1990) to appreciate the full range of functional adaptations and other morphological variations in ascidians, (with the exception of the Didemnidae).

adhesive organs: Each of the 4 types of adhesive organs present in the families discussed below, occurs also in other possibly related aplousobranch families.

1. Deeply invaginated tubular adhesive organs, as in Pycnoclavellidae, are in Euherdmaniidae. They are arranged in a triangle when 3, or in the median line when only 2. They suggest a relationship with Pycnoclavellidae.
2. The 3 median adhesive organs in Pseudodistomidae have a hollow, completely eversible axial protrusion in a deep epidermal cup and are either sessile or stalked. The axial protrusion is flat-topped or conical, and apparently lacks the columnar cells found in the axial cones of Holozoidae (*Distaplia*: see Cloney 1977). When everted it is thin-walled and balloon-like, and may have closer affinities with the adhesive organs of Pycnoclavellidae than any others.
3. The 3 median adhesive organs in Protopolyclinidae are stalked, and have an axial cone composed of long columnar cells in a deep epidermal cup. They resemble the adhesive organs of Holozoidae (see Cloney 1977) and Didemnidae (see Turon 1991).
4. The 3 stalked adhesive organs in the anterior mid-line in Ritterellidae and Polyclinidae have a shallow, wide axial cone in a tight epidermal cup. These resemble the adhesive organs of Polycitoridae, although they are smaller. Their relationship to the adhesive organs of Clavelinidae, and Holozoidae awaits investigation.

Epidermal ampullae may also have an accessory adhesive function. (See also **larvae, ampullae, vesicles**).

ampullae, epidermal —, larval —: Outgrowths of the anterior larval epidermis, possibly accessory adhesive organs. In Aplousobranchia they are absent from *Pycnoclavella*, *Euherdmania* and a few other species level taxa in other genera in which size reduction appears to have resulted in simplification.

Ampullae project from the base of triradial adhesive organs (Clavelinidae, Holozoidae). Ampullae arise from lateral ridges along each side of median adhesive organs and also from the median line alternating with them (Polycitoridae, Protopolyclinidae n.fam., Ritterellidae n.fam., Pseudodistomidae n.fam., Polyclinidae). In the new families Protopolyclinidae (*Monniotus*) and Ritterellidae (*Dumus*), and in Polyclinidae (*Polyclinum*, *Aplidiopsis* and some *Aplidium* spp.) the terminal ends of the ampullae have a cap of modified, possibly secretory cells. (See **larvae, vesicles**).

ampullary vesicles: see **vesicles**

anal opening, anus: The rectum continues anteriorly, embedded in the body wall along the dorsal border of the pharynx. Its opening into the atrial cavity is invariably bilabiate in the present aplousobranch families. Its position relative to the atrial apertures (which are normally antero-dorsal) appears determined by selective pressures affecting the position of gonoducal openings. Faecal pellets are found in the rectum but never in the atrial cavity. Presumably, when necessary, the anus is brought into a position near the base of the atrial siphon by muscular action, so that the faecal pellets can be ejected directly to the exterior. Although the oviduct is sometimes diverted into a brood pouch, or is turned ventrally, the opening of the vas deferens is usually associated closely with the anus, the advantage possibly being that sperm also can be expelled directly to the exterior with the excurrent water.

In Placentelidae n.fam., in which numerous embryos are incubated in what probably is an elaborate brood pouch in the distal part of the oviduct (where it lies in the atrial cavity), the anus is in a primitive position in the anterior part of the atrial cavity, opposite the second or third row of stigmata. This is in a position comparable with most Diazonidae, in which the gonoducal openings, at the base of the atrial aperture, are associated with the release of gametes directly to the exterior for external fertilisation.

The anus and gonoducal openings are at mid-thoracic level in most other genera discussed below. In all these families fertilisation and incubation is either in the atrial cavity or in the distal part of the oviduct. Only in Euherdmaniidae and the (probably) related Pycnoclavellidae, both with characteristically long abdomina, are anal and gonoducal openings at the base of the atrial cavity; and in both fertilisation is at the base of the oviduct — at the posterior end of the long abdomen.

apertures: In most aplousobranch ascidians, irrespective of the form of their systems, branchial apertures are 6-lobed. Exceptions in which the branchial apertures are 8-lobed are in some *Ritterella* spp. (viz. *R. pedunculata*), *Aplidium* spp. (e.g. *A. amorphatum*, *A. protectans*) and *Morchellium*. Apparent subdivision of branchial lobes in some species *Aplidium* (e.g. *A. macrolobatum* n.sp. and *A. incubatum* n.sp.) results from contraction of a band of muscles that extends up the centre to the tip of each lobe.

Separately opening 6-lobed atrial, as well as branchial, apertures interrupt the surface test of colonies

in the new families Placentelidae, Protopolyclinidae, Ritterellidae, Euherdmaniidae, and Pseudodistomidae. None of these contain genera with true cloacal systems although other colonial systems, or rudimentary cloacal systems, sometimes occur. Some narrow, stalked Ritterellidae n.fam. (*R. asymmetrica*, *R. pedunculata*) have the zooids in colonial systems with atrial apertures in a row along one side of the flattened, terminal edge of each stalk, and branchial apertures in a row on the opposite side. In other species (*R. papillata* n.sp., *R. cornuta* n.sp., *R. compacta* n.sp.) the atrial apertures are in the centre of the terminal end of lobes of the colony surrounded by the branchial apertures to form rudimentary cloacal systems in which excurrent water from all zooids is ejected in a single stream from the centre of the circular system. Similar rudimentary cloacal systems occur in Polycitoridae (see Kott 1989, 1990). At least in *R. cornuta* n.sp., *in situ* photographs show the flat terminal end of the colony lobe directed away from the oncoming current; and the excurrent stream of water from the centre of each end is entrained by the current as it passes the colony. The arrangement of the apertures of the separate zooids of *Monniotus* spp. is similar to *Ritterella asymmetrica* and *R. pedunculata*, with atrial apertures on the convex side of the spoon-shaped head, and branchial openings on the concave side. A large flap of test along their upper margin directs the branchial apertures downwards (Kott 1989). Also in Protopolyclinidae n.fam., colonial systems of *Condominium* n.gen. have zooids arranged in single lines along flat fan-shaped lamellae. Atrial apertures open in a line on the convex side of the lamella, near and parallel to the top of the colony, on the opposite side to the groove in which the branchial apertures are concealed. The row of atrial apertures are also concealed in a groove when zooids contract.

Very likely the linear arrangement of zooids and their apertures in the hard, sandy, often rigid test is a result of the pressures to direct and separate the respective incurrent and excurrent ciliary streams in these species with separately opening zooids. The compression of the atrial aperture into a transverse opening or slit and the division of its rim into an anterior and a posterior lip usually with 6 lobes on each (e.g. *Monniotus*, *Condominium* gen. nov. and some sandy *Ritterella* spp.) further controls and directs the incurrent and excurrent streams of water.

The relatively large, usually gelatinous, separate zooids in Euherdmaniidae often have large external lobes around the apertures (e.g. *E. dentatosiphonis*, *E. translucida* n.sp.) that resemble those of Stomozoidae (see Kott 1990), although in the latter family the zooids are not separate, being embedded in common test. The function of these enlarged lobes around the apertures, which involve the test as well as the body wall of the zooids, is not established. It is possible that they help to direct the ciliary current, and, to some extent may act as sense organs through the pigment spots at their base which, like similar pigment spots in *Ciona*, Diazonidae and some Phlebobranchia (see Kott 1985, 1990), may be light sensitive. Generally, the lobes around the apertures have musculature associated with the longitudinal muscle bands of the thorax, and the sphincter muscle that surrounds each aperture behind the lobes.

Zooids in stalked colonies of Pseudodistomidae are arranged in the colony like those of some species of Clavelinidae (*Nephtheis*), and Holozoidae (*Sigillina*), all with atrial apertures uppermost and branchial apertures directed toward the stalk so that each stalked head forms a single colonial (but not cloacal) system as discussed by Kott (1989, 1990).

In Polyclinidae, the zooids are arranged in cloacal systems, either around cloacal cavities, or along each side of canals that converge to common cloacal apertures. The atrial apertures open into the sides or base of these cloacal cavities or canals. The openings either are relatively large, exposing part of the branchial sac to the cloacal cavity (as in *Sycozoa* or *Distaplia*); or there is a short, narrow protuberant siphon with a distinct sphincter muscle and a small terminal aperture. Each opening has a flattened atrial lip (or tongue) projecting from its upper rim or from the body wall anterior to the opening. This projection is strap- or leaf-like, triangular or subdivided into 2 or 3, and its tip is straight edged, pointed, bi- or tri-dentate or serrated. Sometimes the circular muscle around the opening continues through the base of the lip, and muscle fibres from the sphincter extend out into the lip (e.g. *Aplidium uteute*, *A. altarium* and the majority of *Synoicum* spp.). Other species, usually with protuberant siphons, have the sphincter muscle (and the aperture) independent of the atrial lip (*Aplidium crateriferum* and related species, and *Polyclinum* spp.).

The size of the atrial lip varies according to its role in effecting the closure of cloacal apertures and contraction of the cloacal canals. An example can be seen in *Polyclinum vasculosum* in which the anteriorly oriented atrial aperture is in the base of the cloacal canals, while the large atrial lip stretches along the top of the canal, and in some cases reaches and is inserted into the test around the cloacal aperture.

ascending limb of gut loop: see **gut, gut loop**.

atrial aperture, — lip, — tongue: see **apertures**.

atrial cavity: In taxa in which it opens directly to the exterior through a 6-lobed atrial aperture, the atrial cavity, its size varying with the size of the thorax, is a relatively contained chamber in which (often large) numbers of embryos complete their development to tailed larvae. Only in some *Pseudodistoma* is a special incubatory pouch constricted off from the atrial cavity.

In Polyclinidae the atrial cavity is a similarly contained chamber in those species in which the atrial aperture is a small anteriorly directed circular opening separate from the atrial tongue (viz. many *Polyclinum*, *Sydneioides*, and *Aplidium* species, and some *Synoicum* species). In the species in which the

atrial tongue is part of the rim of the aperture and the circular muscles of the aperture diverge out into the atrial lip, the aperture itself is less restricted, and when relaxed is a large opening exposing the atrial cavity directly to the cloacal cavity. Both types of atrial aperture are present in *Aplidium* and *Synoicum*. No apparent correlation exists between the size and form of the atrial aperture and cavity and the size and number of embryos being incubated in the chamber. Only in *Polyclinum*, in which small circular atrial apertures prevail, are the embryos and larvae consistently small (trunk appreciably less than 1 mm long). In this genus embryos also are relatively numerous (usually more than 5 being incubated at a time). Although large atrial cavities result from the relatively narrow branchial sacs in the wide thoraces, the embryos seldom fill the atrial cavity, and in many species they are removed entirely from it, being incubated in a brood pouch separate from the atrial cavity. Under these circumstances, the atrial cavity is not occluded by embryos, and possibly remains functional during the period of their development.

The atrial cavities of small *Aplidium* zooids with short, narrow branchial sacs, are relatively small and are subject to further constriction by longitudinal muscles which extend the length of the zooids.

Other variations in the configuration of the atrial cavity occur as a result of the connectives which conduct transverse muscle fibres from the transverse branchial vessels across the atrial cavity to the parietal body wall. In the large zooids of *Synoicum castellatum* n.sp. a row of these connectives appears to divide the atrial cavity into dorsal and ventral chambers (see *S. castellatum* n.sp. below). It is possible that these chambers are present also in smaller zooids, but not so readily observed.

In the taxa reviewed below, the ventral pouches in the atrial cavity observed in *Sycozoa* and *Distaplia* (see Kott 1990) are not present. These are formed where the cavity extends ventrally over the perforated area of pharyngeal wall but does not penetrate over the triangular areas of imperforate pharynx between the ventral ends of the rows of stigmata. (See also **incubation of embryos**).

branchial papillae: possible vestiges of the branchial papillae which support the internal longitudinal branchial vessels in Phlebobranchia, and some aplousobranch families (Cionidae, Diazonidae), occur in Protopolyclinidae n.fam. (*Protopolyclinum*, *Monniotus*), Ritterellidae n.fam. (*Ritterella compacta* n.sp., *R. cornuta* n.sp., *R. multistigmata* n.sp., *R. papillata* n.sp.) and Polyclinidae (*Polyclinum*). These branchial papillae are flat, rounded to short tongue-like projections from the transverse vessels.

Nothing is known of their function and their status as vestiges of phlebobranch branchial papillae is speculative.

branchial sac: In the present group of families the branchial sac becomes progressively smaller, with fewer stigmata and fewer rows of stigmata, in parallel with the reductions in zooid size. Similar trends can be observed in Polycitoridae (*Polycitor* to *Eudistoma*) and Holozoidae (*Sigillina* to *Sycozoa* and *Distaplia*). Placentelidae n.fam. have a large broad pharynx with many rows of numerous stigmata. In Protopolyclinidae n.fam. the number of rows of stigmata as well as the length of each row are as great or greater (up to 20 rows of up to 50 stigmata in *Condominium* n.gen.) than in Placentelidae n.fam. In Ritterellidae n.fam. the zooids are reduced in size and although stigmata are in up to 16 rows, often there are only 5, and in *Dumus* only 4. The number of stigmata in each row are similarly reduced from a maximum of 35 to 12.

The branchial sacs (together with the solitary zooids) of *Euherdmania*, which does not replicate as freely as other taxa, remain relatively large with numerous rows of up to 100 stigmata per row.

Pseudodistomidae n.fam. have 3 long rows of stigmata, in a wide pharynx.

The greatest size reduction in zooids can be observed in the polyclinid genus *Aplidium* in which prolific replication occurs, and zooids are arranged in cloacal systems. In this genus the stigmata occasionally are in only 5 rows. Although the length of the stigmata often is reduced, the number of rows is not, and most species have from 12 to 20 rows of stigmata. *Synoicum* species have similar reductions in size of the branchial sac. The most conspicuous difference between these genera and other polyclinid genera is their reduction in the size of the perforated pharynx. *Polyclinium* and *Aplidiopsis* have relatively large branchial sacs.

Internal longitudinal branchial vessels are present only in Cionidae and Diazonidae; and the only vessels in the branchial sac of all other aplousobranch taxa are transverse. The primary transverse vessels are the unperforated expanses of the pharyngeal wall between the rows of stigmata. On their mesial side, the walls of these vessels are ciliated endoderm projecting into the lumen of the pharynx. On the parietal side the epithelium is ectodermal and not ciliated. Transverse muscle fibres are in the transverse vessels and these join the muscles of the parietal body wall through connectives that cross the atrial cavity (see **atrial cavity**; *Synoicum castellatum* n.sp., below)

Parastigmatic vessels, extending across the stigmata halfway between the primary transverse vessels, sometimes subdivide the stigmata along their length creating additional rows. More often they occur in species with long stigmata and persist as inconspicuous strands which hold the delicate interstigmatal bars in place, and prevent distortion of the stigmata. Parastigmatic vessels occur in Protopolyclinidae n.fam. (*Monniotus* spp. and *Condominium* n.gen.) and Ritterellidae n.fam. (e.g. *Ritterella asymmetrica*, *R. multistigmata* n.sp.). Despite the large size of *Euherdmania* zooids, the stigmata are relatively short and disposed in numerous rows. Parastigmatic vessels are not known in this genus nor are they known in the short branchial sacs of Pseudodis-

tomidae n.fam. In Polyclinidae they are known in some species of *Aplidium* with relatively large branchial sacs (e.g. *Aplidium amorphatum*, *A. parastigmaticum* n.sp.).

branchial tentacles: although these are not specifically counted in the descriptions that follow, a ring of short, relatively stumpy tentacles of various sizes is always present at the base of the branchial siphon, protecting the incurrent aperture. Intrageneric variations in the tentacles do not appear significant taxonomically.

branchial vessels: see **branchial sac**.

brooding, brood pouch: see **incubation**.

budding: see **replication**.

cloacal cavities, — systems: As in Polycitoridae (see Kott 1990) some other taxa with independently opening atrial apertures and embedded zooids have their zooids arranged in incipient or rudimentary cloacal systems. Thus, in Ritterellidae n.fam., *R. papillata* n.sp. and *R. cornuta* n.sp. have zooids arranged in circles with their atrial apertures in a depression in the centre of the circle and their branchial apertures around the periphery; and in *R. compacta* n.sp. the excurrent apertures open into a circular chamber lined with sand which appears to be an invagination in the surface of the colony.

In Polyclinidae a high degree of organisation into cloacal systems is achieved. These systems range from simple circles of zooids around circular chambers with a central cloacal aperture to rows of zooids arranged along each side of branching canals which converge to a cloacal aperture. Sometimes partitions of zooid-free test occur between adjacent systems, or between parts of the same system (i.e. between converging canals); but in other species the systems are crowded together. In preserved or contracted colonies, zooid-free areas of test, being solid and without cloacal cavities or chambers containing zooids, are prominent and usually protrude from the surface. This is an artefact, for in living, extended specimens, the cavities and zooids are expanded and the surface over them is not depressed.

In Polyclinidae there are relatively few taxa (compared with Holozoidae) in which the colony is a single system (e.g. *Aplidium australiense*, *Polyclinum orbitum* n.sp.). More often colonies, even those with large, regular, circular systems are relatively irregular, and contain a number of cloacal systems, each with a conspicuous cloacal aperture. The systems have the capacity to subdivide forming relatively large, bulky colonies. Despite the capacity of Polyclinidae to form large colonies of one or more systems, the cloacal cavities themselves are relatively narrow canals and small, rounded chambers rather than the extensive 3-dimensional cavities of Didemnidae.

The strength and rigidity of the test, especially when this is firm and gelatinous, or contains embedded sand and/or calcareous particles contributes to the maintenance of colony shape including surface features such as ridges and grooves that affect the organisms' interactions with the environment (such as direction of current flow: Kott 1989). The pressure of excurrent water in the common cloacal cavity (when one is present) also contributes to maintenance of the shape and the configuration of the surface, of the colony. Thus, both factors contributing to the strength and rigidity of the test (such as embedded sand), and also to the turgidity of a large, 3-dimensional cloacal cavity (such as efficient replication increasing the number of zooids contributing to the internal pressure within the cloacal cavities), constitute adaptive advantages favoring the evolution of large, 3-dimensional colonies.

In some species of *Polyclinum*, the surface test has a thin, brittle layer of sand but the internal test is soft. In this case their round colony shape may be maintained by the water pressure in the large pharynges of the crowded zooids rather than the brittleness of the surface layer of test. (See also **apertures, colonial systems, colonies**).

colonial systems: In other taxa with independently opening atrial apertures, the zooids are not embedded in common test; or are arranged in colonial systems other than cloacal ones; or, rarely, do not have any obvious systematic arrangement in the colony. *Monniotus* and *Euherdmania* zooids either are solitary; or separate from one another, attached to common test or stolons only at their posterior end, and, like separate Diazonidae, Clavelinidae, and Pycnoclavellidae, function as solitary individuals and do not form systems of any kind. As with cloacal systems, other sorts of systems have zooids so arranged to ensure that the functioning of the whole colony exceeds the efficiency of the sum of its component zooids.

Although zooids of *Ritterella compacta* n.sp. *R. cornuta* n.sp. and *R. papillata* n.sp. are in circular rudimentary cloacal systems with their atrial apertures in the centre, *R. asymmetrica*, *R. pedunculata*, *R. multistigmata* n.sp. and *Condominium* gen. nov. have their zooids arranged around fan-shaped stalked colonies, with the branchial and atrial apertures on opposite sides of the colony margin. Incurrent and excurrent streams, respectively, reinforce one another, and are kept apart; and the long narrow stalks enable the colony to change its orientation with the prevailing currents.

Stalked *Pseudodistoma* with all atrial apertures directed to the top of the colony and the branchial apertures directed downwards towards the point of attachment are equally flexible with regard to changes in current flow. Other benefits from this uniform arrangement of apertures include protection of the open incurrent apertures from falling sediments (Kott 1989; see also **apertures, cloacal systems**).

colonies: The size and form of colonies reflects their phylogeny, toughness of test and amount and type of embedded material. More primitive families such as Diazonidae, Clavelinidae and Pycnoclavellidae, do not usually form particularly large self-supporting colonies. However, generally other aplousobranch

families have firm and gelatinous test, resembling the test of phlebobranch families in consistency; or it is strengthened externally or throughout with sand or other hard (including calcareous) particles. When strengthened, large often complex self-supporting colonies are formed. Occasionally species such as *Pseudodistoma fragile* and *P. gracilum* with particularly soft almost fluid test also have relatively large colonies, possibly occupying sheltered habitats.

The complexity of colonies of the Ascidiacea is most evident in colonies in which the embedded sand makes the test hard, brittle and allows it to form massive 3-dimensional branching colonies (e.g. *A. solidum*); or in intricate colonial systems (e.g. *A. crateriferum*, *Condominum areolatum* n.gen., n.sp.). However, although complexity in shape appears to require sand or other inclusions in the test, the size of colonies *per se* is not related to sand inclusions (e.g. gelatinous colonies of *Polycitor* and *Aplidium* become as large as some of the sand-strengthened colonies in these genera).

As well as affecting the size and form of the colonies, the consistency of the test, which is directly affected by the type and quantity of material embedded in it affects the configuration of the surface test, which, in turn, can modify the currents flowing over the colony and influence its interactions with the environment. In many *Ritterella* spp. and in *Monniotus* a layer of brittle sand-embedded surface test protects the incurrent and excurrent apertures and separates the currents flowing through them. In Polyclinidae the operation of the colony is enhanced by its ability to sort sand and to determine precisely its distribution. For instance, in *Aplidium tabascum* n.sp. a single line of fine sand particles outlines the margins of the firm zooid free areas that protect the branchial apertures; and in *A. caelestis* and *A. macrolobatum* n.sp. fine sand particles are embedded in the thin, flexible test over cloacal cavities, while coarser grains are in the rigid test between the systems.

Colony size and shape does not appear affected by the development of cloacal systems, except that colonies consisting of a single system are a finite size and shape (e.g. *Aplidium altarium* n.sp.) and generally are smaller and more regular than those with multiple systems.

Environmental pressures such as substrate and current flow probably have most influence on the size and shape of the colonies found in any habitat. Thus stalked species appear to occupy habitats where surge alternates the direction of water flow past the zooids; and large spherical, oval, or irregular colonies occupy sea floor habitats at depths where strong currents are not likely to dislodge them from substrates.

Extensive areas of sandy substrate favour large mixed populations of *Monniotus radiatus* n.sp., *Dumus areniferus*, *Ritterella pedunculata*, *R. asymmetrica*, and *R. papillata* n.sp., which all have similar fine, sandy, finger-like colonies embedded in sand — the individuals being more or less held together and stabilised by the sand that accumulates around them (see Kott 1989); and, at the same time, they stabilise the sand. As well as these narrow stalked colonies with hair-like test projections and basal stolons that form sandy aggregates and mats in and over the substrate (e.g. *Pycnoclavella* spp.: Kott 1990, *Ritterella* spp., *Monniotus* spp.), there are other types of colonies that stabilise sandy substrates and protect them from erosion. These are colonies with basal test forming root-like projections that hold them firmly in the substrate (e.g. *Aplidium geminatum* n.sp.), and colonies embedded in the substrate and forming 3-dimensional reticula and branching lamellae (e.g. *Aplidium acroporum* n.sp., *A. petrosum* n.sp., *A. solidum*, and *Polyclinum terranum* n.sp.). (See also **cloacal cavities, colonial systems**).

descending limb (of gut loop): see **gut.**

dorsal lamina, — languets: No continuous fold occurs along the mid-dorsal line of the pharynx in Aplousobranchia as in some Stolidobranchia and Phlebobranchia. Instead pointed languets arise from the transverse vessels to the left of the mid-line, and curve over to the right. These channel the mucous food cord (gathered from the sheets moving dorsally over each side of the pharynx) as it moves posteriorly to the oesophagus.

duodenum: see **gut.**

epidermal ampullae: see **ampullae.**

epidermal vesicles: see **vesicles.**

excurrent aperture: see **apertures.**

fertilisation: About half the extant Ascidiacea are solitary species which, with few exceptions (see below), are externally fertilised. The other half are colonial, and these, with the exception of the Diazonidae, are fertilised internally. The colonial species are predominantly Aplousobranchia, although taxa of Phlebobranchia (Perophoridae) and Stolidobranchia (Botryllinae and Polyzoinae) are included. Solitary species are predominantly Stolidobranchia and Phlebobranchia, only 2 genera of Aplousobranchia (*Ciona* and *Rhopalaea*) being included.

With the exception of *Polycarpa* and some Molgulidae and Agnesiidae, solitary Ascidiacea have long and relatively few male and female gonads, and their ducts open together near the anus, at the base of the atrial siphon. Released gametes thus are ejected, and presumably dispersed with the excurrent ciliary stream. Gametes also are released in the excurrent water as the animal rythmically squirts to irrigate the atrial and branchial cavities. In both cases waste products and gametes are projected well away from the animal where they are not likely to contaminate the incurrent stream (see Hoshino *et al.* 1986, Kott 1989b).

If both male and female gametes of the same mature individual are released together there would be opportunities for self-fertilisation. However there is growing evidence that individuals are generally self-sterile (Santis and Pinto 1991, Fuke 1983, Kawamura *et al.* 1987, Cloney 1990, Litscher and

Honegger 1991). Further, species are not necessarily functional hermaphrodites, and may be either protandrous or protogynous. Other mechanisms may exist to prevent self-fertilisation, one being the possibility that ejected sperm are dispersed further away than ova.

The stimulus for release of gametes is not understood, although their are obvious advantages for one to exist. Under certain conditions light is known to trigger gamete release. Carlisle (1951) proposed that *Ciona intestinalis* released gametes and stopped secreting mucus from the endostyle in response to the presence of a gamete of the same species in the incurrent feeding stream. Although it is an apparent advantage for mucus secretion to stop when fertilisation is internal, it is not for externally fertilised species.

In *Polycarpa*, short gonads and their ducts are scattered over the body wall, and the openings of the ducts are removed from the atrial aperture. Presumably this results in longer retention of gametes of both sexes in the atrial cavity than would be the case if they were released at the base of the atrial siphon. In certain species (*P. intonata*, *P. tinctor*, *P. tinctorella*: see Kott 1985) even longer retention results from the ventral orientation of the short gonoducts, and indeed these species are internally fertilised and embryos are brooded in the atrial cavity. Certain molgulid species are analgous to *Polycarpa* in respect to the arrangement of their male and female gonoducts, and also are internally fertilised, brooding, species. They all have the oviducal apertures turned ventrally, and the openings of the vas deferens distant from the atrial aperture. *Molgula calvata* and *M. manhattensis* (see Kott 1985) have short, multiple openings of the sperm duct along the length of the ovary; and *M. ellistoni*, *M. sabulosa* and *Eugyra* spp. (see Kott 1985) have a short vas deferens, at the proximal end of the ovary, turned ventrally. Although the reproductive strategy of *Adagnesia* spp. is not known, both gonoducts are turned ventrally (see Kott 1985) and probably embryos are brooded internally. Only one species of the Pyuridae, *Pyura littoralis* (see Kott 1985), has short female ducts while retaining a long vas deferens. This may be an adaptation for internal fertilisation, although embryos have not yet been found in the atrial cavity.

It is not known if these internally fertilised solitary species are self-sterile or not. If they are, the reasons for the adaptations found in the majority of these species, which apparently ensure the retention of sperm as well as ova in the atrial cavity, are difficult to understand. Further, if they are self-sterile, it is possible that mucus secretion is interrupted to allow sperm for cross fertilisation to reach the atrial cavity through the pharynx. In *Ecteinascidia turbinata*, at least, it appears not to be drawn in through the atrial aperture with relaxation of body muscles following contraction and squirting (Ryland *pers. comm.*).

Whereas only relatively few solitary species have evolved devices for internal fertilisation, this strategy is universal in colonial species, and once it has evolved it appears never to be lost. The family Diazonidae, which contains some genera retaining a solitary habit, and the related and supposedly primitive solitary Cionidae are the only aplousobranch taxa externally fertilised.

In colonial internally fertilised species (as in solitary ones) the position of each gonoduct relative to the others and to the atrial aperture probably is related to patterns of gamete release and fertlisation. Although the oviduct is often displaced when it acts as a brood pouch, the vas deferens and anus of colonial species open together, usually part of the way up the thorax, and not necessarily close to the atrial aperture. The atrial cavity, although it is often distended with embryos, never contains faeces outside the rectum, and presumably faecal pellets are released by the contraction of the body wall muscles, which irrigates the atrial cavity and brings the anus close to the atrial aperture. Since the opening of the vas deferens is associated with the anus it is possible that gametes are also released in this way. In holozoid genera with cloacal systems, and in the Didemnidae, large atrial apertures often expose anal and gonoducal openings directly to the cloacal cavity. This also happens in some Polyclinidae (*Aplidium*, *Synoicum* and a few *Polyclinum*). Thus, the opening of the male duct of colonial, internally fertilised species (as in solitary externally fertilised ones) is usually positioned where sperm released from it are most likely to be expelled to the exterior, either directly or through the cloacal cavity, rather than being retained in the atrial cavity for self-fertilisation. It is not known whether or not embedded colonial zooids have a pattern of rythmic squirting, like solitary and independent colonial ones, to increase means by which sperm might be released.

Further, colonial, like solitary, species have been shown to be self-sterile (e.g. *Diplosoma listerianum*: Ryland and Bishop 1990; *Botryllus schlosseri*: Sabbadin 1979). In addition to the growing evidence of cytological and chemical mechanisms for self-sterility, the existence of functionally gonochoric colonies in the genus *Syzozoa* (see Kott 1990), and of sequentially hermaphroditic colonies in many other taxa, support the view that colonial, as well as solitary, ascidians are not generally self-fertilised. Sabbadin (1979) reports a protogynous condition for *Botryllus*. Further evidence of protandry or protogyny exists when embryos but not mature male gonads are present and when there are mature male gonads but no embryos suggesting that the male gonads mature either before or after the female ones (see below).

If, as the evidence suggests, internally fertilised colonial species are not self-fertilised, sufficient concentrations of sperm must reach the atrial cavity from outside the zooid for some to enter the oviduct, and move to the fertilisation chamber (the brood pouch, or the proximal end or top of the oviduct, or the atrial cavity) at the time that oocytes reach maturity. Thus it is probable that advantages associated with the

synchronous release of gametes are as great in internally fertilised colonial species as they are in externally fertilised solitary ones, especially as colonial zooids are small, with relatively small ovaries, few ova and often ephemeral gonads. Again, little is known of mechanisms triggering such a synchronous release. Further it is not known how sperm enters the atrial cavity. Ryland (*pers. comm.*) found that external material was not drawn into the atrial cavity of *Ecteinascidia turbinata* following its partial evacuation by squirting. It is not kown whether or not embedded zooids do squirt, however even if they do it seems unlikely that sperm could enter zooids through common cloacal chambers against the direction of the ciliary current. Even in independently opening zooids it is unlikely that it would enter directly through the atrial aperture. The alternative hypothesis is that the process reported by Carlisle (1951) for *Ciona intestinalis* is present in colonial species viz. that mucus secretion is interrupted so that sperm entering the pharynx can pass through the stigmata into the atrial cavity, thence into the oviduct

The only colonial, internally fertilised families which seem to be analogous with *Polycarpa*, *Molgula*, *Eugyra* and *Adagnesia* species (with short, and ventrally directed vas deferens suggesting retention of sperm in the atrial cavity) are Pycnoclavellidae and Euherdmaniidae, with the gonoducal and anal openings at the base of the atrial cavity. Possibly these families also have mechanisms to prevent self-fertilisation.

The relatively large size of the testis in relation to the ovaries in most colonial species indirectly supports the view that generally cross- rather than self-fertilisation is likely. Otherwise the production of a large amount of sperm for the fertilisation of few oocytes within the same zooid in colonial species would not be economic. Further, it is difficult to entertain an hypothesis that the well established mechanisms ensuring self-sterility reported in Cionidae (see Kawamura *et al.* 1987, Cloney 1990, de Santis and Pinto 1991), Ascidiidae (Litscher and Honegger 1991) and Pyuridae (Fuke 1983) are exceptions from a general condition; especially when selection for short-lived free-swimming, viviparous larvae occurring simultaneously (see Kott 1974, 1982) results in the maintenance of crowded populations with maximal opportunities for gene exchange. (See also **incubation of embryos**).

gastric folds: see **gut**.

gastro-intestinal gland: see **gut**.

gonads: unlike the families discussed in Part 2 (Kott 1990) in which they are in the gut loop, the testis follicles and small ovary of most of the families discussed below are in a posterior abdomen behind the gut loop. The exceptions are some *Euherdmania* (*E. digitata*, *E. dentatosiphonis*, *E. translucida* n.sp.) in which they sometimes are in the gut loop, and *Sidneioides* in which the ovary is in the thorax. In Protopolyclinidae n.fam., *Polyclinum* and *Aplidiopsis* the testis follicles are bunched together in a sac-like posterior abdomen separated from the abdomen by a narrow neck with the small ovary surrounded by the testis follicles. In *Sidneioides* a similar sac-like posterior abdomen contains the male follicles, but the ovary is halfway up the thorax, with a short oviduct opening directly into the atrial cavity.

In other taxa (*Euherdmania*, *Ritterella*, *Aplidium*, *Synoicum*, *Morchellium*) there is no constriction between abdomen and posterior abdomen. The testis follicles in these taxa either are bunched together in a short, thick posterior abdomen, or arranged in one or two longitudinal series in a sometimes thread-like posterior abdomen which is many times the length of the rest of the zooid. In many species of Pseudodistomidae n.fam. gonads seem intermediate between those with testis follicles bunched behind the ovary, and those with testis follicles in a longitudinal series in the posterior abdomen. In most known species of this family the male follicles are bunched together around the ovary in a small part of a long thread-like posterior abdomen. In specimens of *Pseudodistoma candens* n.sp., the vas deferens, distended with sperm, is seen to originate at a point level with the ovary, about halfway down the cluster of male follicles, as if the gonads had turned onto their side to fit into the thin posterior abdomen. *Pseudodistoma gracilum* n.sp. and *Synoicum atopogaster* have a similar arrangement of male follicles.

In genera with male follicles in longitudinal series the ovary is invariably anterior to them and the vas deferens is joined by short vasa efferentia as it extends up the side of the posterior abdomen. When 2 series of testis follicles are present the vasa efferentia alternate between the rows. Male follicles are in a single series when a second is not developed. This appears to be an ephemeral condition and does not constitute a genetic difference. Male follicles arranged in longitudinal series can appear bunched when they are drawn together with contraction of the long posterior abdomina. However, in certain species (*Aplidium altarium*, *Aplidium uteute*) the testis follicles are actually bunched, with short vasa efferentia joining them to a relatively short vas deferens, in a short posterior abdomen.

The ovary is always small in these families, producing relatively few eggs for internal fertilisation and brooding. Testes, however, are relatively large, but always composed of numerous separate follicles rather than a large single one, as in most taxa of the Ascidiacea. Large, undivided testes are present only in some *Perophora* spp., and in some Polyzoinae (see Kott 1985; see also **fertilisation**).

gonoducal openings, gonoducts: see **fertlisation**.

gut, gut loop: Distal to the large pharynx, the gut of aplousobranch ascidians always forms a simple, narrow and usually vertical U-shaped loop, which occupies the length of the abdomen. In the present group of families (characterised by the presence of the gonads behind the gut loop in a posterior abdomen), the range of variations resembles those found in those aplousobranch families in which the gonads

are enclosed in the gut loop (see Kott 1990). These variations are:

1. The length of the oesophagus. In Euherdmaniidae this is long, as it is in Pycnoclavellidae and Polycitoridae and to some extent in Clavelinidae, with the stomach in the posterior end of a long abdomen. The oesophagus is relatively short, with the stomach halfway down the abdomen, in Protopolyclinidae n.fam., Ritterellidae n.fam. and Polyclinidae (as it is in Holozoidae and some Clavelinidae). In Pseudodistomidae n.fam. (as in Diazonidae) the oesophagus is of various lengths, sometimes being moderately long. It is almost twice the length of the post-pyloric part of the gut loop in *Pseudodistoma aureum* and even longer in *Anadistoma* n.gen. Occasionally a prestomach enlargement is in the oesophagus, as in *Aplidium altarium*. The only other genus in which this is known is *Clavelina* (*C. moluccensis*, *C. cylindrica*: Kott 1990).

2. The orientation of the stomach. This usually is oblique to the long axis of the zooid, with the oesophagus curving ventrally to enter the cardiac end of an asymmetrical stomach with a short dorsal border and a long curved ventral border. Only in *Aplidium*, *Morchellium*, and in some species of *Ritterella* is the oesophagus straight, entering the cardiac end of a more or less radially symmetrical, vertical barrel-shaped stomach.

   In *Polyclinum* and *Sidneioides* the gut loop usually is horizontal, and slightly twisted, the right or descending limb moving around to lie above the ascending limb, and the posterior end of the loop curving dorsally. The horizontal orientation of the gut loop is reminiscent of Cionidae, and Holozoidae (*Sycozoa*, *Distaplia*).

3. Post-pyloric subdivisions of the gut. These consist of a wide duodenum immediately behind the stomach, and a narrow mid-intestine that expands into a large oval, posterior stomach about halfway along its length. There is thus a proximal (post-pyloric) part of the mid-intestine, as well as a distal (pre-rectal part). This arrangment is found in most other aplousobranch families (see Kott 1990). Only very rarely is there a departure from this pattern — viz. in Pseudodistomidae n.fam. the proximal part of the mid-intestine is wider than usual and is more or less continuous with the duodenum, an external crease marking their junction.

   Pockets in the proximal end of the rectum on each side of its junction with the distal section of the mid-intestine form a rectal valve in many species of aplousobranch, especially *Ritterella*, *Aplidium*, *Aplidiopsis*, *Synoicum*, *Polyclinum*.

   It is possible there are some intraspecific variations in the development of this valve and its appearance is affected by artefacts of preservation and gut contents. It is associated with the long, straight, vertical ascending limb of the gut loop in these families of the Aplousobranchia.

4. The stomach wall is either smooth, both inside and out, interrupted only by a typhlosole (or suture line) along the dorsal border; or it is folded; or, as in *Synoicum*, *Morchellium* and *Aplidiopsis*, its internal lining is raised into circular or irregular glandular areas, and the external surface may also be raised into mulberry-like swellings.

   In *Pseudodistoma* the short, wide stomach is partially divided into 4 shallow, longitudinal compartments. *Aplidium* species, with relatively small zooids and narrow short stomachs, have a relatively large glandular area achieved by longitudinal folding of the stomach wall into from 5 to 30 often deep folds. *Euherdmania*, *Monniotus* and *Ritterella* have similar, though not so numerous longitudinal folds in the stomach wall.

5. A gastro-intestinal gland, with a duct from the pyloric end of the stomach breaking into branches around the ascending limb of the gut, probably always is present in all families of Aplousobranchia, although it is usually conspicuous only in Polycitoridae, and has a storage vesicle only in some Holozoidae.

head: The expanded terminal free end of stalked solitary and colonial ascidians is termed the head. It accommodates the thoraces, which, when expanded, are the widest part of the zooid or individual, and colony and zooid openings are on its surface. The narrow abdomina and posterior abdomina are in the stalk.

heart: The heart is a delicate curved tube in the posterior end of the posterior abdomen in most of the genera discussed below. The exception is *Placentela*, the monotypic genus from the north-western Pacific, which has its heart in the abdomen, presumably retained there in a primitive position while the gonads spill back behind the gut loop (see Nishikawa 1984b).

incubation of embryos: all families discussed in the present work are internally fertilised and embryos, brooded internally by the parental zooids, are released as tailed larvae. The process of replication is well developed. Zooids as a consequence are small and simplified, but numerous (see Kott 1990). Thus, despite the fact that in most cases the embryos are relatively small (< 1 mm) and yolky, few are produced and incubated at a time by any one zooid. The number of larvae being produced by the whole colony is maintained by the large numbers of zooids producing few embryos, rather than few zooids producing a large number.

Larger embryos are found in *Euherdmania*. In this genus eggs are fertilised at the base of the oviduct and are incubated in the oviduct as they move up the long abdomen, as in the possibly related Pycnoclavellidae (see Kott 1990). Relatively large embryos are also produced in *Pseudodistoma* in which the eggs of some species appear to be fertilised and incubated, usually one at a time, in a brood pouch constricted off from the posterodorsal corner of the thorax.

In most of the other taxa discussed below, eggs are fertilised, and the relatively small embryos are incubated in the atrial cavity. Only in *Polyclinum*, which has zooids with large roomy atrial cavities, do the

TABLE 2. Summary of epidermal elements at anterior end of larval trunk in aplousobranch families.

particularly small embryos (larval trunk seldom more than 0.6 mm long) appear not to occlude the pharynx, even when relatively large numbers are present at a time (up to 12 embryos: *P. fungosum*). Nevertheless, it is in this genus that a brood pouch sometimes is present (*P. marsupiale*, *P. tsutsuii*, *P. terranum* n.sp.) constricted off from the body wall in a unique position, about halfway along the dorsum of the thorax at the level of the anus. It is most probable that fertilisation as well as incubation of embryos, takes place in it; or in the atrial cavity.

Only very few *Aplidium* species (*A. uteute*, *A. altarium*) have a brood pouch, at the postero-dorsal corner of the atrial cavity, in which embryos are incubated. In this genus, fertilisation generally appears to be in the top of the oviduct or in the atrial cavity.

incurrent aperture: see **apertures**.

larvae: The larvae of the taxa formerly grouped in the single family Polyclinidae, as originally defined, demonstrate its polyphyletic nature. The larvae of the new families proposed below can be characterised by their size, adhesive organs, ectodermal vesicles and ectodermal ampullae (see Table 2). The Euherdmaniidae have adhesive organs that are invaginated tubes that evaginate on settlement, as in the family Pycnoclavellidae; the relatively large larvae of Pseudodistomidae n.fam., as do Polycitoridae, have large adhesive organs and ectodermal ampullae be-

tween and lateral to the median adhesive organs; the generally smaller larvae of Polyclinidae *emend.*, Protopolyclinidae n.fam., and Ritterellidae n.fam. usually have ectodermal vesicles which separate off from the larval epidermis into the test between and alongside the median adhesive organs. There are also differences between genera in the origin of the ectodermal vesicles (see **vesicles** below).

All the larvae of the families discussed below have a discrete mass of yolk cells in the middle of the trunk. Larval ocellus and otolith are present in all genera. Although *Euherdmania* has similar adhesive organs to *Pycnoclavella*, the larvae do not appear to have a tendency to loss of the ocellus as do those of *Pycnoclavella*.

With the exception only of *Euherdmania* in which the invaginated tubes are triradially arranged, the 3 adhesive organs are in the anterior median line. Only *Aplidium triggsense* (with 12), and *A. multipapillatum* Millar, 1975 (with 8), have a different number of adhesive organs, all in the median line.

muscles: With the exception of sphincter muscles around the apertures, the body musculature in the parietal body wall is usually longitudinal, although fibres are exchanged with adjacent bundles. Transverse fibres are present, forming a network with the longitudinal ones, only in *Ritterella multistigmata* n.sp. and *Anadistoma* n.gen. These transverse fibres may originate as branches from the longitudinal muscle bands. Also in *Ritterella*, oblique muscles similar to those in the Clavelinidae cross the thorax from the endostyle to the postero-dorsal corner of the thorax. Longitudinal and oblique muscles extend in a band along each side of the abdomen and posterior abdomen, as they do in most of the genera. Only some *Aplidiopsis* species, *Polyclinum* and *Sidneioides* are exceptions with short longitudinal muscles confined to the anterior part of the thorax.

In some Pseudodistomidae n.fam. (*P. oriens* n.sp., *P. candens* n.sp) at least some fibres of the longitudinal muscles extend along a vascular stolon posterior to the posterior abdomen and heart. The presence of these muscles on the long, distinct vascular stolon is reminiscent of *Sigillina* (Holozoidae, see Kott 1990). The presence of both a gonad-containing posterior abdomen, and a vascular stolon with muscles (apparently homologous with a similar organ in *Sigillina*) in certain *Pseudodistoma* species suggests that the vascular stolon of Holozoidae is a separate structure rather than being homologous with the posterior abdomen of Polyclinidae, Ritterellidae n.fam., Pseudodistomidae n.fam. and Protopolyclinidae n.fam.

In all taxa, transverse fibres are present in the transverse vessels. These are fibres that derive from longitudinal muscle bands. These muscles are seen clearly in the large zooids of *Synoicum castellatum* n.sp., branching off longitudinal muscles and entering the transverse vessels through connectives from the parietal body wall about one-third of their length from the dorsal mid-line. Ventrally they divide into branches each side of the endostyle.

The large atrial lips of *Polyclinum* and species of other genera in Polyclinidae are also muscular. Branches from the ventral thoracic longitudinal muscles extend out into these tongues, and circular muscles from around the atrial apertures also are diverted out along them. These large atrial lips insert into the test to protect the atrial openings into the cloacal cavities, and in some cases, insert into the rim of common cloacal apertures and exert some control over these excurrent openings.

Anteriorly, the longitudinal muscle bands extend onto the siphons, where there is exchange of fibres with circular (including sphincter) muscles, longitudinal fibres are then organised into bands, one extending into the each lobe around the rim of the aperture. When these muscles are concentrated into the tip of each lobe they depress it and divide the tip of the lobe into 2 (e.g. *Ritterella dispar*, *Aplidium macrolobatum* n.sp.).

parastigmatic vessels: see **branchial sac**.

posterior abdomen: see **gonads**.

replication: In these well developed aplousobranch families replication takes place by horizontal division of the posterior abdomen and/or the abdomen, and usually is prolific. The process has not been specifically studied in Australian species. However the process is similar in the range of polyclinid species studied by Berrill (see 1935 for review), Nakauchi (1966–1987), and Nakauchi and Kawamura (1974a–1986). The process is the same in *Ritterella* (see Nakauchi 1977).

Generally reserve food cells (trophocytes) pack the abdomen and posterior abdomen. Sometimes the thorax and abdominal organs are resorbed but in other species they remain functional during the budding process (see *Ritterella pulchra*: Nakauchi, 1977). The abdomen and/or posterior abdomen are then divided, by constriction of the epidermis, into numerous buds. A segment of epicardial tube is contained in each, and is the regenerative tissue for the new vegetative zooid which develops from each bud.

In *Polyclinum* vegetative zooids with relatively long strap-like vegetative posterior abdomina (as opposed to the short sac-like posterior abdomen of sexual zooids) are found crowded in the growing margins of colonies (see *P. vasculosum*).

Although moderately long, sometimes branched, vascular appendices are present in Ritterellidae, and shorter ones are present in most of the other families, these seem not to be involved in the process of replication as they are in Holozoidae.

Pseudodistomidae n.fam. have a long vascular stolon with longitudinal body muscles extending along it as in *Sigillina* (Holozoidae). This supports the view that this family is related to *Sigillina* (Holozoidae). The method of replication in the Pseudodistomidae n.fam. is not known, nor is it known that the vascular appendix has a role in the process. Although Brewin (1958) found 'bud-like masses' lying be-

neath the zooids of *P. cereum*, and juvenile replicate zooids are found in the stalk of developing lobes of *P. oriens* n.sp., it is not known whether these developed from the vascular stolon in a process that resembles that of Holozoidae (see Kott 1990); or if they developed from the posterior abdomen and/or abdomen of the parental zooids by horizontal strobilation, as in Polyclinidae. A continuation of the epicardial tube into the vascular stolon of *Pseudodistoma* has not been found.

vesicles, ampullary —, epidermal —, larval —: Hollow spheres, about 0.01 to 0.05mm diameter with an epithelial wall, usually occur in the test of the larval trunk in Protopolyclinidae, Ritterellidae and Polyclinidae. The fine strands attaching them to the larval epidermis sometimes sever as larvae mature. Like the enlarged epithelial cells on the tips of some ampullae, the epidermal cells occasionally are larger on the outside surface of the vesicle than on its mesial wall.

In *Monniotus* (Protopolyclinidae), *Polyclinum* and *Synoicum*, the vesicles exclusively branch off fine strands that detach from the epithelial wall on each side of the mid-line and trail through the test. The ventral strands arise from about one half to two-thirds of the way from the anterior end of the trunk, one extending to the posterior end of the trunk near the posterior-horns of the haemocoelic cavity where the vesicles form a tight cluster, and another shorter one trails anteriorly. Similar pairs of epithelial strands from the anterior end of the dorsal surface trail posteriorly on each side of the dorsal mid-line to the vicinity of the branchial aperture, and in *Monniotus* a corresponding pair of strands extend antero-ventrally on each side of the adhesive organs. The vesicles are especially numerous postero-ventrally. Dorsal and ventral clusters of vesicles arising from similar test strands are present in some larvae of *Aplidium* (*A. lunacratum* nom. nov., *A. multilineatum* n.sp., *A. ornatum* n.sp., *A. protectans* n.sp., *A. robustum* n.sp. and *A. tabascum* n.sp.), but the postero-ventral test strand is much shorter and a postero-ventral cluster of vesicles near the base of the tail does not occur. Larvae of the majority of *Aplidium* species have vesicles directly attached by their short sometimes branched hair-like filament to the larval epidermis rather than to an epithelial strand trailing through the test. These vesicles are arranged in single or multiple series to form a lateral arc around the anterior end of the larval trunk on each side of the lateral line, and sometimes also in the median line between the adhesive organs (Table 2).

The enlarged epithelial cells on the outside of the vesicles suggest that they may be involved with adhesion to the substrate.

Vesicles are not present in the larvae of Clavelinidae, Holozoidae, Polycitoridae, Pycnoclavellidae, Euherdmaniidae and Pseudodistomidae n.fam.

Family POLYCLINIDAE *sensu* Milne Edwards, 1842

Polyclinidae Milne Edwards, 1842 is distinguished from other aplousobranch families by the presence of gonads and heart in a posterior abdomen which also serves as the vegetative stolon. Genera of Diazonidae, in which gonads and heart are sometimes in a posterior abdomen, have internal longitudinal branchial vessels to distinguish them. Certain species of Holozoidae have gonads in a posterior abdominal sac but it is separate from the vegetative stolon (see Kott 1990), the holozoid heart is in the abdomen (rather than the posterior abdomen), and the larvae usually have adhesive organs triradially arranged (rather than in the median line). Certain species of *Euherdmania*, formerly assigned to Polyclinidae, have no posterior abdomen and, with the gonads and heart in the abdomen, can be mistaken for *Polycitor*. Larval characters must then be relied on to distinguish them (see below, Euherdmaniidae).

Like Polycitoridae, the present group of families have longitudinal and oblique muscle bands that extend from the thorax along the length of the zooid. Also, transverse muscle fibres are in the transverse branchial vessels. However, usually they lack the thoracic bands that form an external coat in the parietal body wall of Polycitoridae. Exceptions, in which transverse muscle bands are present in the parietal body wall to form a meshwork with the longitudinal ones, are *Condominium* n.gen., *Ritterella multistigmata* n.sp., *Anadistoma* n.gen. and *Euherdmania fasciculata* Monniot, 1983.

Taxa in Polyclinidae were assigned to one of 2 subfamilies, Euherdmaniinae and Polyclininae, grouped on the basis of shared convergent characters. Thus, *Protopolyclinum*, *Euherdmania*, *Dumus*, *Ritterella*, *Placentela*, *Pseudodistoma*, *Monniotus*, *Citorclinum* and their synonyms which lack cloacal systems comprised Euherdmaniinae; and *Polyclinum*, *Aplidium*, *Synoicum*, *Sidnyum*, *Aplidiopsis* and *Morchellium* which all have cloacal systems were in Polyclininae. However, considerations of larval and adult morphology (set out below) suggest other family groupings (Tables 1,2) that more closely reflect their probable phylogeny, and acknowledge closer relationships with other taxa of Aplousobranchia than those with genera formerly included in the polyphyletic Polyclinidae as defined by Milne Edwards (1842) and subsequent authors (see Berrill 1950).

In developing this new classification, the characters that have been relied on to indicate higher taxon relationships include the length of the oesophagus — a short oesophagus one- to two-thirds the length of the abdomen as in Holozoidae, or a long oesophagus more than two-thirds of the length of the abdomen as in Polycitoridae; the presence or absence of structural folds in the stomach wall, and the shape and orientation of the stomach — whether it is vertical and barrel-shaped or oblique and shortened dorsally; the size of the branchial sac, and number of rows of stigmata; the type of larval adhesive organs — eversible axial cones in shallow epidermal cups, or pycnoclavellid inverted, tubular ones; and the site of fertilisation and incubation of embryos, e.g. in the distal (thoracic) part of the oviduct as in Diazonidae (see Protopolyclinidae n.fam., Ritterellidae n.fam.), or in the base (abdominal part) of the oviduct as in Pycnoclavellidae (see Pseudodistomidae n.fam. and Euherdmaniidae), or in the atrial cavity (see Polyclinidae). Generally, the presence of branchial papillae, long and numerous rows of stigmata, the anus opening well anteriorly, a large number of embryos, and bunched male follicles indicate more primitive taxa than those without branchial papillae, and with narrow thoraces, few rows of stigmata, and testis follicles in longitudinal series.

Most of the taxa in these families have well developed rectal caeca (a rectal valve) at the base of the ascending limb of the gut loop. This probably is an apomorphic character associated with the vertical gut loop. It is known also in *Hypsistozoa*, *Neodistoma* and in some *Distaplia* (see Kott 1990).

Of the following 6 families (which include all the genera formerly included in Polyclinidae), only the monotypic family Placentelidae n.fam. from the north-western Pacific does not occur in Australia. In the other families, all reported from Australia, the only genera that do not occur here are *Protopolyclinum* Millar, 1960 (Protopolyclinidae n.fam.), *Citorclinum* Monniot and Millar, 1988 (Pseudodistomidae n.fam.), and *Pharyngodictyon* Herdman, 1886 (Ritterellidae n.fam.).

Key to families of the genera formerly comprising Polyclinidae Milne Edwards, 1842

1. Atrial apertures 6-lobed; cloacal systems rudimentary or lacking 2

   Atrial apertures not 6-lobed; cloacal systems well developed .... POLYCLINIDAE *emend.*

2. Stigmata in 3 rows ..... PSEUDODISTOMIDAE n.fam.

   Stigmata in > 3 rows 3

3. Stomach at posterior end of long abdomen ..... EUHERDMANIIDAE

   Stomach near the middle of short abdomen . 4

4. Heart in the abdomen ..... PLACENTELIDAE n.fam.

   Heart in the posterior abdomen 5

5. Posterior abdomen short, tapering, sometimes separated from abdomen by a constriction ..... PROTOPOLYCLINIDAE n.fam.

   Posterior abdomen not short, tapering, never a constriction between posterior abdomen and abdomen ..... RITTERELLIDAE n.fam.

Family PLACENTELIDAE n.fam.

The monotypic family is characterised by its numerous rows (12 or more) of numerous stigmata (up to 50), relatively short oesophagus, smooth stomach, the anus at the top of the branchial sac (level with the second or third row of stigmata), heart in the abdomen, numerous embryos being incubated in the terminal part of the oviduct in the atrial cavity, almost sessile median larval adhesive organs with an eversible axial cone in an epidermal cup, and 4 rows of stigmata in the larvae. The body muscles are longitudinal and oblique on the thorax and have not been observed on the abdomen or the posterior abdomen.

The type species of the genus *Placentela*, *P. crystallina* Redikorzev, 1913, has been well studied (Tokioka 1968, Nishikawa 1984b). In the latter study Nishikawa examined the existing material (including types) of *Placentela crystallina* and its synonym *Sigillinaria clavata*. The species has embedded zooids and up to 60 eggs and developing embryos in what appears to be an internal brood pouch in the distal end of the oviduct in the atrial cavity. The heart is in the abdomen with the anterior part of the gonads, while the remainder of the gonads and the epicardial sacs are in the posterior abdomen. Gonads spill over from the gut loop into the posterior abdominal extension as they do in *Hypsistozoa* (see Kott 1990). There is parenchymous material in the posterior abdomen of *P. crystallina*, which

Nishikawa (1984b) believed would be the site for formation of replicate zooids.

Kott (1963) first proposed the synonymy of *Sigillinaria clavata* Oka, 1933 and *Homoeodistoma michaelseni* Redikorzev, 1927 with *Placentela crystallina*. All 3 are from the sea of Okhotsk and the Kamchatka Peninsula (north-western Pacific). Nishikawa (1984b) subsequently established the synonymy of *S. clavata* with *P. crystallina*, but did not include *H. michaelseni* in his study. The latter species as well as having the same general colony and zooid morphology (including 12 rows of stigmata, and the anus and gonopores opening at the top of the branchial sac), is sympatric with *P. crystallina* and is here considered synonymous with it.

Species assigned to *Sigillinaria*: Brewin, 1950b (see also Brewin 1958) are not congeneric with *Sigillinaria* Oka (*Placentela*). They have long or short oesophagus, folded or smooth stomach, 3 or more rows of stigmata and some have parastigmatic vessels. Subsequently Brewin (1958) on the basis of "parallelism in classification", reassigned species to genera solely on the presence or absence of stomach folds — those with stomach folds to the genus *Pseudodistoma*, and those without to *Homoeodistoma*. Thus *S. arenosa* Brewin, 1950 and *S. novaezelandiae* Brewin, 1950 were erroneously assigned to *Homoeodistoma* (respectively *Ritterella* and *Pseudodistoma*, see below).

Homoeodistoma longigona Tokioka, 1959 from the Sea of Japan (Wakasa Bay) differs from *H. michaelseni* (*Placentela crystallina*) in the position of the anus (opposite the sixth or seventh row of stigmata — in a pharynx with 20 rows), the position of the heart (at the end of the posterior abdomen), yellow pigment spots in the lobes of the apertures, and a long, narrow posterior abdomen with testis follicles and eggs in longitudinal series. Although a similar longitudinal series of ova is in the proximal end of the oviduct in *Euherdmania*, the long oesophagus of the latter genus is lacking. Millar's (1963) proposal that *H. longigona* is a diazonid may be correct (see Kott 1990, p.33); or it may be related to Ritterellidae (see *R. arenosa* below).

Holozoidae and *Placentela* (see Nishikawa 1984b) have similar large larvae with well developed adult organs and almost sessile adhesive organs, zooids with short oesophagus, and gonads sometimes extending into the posterior abdomen which also contains an epicardial sac. However, in view of the primitive characters of *Placentela*, viz. numerous stigmata, the large number of embryos being brooded, the large testis and the anterior position of the anus, a diazonid ancestor is more likely than a direct relationship.

Although sessile everting adhesive organs and fertilisation at the top of the oviduct occur in Clavelinidae they probably are characters convergent, rather than homologous, with those in *Placentela*. A relationship with Polycitoridae is unlikely in view of the large number of embryos, the relatively short oesophageal neck (the cardiac end of the stomach is about halfway down the abdomen), the anterior position of the anus, and the absence of transverse thoracic muscles.

The type species *P. crystallina*, and *P. translucida* Kott, 1969 from the Antarctic Peninsula are the only species known. The genus has not been recorded from Australian waters. *Placentela areolata* Kott, 1963, *P. ellistoni* Kott, 1972b and *Homoeodistoma omasum* Monniot, 1987 are incorrectly assigned (see *Condominium* n.gen, Protopolyclinidae n.fam. below).

Family PROTOPOLYCLINIDAE n.fam.

Zooids are embedded or separate, with both apertures 6-lobed, the atrial apertures opening separately to the exterior. The pharynx is large, and stigmata are numerous, arranged in 9 or more rows, with or without parastigmatic vessels. Branchial papillae often are on the transverse vessels. The anus opens one third to halfway up the atrial cavity. The oesophagus is short, and curves ventrally to enter the dorsally shortened, obliquely oriented stomach about halfway down the relatively small abdomen. The stomach has (sometimes only faint) longitudinal ridges in *Monniotus*, but irregular ridges or a smooth stomach in the other genera. Gonads, in a broad tapering posterior abdomen (constricted off from the abdomen only in *Protopolyclinum*), consist of numerous bunched testis follicles and a smaller ovary anterior to the testis. Embryos are incubated in the distal end of the oviduct in the posterior part of the atrial cavity.

In the characteristically large thorax, short oesophagus, small abdomen, anterior position of the anus, tapering posterior abdomen, numerous bunched male follicles, and incubation of embryos in the distal part of the oviduct this family resembles *Placentela* (Placentelidae, see above), which, however, differs in having the heart in the abdomen. Further, the presence of branchial papillae, suggests an origin direct from a diazonid ancestor.

The numerous small bunched testis follicles in a broad posterior abdomen, the occasional presence of branchial papillae, the dorsally shortened stomach, and the larval vesicles branching off posteriorly- and anteriorly-trailing stalks on each side of the dorsal and ventral mid-lines suggest a relationship with *Polyclinum*, although *Monniotus*, with shallow longitudinal stomach ridges, may have diverged from the main polyclinid line.

The Antarctic *Tylobranchion* Herdman 1886, has branchial papillae, short oesophagus and folded stomach, but its branchial papillae are forked and it has cionid-type larvae indicating a closer affinity with Diazonidae (see Kott 1990).

Ritterellidae n.fam., often with branchial papillae and larvae like the present family, are distinguished by their narrow zooids, usually with testis follicles in one or 2 longitudinal series and vertical barrel-shaped stomach.

The family, known only from Indo-West Pacific and Australian temperate waters, contains 3 genera, *viz. Condominium* n.gen., *Monniotus* Millar, 1988 and *Protopolyclinum* Millar, 1960 (monotypic, known only from New Zealand).

Key to genera of Protopolyclinidae

1. Zooids embedded 2
   Zooids not embedded ..... *Monniotus*
2. Branchial papillae present; colonial systems not present ..... *Protopolyclinum*
   Branchial papillae not present; colonial system present ..... *Condominium* n.gen.

Genus **Monniotus** Millar, 1988

Type species: *Monniotus ramosus* Millar, 1988

Zooids are contained separately in the terminal branches of the narrow sandy stalks that comprise the colony. The test consists of a delicate membrane to which sand adheres making a firm brittle casing for the zooid which, when expanded, completely occupies the space inside and adheres closely to the inside of the sandy casing. Body muscles are longitudinal, extending the whole length of the zooid. Rows of stigmata are numerous (up to 10) and one or more branchial papillae are on the transverse vessels, and also on the parastigmatic vessels when these are present. The gut loop is short, and the stomach has only very faint internal longitudinal ridges on the parietal wall. The posterior abdomen is long with the small ovary in front of the bunched follicles of the large testis. The posterior abdomen is especially broad when testis follicles are mature. Testis follicles and embryos are never present at the same time, and the genus appears protandrous (see also Millar 1988). Fertilisation is in the distal part of the oviduct (in the thorax), where a longitudinal developmental series of up to 6 embryos at a time are found being incubated. The larval adhesive apparatus resembles that of *Polyclinum*, in the 3 median adhesive organs, epidermal vesicles branching off trailing epidermal strands, and median and lateral ampullae with columnar epithelial cells, similar to those in the adhesive organs, forming a cap on the tip as in *Polyclinum*. However, the adhesive organs themselves are deeper than those in the latter genus.

In all known species, the incurrent aperture opens in the centre of a transverse, curved strip of delicate, sand-free, test. The sand-strengthened test anterior to the naked strip curves down over the aperture to form a protective lip.

Although a phylogenetic relationship is not implied, the colonies resemble those of *Ritterella* spp., especially those of *R. cornuta* which have narrow sandy lobes, regularly spaced branchial papillae and numerous rows of stigmata. However, in *Ritterella* the zooids are organised into single colonial (not usually cloacal) systems, while in *Monniotus* they are separate from one another, one in each lobe of the colony, the lobes joined basally to common stolons. Colonies also resemble those of *Euherdmania claviformis*, having separate zooids in narrow, sandy stalks. Millar (1988) distinguished *Monniotus* from *Euherdmania* by its branchial papillae. However, these are variable, reduced to one per row in *M. australis*. A more reliable and plesiomorphic difference from *Euherdmania* is the short oesophagus, resembling *Ritterella* and *Aplidium* rather than *Pycnoclavella* (to which *Euherdmania* appears to be most closely related).

The genus is recorded only from Australian temperate waters and from the western Indian Ocean. Two of the 3 known species are indigenous to Australian waters. The western Indian Ocean *M. ramosus* most resembles the eastern Australian species *M. radiatus* n.sp., having numerous papillae on each transverse vessel (see below). *Monniotus australis*, known from western and southern Australian waters, has only a single papilla on each vessel — in the centre of each side of the body.

Monniotus australis (Kott, 1957)
(Fig. 1. Plate 1a)

Euherdmania australis Kott, 1957, p. 103 (part, not specimens from Camden Haven *M. radiatus* n.sp.); 1972b, p. 172.

Distribution

New Records: Western Australia (Houtmans Abrolhos, WAM 1016.83; off Dongara, WAM 926.89 929.89). South Australia (Great Australian Bight, SAM E2099–100 E2103 E2416, QM GH4147).

Previously Recorded: South Australia (Elliston Bay — QM G9291 Kott 1972b; Waldegrave I. — SAM E2111–2; Investigator Strait — Kott 1972b). Victoria (Port Phillip Heads — holotype AM Y1317 Y1165 Kott 1957).

Description

External Appearance: The colonies are straight-sided, club-shaped lobes, tapering to common stolons at their narrow basal end. The terminal, expanded part is triangular in section with a flattened, triangular, slightly oblique free end. The lobes are from 1cm (Western Australia and Bass Strait) to 4cm (Great Australian Bight) long, and only rarely divided along their length. Sand grains are packed in a single layer in the very thin test to form a hard, rigid but brittle coat. Delicate internal test without sand is present only posterior to the thorax, which, when expanded, fills the inside of each lobe, the body wall adhering closely to the rigid sand-filled coat. The branchial aperture is directed downwards from the middle of the base of the triangular free end of the head just below its margin. The atrial aperture is directed upwards from just inside the apex of the triangle on the free end of the lobe. The openings are sometimes transverse, with 3 well separated small pointed lobes on each lip of the opening.

Internal Structure: The body wall is very delicate with about 12 fine longitudinal and oblique muscles extending the whole length of the zooid from the thorax to the posterior end of the long, narrow posterior abdomen. About 30 pointed tentacles of various sizes are in a circle around the base of the branchial aperture. The neural duct is short and funnel-shaped with a circular opening into the pharynx. There are 9 or 10 rows of about 30 stigmata anteriorly, but posterior rows are shorter. All except the posterior 3 rows are crossed by a parastigmatic vessel. The transverse and parastigmatic vessels each have a single tongue-shaped to pointed papilla in the centre. Triangular dorsal languets are also on the parastigmatic vessels as well as on the primary transverse vessels. The oesophagus is curved and narrow, opening into the stomach about halfway down the very small abdomen (never more than half the length of the thorax and often less). The stomach has about 12 shallow, often inconspicuous glandular ridges, on its parietal wall. These are obscured when the abdomen is contracted. The mesial wall of the stomach has irregular ridges. A long narrow duodenal region and oval posterior stomach are in the descending limb of the gut loop. A rectal valve is at the junction of the mid-intestine and rectum. The anus opens half-way up the thorax. Its rim is bilabiate, but each lip is subdivided into a fringe of pointed lobes. Gonads consist of numerous small follicles bunched in a long grape-like or narrow cylindrical mass around the vas deferens. A 4- or 5-egg ovary is in the top of the posterior abdomen.

Specimens from Price I. collected in April (QM GH4147), and Encounter Bay collected in October (SAM E2111–2 E2416) have up to 8 embryos aligned in a developmental sequence in the distal part of the oviduct (in the posterior half of the thorax). Thus there appear to be at least 2 breeding seasons.

The larval trunk is 1.1mm long. A median ampulla with a cap of modified columnar epidermal cells is in each interspace between the adhesive organs and 4 rounded lateral ones are on each side of the median adhesive organs. Numerous, crowded ectodermal vesicles are present along each side of the median line from the postero-ventral corner and around the anterior end of the trunk to the branchial aperture. These branch off the sides of fine stalks from the larval ectoderm which trail anteriorly and posteriorly along each side the dorsal and ventral mid-lines of the trunk, and especially cluster around the postero-ventral horns of the haemocoele near the base of the tail. The adhesive organs have an eversible axial cone in a deep tulip-shaped cup.

Remarks

The larval trunk appears to be similar to that of *M. ramosus* Millar, 1988. The branchial sac of the present species (which has a geographical range from western, across southern Australia to Bass Strait) has only a single papilla on each transverse vessel, while the eastern Australian *M. radiatus* n.sp., although it has colonies similar to the present species, has a branchial sac with numerous papillae like that of the African *M. ramosus*.

The zooids appear to arise from a central axial stalk in 2 (WAM 926.89 and 989.89) of the west-

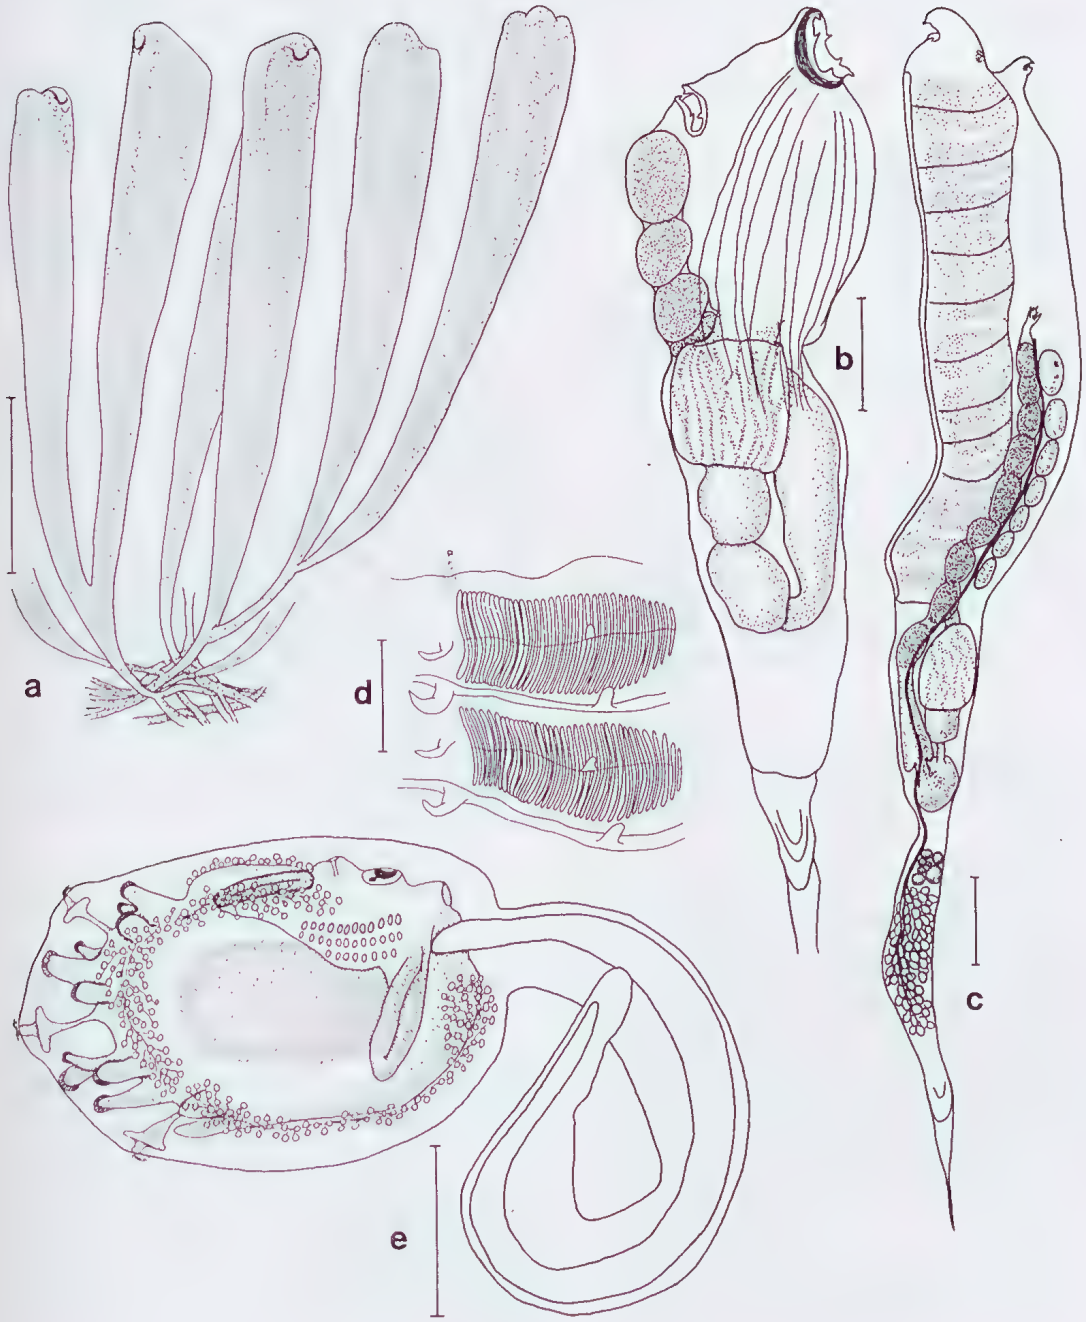

FIG. 1: *Monniotus australis* — **a**, part of colony (QM GH4147); **b**, immature zooid with thorax contracted (WAM 929.89); **c**, mature zooid with embryos in oviduct (SAM E2112); **d**, portion of branchial sac showing papillae on primary transverse and parastigmatic vessels (QM G9291); **e**, larva with some partly everted adhesive organs (SAM E2112). ern Australian colonies. However this is only apparent, as zooids radiate out from basal stolons fixed around a stem of weed.

Monniotus radiatus n.sp.
(Fig. 2)

Euherdmania australis Kott, 1957, p. 103 (part, specimen from Camden Haven).

DISTRIBUTION

TYPE LOCALITY: New South Wales (Nambucca Heads, 13m, coll. J.E. Watson 11.1.72, holotype QM G10012 *MV F58435*).

FURTHER RECORDS: Victoria (Portland, QM GH93), New South Wales (Camden Haven — paratypes AM G1356 Y1120 Kott 1957).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are a sandy mass of upright, club-shaped lobes, up to 2.5cm long, often with one or two branches along their length. The widest part, i.e. the terminal free end not more than 3mm in diameter. These lobes arise from a common basal mass. Each lobe contains a single zooid.

The thick, terminal part of each lobe is triangular in section and the free end is a flat isosceles triangle, with the branchial aperture directed downwards from the middle of the base of the triangle, just below its margin. The atrial aperture is directed upwards from the upper surface just inside the apex of the triangle.

INTERNAL STRUCTURE: The contracted zooids are about 8mm long, divided into thorax, short abdomen, and a relatively long posterior abdomen (up to half the total zooid length). Apertures are both 6-lobed on short siphons, the branchial one turned ventrally, and the short, atrial siphon directed dorsally, at right angles to the longitudinal axis of the body. A mesh of very fine longitudinal and transverse muscle bands is on each side of the thorax, and the longitudinal bands continue along each side of the abdomen and posterior abdomen.

The thoraces of these zooids are relatively large, with 9 rows of about 20 stigmata. Each row except the last 3 (in which the stigmata are shorter) are crossed by parastigmatic vessels. Each of the parastigmatic and the primary transverse vessels have about 10 rounded tongue-like papillae on them. The papillae on the parastigmatic vessels are smaller than those on the primary transverse vessels. A pointed trianglar dorsal languet is in the mid-line (over the dorsal sinus) also on both parastigmatic and transverse vessels. The parastigmatic vessels appear to be bisecting the rows of stigmata, and increasing their number.

The oesophagus is relatively short, the small stomach (with 12 shallow longitudinal ridges) is halfway down the abdomen and there is a duodenal region and a mid-intestine in the distal part of the descending limb of the gut loop.

Gonads consist of bunched male follicles and a small ovary. Larvae are not known for this species.

REMARKS

The shape of both colony and zooids, including the orientation of their apertures resemble both the Australian *M. australis* and the type species from Mozambique (Millar 1988). The African species differs from the present one in having less regular colony lobes which branch more along their length and appear to be less rigid, zooids with more rows of stigmata, and without parastigmatic vessels. However, in the present species absence of these vessels from the posterior rows of short stigmata indicates that they are actively bisecting the rows of stigmata to increase their number and this may not be a reliable distinction between the species.

Monniotus radiatus overlaps the range of *M. australis* in Bass Strait.

Genus **Condominium** n. gen.

Type species: *Placentela areolata* Kott, 1963.

The genus has large, embedded zooids, arranged in an integrated colonial system but not in cloacal systems. Six-lobed branchial openings directly to the exterior are on one side of the colony, atrial openings on the other. Stigmata are in numerous (at least 12) rows. Transverse as well as longitudinal muscles are present on the thorax. Parastigmatic vessels are present occasionally, but branchial papillae are not. The oesophagus is short, and curves to open along the dorsal side of the shield shaped, bilaterally symmetrical, smooth stomach which is halfway down the abdomen. Testis follicles are bunched, and the ovary is anterior to the testis.

The genus is monotypic, being known only from its type, an indigenous Australian species with a range around the continent.

DISTRIBUTION

NEW RECORDS: Western Australia (Cockburn Sound, WAM 582.31). South Australia (Taylor I., QM GH4161). New South Wales (Lord Howe Is, QM GH4380). Queensland (Heron I., QM GH4937; Central Section, Great Barrier Reef, QM GH5418). Northern Australia (Torres Strait, QM GH4931–6).

PREVIOUSLY RECORDED: South Australia (Great Australian Bight — AM U3925 Y1316 Kott 1972b). Queensland (Mackay — Kott 1963). New Caledonia (Monniot 1987).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are very irregular, with curved, fan-shaped lamellae, from 2 to 4cm along their outer edges, joined basally to common test, and sometimes forming a cornet. Some specimens have lamellae fitting around one another like the petals of a rose (QM GH4161), but in others they arise at random from the common test. The test is brittle with sand externally, but not internally. Internally only a thin layer of fairly tough, translucent test separates the zooids, which lie parallel to one another in a single layer in each lamella. The branchial apertures, directed downwards, open into a groove that is just behind and parallel to the rounded rim on the outer curve of each lamella. The atrial apertures open horizontally into a less well defined groove on the opposite side (inner curve) of the lamella, lower down than the row of branchial apertures. The grooves receiving the apertures are conspicuous in the preserved specimens, although the sand adhering to the outside of the colony obscures the actual openings. In photographs the atrial apertures of living specimens are seen directed upwards from a convex surface, the groove concealing them having disappeared.

INTERNAL STRUCTURE: Zooids are large but

transparent. Their total length, even when contracted is about 1.5cm, with thorax, abdomen and posterior abdomen of about equal length. The branchial aperture usually is turned ventrally. The atrial aperture extends laterally from about one third of the distance down the dorsal surface (level with the fourth row of stigmata). Each aperture has 6 minute pointed lobes. Numerous parallel longitudinal muscles are on the thorax, and these cross bands of transverse fibres on the parietal body wall outside each transverse branchial vessel. Fibres from these transverse bands continue into the branchial vessels through the branchial connectives. Longitudinal muscles continue along the abdomen and posterior abdomen. There is a strong but narrow sphincter muscle around the base of each short siphon. The opening of the neural gland is a funnel-shaped ciliated pit. The long rectangular stigmata are numerous, about 50 in each of 17 to 20 rows. Branchial papillae are not present. Very fine parastigmatic vessels are present in the colony from Lord Howe I. (QM GH4380), but not in other specimens.

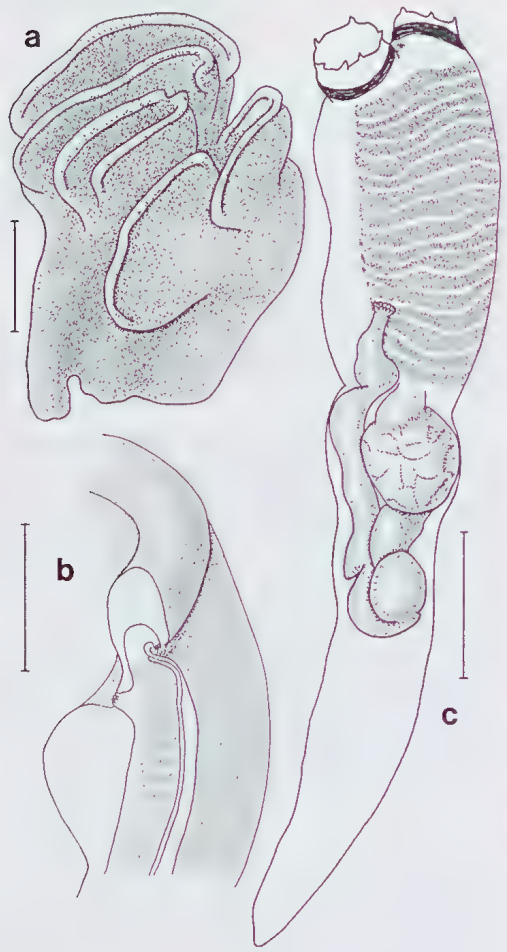

FIG. 3: *Condominium areolatum* gen. nov. — **a**, **b**, colony (QM GH4161) (**a**, external appearance; **b**, section through a lamella); **c**, zooid (QM GH4380). Scales: **a**, 2cm; **b**, 5mm; **c**, 2mm.

The oesophagus is short, and the smooth, almost spherical stomach is in the upper half of the abdomen. The internal wall of the stomach is papillated and sometimes divided randomly into irregular areas and some transverse and irregular wrinkles. Duodenum, posterior stomach and mid-intestine are in the descending limb of the gut loop, the mid-intestine opening into the rectum at the base of the descending or ascending limbs or in the pole of the gut loop. The rectum has two caeca (forming a rectal valve) at its proximal end. The anal opening is near the posterior end of the branchial sac.

Gonads are not present in any of the newly recorded material, although they are present in material from South Australia (Kott 1972b). They consist of a small ovary anterior to the numerous small bunched testis follicles.

Advanced embryos with tails almost completely encircling the trunk (0.44mm) are present in the type material (AM Y3925 Y1316) an ocellus and an otolith are present, but no other organs are developed.

Remarks

Kott (1963) overlooked the unusual and characteristic lamellae in the irregular type colony of *P. areolata* (*Condominium areolatum*).

The colonies of this species (like *Ritterella asymmetrica* n.sp.) have well developed colonial systems that differ from those of most other species of *Ritterella*, which have rudimentary cloacal systems or homologues of them, in which excurrent streams are expelled into depressions or concavities where they reinforce one another (see *Ritterella cornuta* n.sp., below). Instead branchial and atrial apertures, respectively, are in rows parallel with the outer edge, and on opposite sides of the terminal border of colony lobes. In all lobes, the branchial apertures are turned down toward the base of the colony, while the atrial apertures are directed away from it as they are in the separate zooids of *Monniotus*, *Dumus* and *Euherdmania*. In the present species (as in *R. asymmetrica*) the excurrent streams from each of the zooids are separated from incurrent water, and

probably are entrained by the currents that flow over the colony (see Kott 1989).

Colonies newly recorded from Torres Strait are not well preserved. They are very like the more irregular ones of this species taken from other locations, but although the zooids appear to have been identical in size and general outline, details of their structure are obscure.

Homoeodistoma omasum Monniot, 1987 from New Caledonia is conspecific with the present species, its characters falling within the intraspecific range of variations recorded in the Australian populations. Its occurrence in New Caledonia is not inconsistent with the temperate-tropical range recorded for the species.

Despite their considerable colony size and wide geographic range, colonies of this species are seldom recorded. This may be because of the dense coat of sand, concealed zooid openings and irregular colonies which make them inconspicuous and readily overlooked in the field.

Family RITTERELLIDAE n.fam.

The family is erected for colonial aplousobranch species with zooids either entirely embedded, or separate, the former usually organised in colonial, and sometimes rudimentary cloacal systems. Branchial and atrial openings are 6-lobed. Stigmata are in 4 or more rows. Parastigmatic vessels sometimes are present, as are branchial papillae. The oesophagus is short, and the barrel-shaped, vertical stomach has folded or smooth walls. The gonads, in a long posterior abdomen, have the ovary at the top and the male follicles usually in a longitudinal series behind the ovary. The anus opens at least half way up the atrial cavity and there usually is a distinct rectal valve at the proximal end of the ascending limb of the gut loop.

Fertilisation and incubation of embryos is in the distal (thoracic) part of the oviduct. The small (trunk length 1.0mm) larvae have 3 median, narrow-stalked eversible adhesive organs each with a small, shallow axial cone in an epidermal cup. Epidermal ampullae and vesicles suggest affinities either with *Polyclinum* (*Dumus* and the *pedunculata* group of *Ritterella*) or *Aplidium* (*aequalisiphonis* group of *Ritterella*).

Contracted zooids draw away from the surface to the base of the colony, as in Polycitoridae (see Kott 1990).

Many of the species from Australian waters (*Ritterella pedunculata*, *R. asymmetrica*, *R. multistigmata* n.sp., *R. cornuta* n.sp., *R. papillata* n.sp. and *Dumus areniferus*) have colonies like those of the *claviformis* group of *Euherdmania* (see below). Euherdmaniidae are distinguished by their long oesophagus and inverted tubular adhesive organs.

The anterior openings of the anus and the gonoducts, and (in *Ritterella dispar*) incubation of embryos in the distal (thoracic) part of the oviduct, are primitive characters shared with Placentelidae and Protopolyclinidae (e.g. *Monniotus*). The short oesophagus, and small larvae with epidermal vesicles as well as ampullae also occur in Protopolyclinidae from which *Ritterella* is distinguished by its smaller, narrower zooids with fewer male follicles in a long, thread-like or stumpy but never tapering posterior abdomen, barrel-shaped stomach with more pronounced folds and smaller, shallower adhesive organs. However, the relationship of Ritterellidae to Protopolyclinidae is not altogether satisfactorily resolved. A common diazonid ancestor is suggested by the persistence of branchial papillae in both families. The vertical stomach with longitudinally folded wall, and small larvae with shallow, stalked adhesive organs and epidermal vesicles also suggest a relationship with Polyclinidae.

Pharyngodictyon Herdman, 1886, an abyssal genus without stigmata, is represented by 6 species of which only 2 are known from a single specimen (see Millar 1982). Zooids of *P. mirabile* Herdman, 1886, *P. bisinus* Monniot and Monniot, 1991 and *P. mirabile*: Kott 1969 resemble those of some *Synoicum* spp., with a smooth, barrel-shaped stomach, and without a constriction between abdomen and posterior abdomen. However, the zooids of *P. elongatum* Millar, 1982, *P. cauliflos* Monniot and Monniot, 1991 and *P. magnifili* Monniot and Monniot, 1991 have a longitudinally folded stomach. Thus it is possible that the genus is polyphyletic despite the fact that all species have a short oesophagus, zooids opening separately to the surface, and the transverse atrial aperture at the posterior end of the dorsal surface, sometimes with both its anterior and posterior margin divided into rounded lobes (see Kott 1969). Species presently assigned to this genus are separated from Euherdmaniidae by their short gut loop, and from the Placentelidae by the position of the heart (in the posterior abdomen). The vertical, barrel-shaped stomachs are more like *Aplidium*, *Morchellium* and *Ritterella* than the oblique, dorsally shortened ones of Protopolyclinidae, Pseudodistomidae, *Polyclinum* and *Aplidiopsis*. Millar (1982) suggests a relationship between *Protoholozoa* (Holozoidae) and

Pharyngodictyon, but the presence of a posterior abdomen and the shape of the stomach does not support that view. The genus is tentatively assigned to Ritterellidae on the basis of the separately opening zooids, short oesophagus and vertical barrel-shaped stomach.

The genus *Ritterella* (with 5 or more rows of stigmata and folded stomach) is well represented in the Australian fauna. *Dumus* Brewin, 1952 (with 4 rows of stigmata and smooth-walled stomach) is known from 2 species, one possibly indigenous to the temperate waters of New Zealand and southern and eastern Australia, and one from New Caledonia.

Genus **Ritterella** Harant, 1931

Type species: *Amaroucium aequalisiphonis* Ritter and Forsyth, 1917.

The genus contains embedded zooids opening independently, and sometimes organised in colonial systems. Colonies are often, but not always, brittle with sand. The stomach has longitudinal folds in its wall, sometimes shallow and inconspicuous but well defined in other species.

The species of *Ritterella* with parastigmatic vessels are *R. tokioka* nom. nov. and *R. yamazii* Tokioka, 1949 from Japan, *R. arenosa* (Brewin, 1950) from New Zealand, *R. circularis* Monniot, 1987 from New Caledonia, and *R. asymmetrica* and *R. multistigmata* n.sp. from Australia. Kott (1972a) proposed that the presence of 5 primary rows of stigmata (which sometimes are bisected by parastigmatic vessels) is characteristic of *Ritterella*. However, although 5 primary rows occur in many species it is not universal.

The type species *R. aequalisiphonis* (Ritter and Forsyth, 1917) from California was assigned to *Sigillinaria* Oka, 1933 by Van Name (1945), who, like Millar (1960), believed the genera synonymous. However *Sigillinaria* is a synonym of *Placentela* Redikorzev, 1913 (see above). *Distoma pulchra* Ritter, 1901 (*Sigillinaria pulchra*: Van Name, 1945) has a folded stomach, but long oesophagus, and despite its embedded zooids, is more like *Euherdmania* than *Ritterella*.

Most of the species of *Ritterella* can be assigned to one of 2 species groups, viz.:

(1) *Aequalisiphonis* group, containing *R. prolifera* (Oka, 1933), *R. dispar* Kott, 1957, *R. tokioka* nom. nov. (for *R. pedunculata* Tokioka, 1953), *R. sigillinoides* (Brewin, 1958) and *R. glareosa* Monniot, 1974, as well as the type species of the genus. These naked or sandy colonies sometimes are stalked, the zooids are not arranged in distinct systems, and the short, thick posterior abdomina have bunched male follicles. The known larvae (of *R. dispar*, *R. prolifera* and *R. glareosa*) have epidermal vesicles separating directly from the epidermis like larvae of certain *Aplidium* spp. (see Fig. 60).

(2) *Pedunculata* group, containing *R. pedunculata* (Herdman, 1899) and 5 other sandy species, *R. papillata* n.sp., *R. asymmetrica* Millar, 1966, *R. multistigmata* n.sp., *R. cornuta* n.sp., *R. compacta* n.sp., from Australian waters. All have zooids arranged in systems, with sandy, usually narrow-stalked colonies (*R. compacta* excepted), long, narrow posterior abdomina with male follicles in longitudinal series, and larvae with postero-ventral and dorsol vesicles, and anterior ampullae like *Polyclinum*. The naked *Ritterella circularis* Monniot, 1987 from New Caledonia is also a member of this group of species; and *R. yamazii* Tokioka, 1949 from Japan may be.

The known larvae have ectodermal ampullae and clusters of vesicles like those of *Polyclinum*.

Ritterella arenosa (Brewin, 1950) and *R. vestita* Millar, 1960 do not appear to have affinities with either of the species groups (see below). Nevertheless, *Ritterella* appears to be monophyletic.

Ritterella rubra Abbott and Trason, 1958 from California lacks systems, has zooids opening separately to the exterior but has a mulberry-like stomach and curved oesophagus. The species appears to have a similar relationship with *Synoicum* to that of *Ritterella* with *Aplidium*.

Seven species of *Ritterella* are known from Australian waters, 5 from the temperate waters of the southern coast, where the genus appears to have radiated (Table 3). These and other aplousobranch species with separately opening zooids (e.g. *Dumus areniferus*, *Monniotus* spp., and *Condominium areolatum* n.gen.) appear to flourish in the same sandy coastal habitats.

Key to species of *Ritterella* recorded from Australia

1. Lobes of colony long and narrow 2
   Lobes of colony not long and narrow 6
2. Stigmata in 5 rows 3
   Stigmata in more than 5 rows 5
3. Parastigmatic vessels present ..... *R. asymmetrica*
   Parastigmatic vessels not present 4

4. Branchial papillae present ..... *R. papillata* n.sp.
   Branchial papillae not present .. *R. pedunculata*

5. Parastigmatic vessels present .....
   .....*R. multistigmata* n.sp.
   Parastigmatic vessels not present .....
   .....*R. cornuta* n.sp.

6. Colony sandy; zooids in systems .....
   .....*R. compacta* n.sp.
   Colony not sandy; zooids not in systems .....
   .....*R. dispar*

Species recorded from regions other than Australia.

In addition to the species recorded from Australia, which are all indigenous, the genus is known from the eastern Pacific (southern California) by the type species, and from New Zealand and Japan by the following:

Ritterella arenosa (Brewin, 1950) from New Zealand (Great Barrier I. and Hauraki Gulf; see also Brewin 1958). Despite its smooth stomach (which occurs also in *Dumus*) the species, with its zooids embedded (rather than separate) in sandy flat-topped lobes, parastigmatic vessels (like *R. asymmetrica*), 9 or 10 rows of 20 to 24 stigmata, and narrow posterior abdomen with the ovary in front of the longitudinal series of testis follicles, seems most appropriately assigned to *Ritterella*. It shares some characters with *Homoeodistoma longigona* Tokioka, 1959, although the latter species seems to have closer affinities with the Diazonidae (see above, Placentelidae).

Ritterella circularis Monniot, 1987 from New Caledonia has circular systems with the atrial apertures in a central depression as in *R. compacta* n.sp. The species also has a similar number of rows of stigmata. Unlike *R. compacta* its colony is not sandy, has more stigmata per row, has parastigmatic vessels, and lacks branchial papillae.

Ritterella glareosa Monniot, 1974, from 300m on a sea-mount in the northern Pacific, is thought isolated there. The spherical, sand-encrusted species has 5 to 7 rows of numerous stigmata, and the usual slender muscle bands extend the whole length of the body. Testis follicles are bunched, but this could be the result of contraction of the posterior abdomen. They are not as numerous as they are in Protopolyclinidae. As in other species, the rectum and gonoducts extend at least halfway up the atrial cavity, and there is a rectal valve at the proximal end of the ascending limb of the gut loop. The stomach has 5 faint longitudinal folds. The larvae have ectodermal vesicles but no ampullae, and there is an otolith but no ocellus. The species is distinguished from others by the form of its colony and the number of faint stomach folds. The embryos probably are incubated in the distal part of the oviduct, as are the embryos of *R. dispar* and *R. prolifera*, from which the present species is distinguished by its sand encrusted colony, and fewer stomach folds.

Ritterella prolifera (Oka, 1933) from Japan (see Tokioka 1953) closely resembles *R. dispar*, differing from it only in having 6 (rather than 5) rows of stigmata.

Ritterella sigillinoides (Brewin 1958) from Stewart I. has a fleshy stalked colony without sand, no systems, zooids with 5 rows of stigmata, a folded stomach and

TABLE 3. Summary of characters of species of *Ritterella* recorded from Australia

Species	Biogeographic range[1]	Range anticlockwise around Australia	Colony	Systems	Stigmata: no. rows; no/row	Parastigmatic vessels	Branchial papillae	Stomach folds
R. compacta n.sp.	A,te	Gt Australian Bight	sandy, compact cushion	rudimentary cloacal	15;20	absent	10	6
R. cornuta n.sp	A,te	"	sandy stalks	"	9;15–20	absent	15	6+
R. papillata n.sp.	A,te	"	"	"	5;15	absent	15	8
R. pedunculata	A,te	Gt Australian Bight to Solitary Is (NSW)	"	colonial	5;12	absent	0	4–5
R. assymmetrica	A,te	Gt Australian Bight to Port Phillip Bay	"	"	5;20	present	0	15
R. dispar	IWP,tr	NSW to Mackay	naked lobes	none	5;16	absent	0	15

[1] A, indigenous; IWP, Indo-West Pacific; te, temperate; tr, tropical.

neither branchial papillae nor parastigmatic vessels. Colonies superficially resemble *R. prolifera* or *R. dispar*, but these species are sessile, and lack the narrow stalk of the present one.

Ritterella tokioka nom. nov. for *R. pedunculata* Tokioka, 1953 from Japan has 12 rows of stigmata, each crossed by parastigmatic vessels, a short oesophagus and folded stomach. The colonies are stalked heads arising from a basal stolon resembling those of *R. sigillinoides* from New Zealand, but the zooids differ.

Ritterella vestita Millar, 1960 from the North Island, New Zealand. This species has a sandy, stalked head, without systems, zooids with 27 to 34 rows of 40 to 50 stigmata, a folded stomach, and testis follicles in a longitudinal series. It lacks both parastigmatic vessels and branchial papillae.

Ritterella yamazii Tokioka, 1949 from Japan is a soft semitransparent cushion with 5 rows of stigmata with parastigmatic vessels, 10 stomach folds, 2 rows of testis follicles, and epidermal vesicles in the larval test.

Ritterella sp. aff. *aequalisiphonis*: Tokioka, 1967 from Japan, has 14 rows of stigmata. Its naked, clavate colonies distinguish it from most Australian species.

Ritterella asymmetrica Millar, 1966
(Fig. 4. Plate 1e,f)

Ritterella asymmetrica Millar, 1966, p. 361.

DISTRIBUTION
NEW RECORDS: South Australia (Great Australian Bight, SAM E2102 E2104, QM GH4157 GH4195 GH4930; Kangaroo I., QM GH5427; Cape Jaffa, QM GH5445). Victoria (Nelson Bay, MV F57792).
PREVIOUSLY RECORDED: Victoria (Port Phillip — MV H39 Millar 1966).

DESCRIPTION
EXTERNAL APPEARANCE: Colonies consist of upright, sandy, cylindrical to flattened stalks up to 4cm long, branching along their length, with terminal more or less club-shaped but bilaterally symmetrical expansions up to 1cm long and 6mm wide. On one side, the long terminal expansion is slightly flattened, with a scalloped margin. On the other, it is deeply convex. The atrial apertures open around the outside (deeply convex side) of the scalloped margin, and the branchial apertures

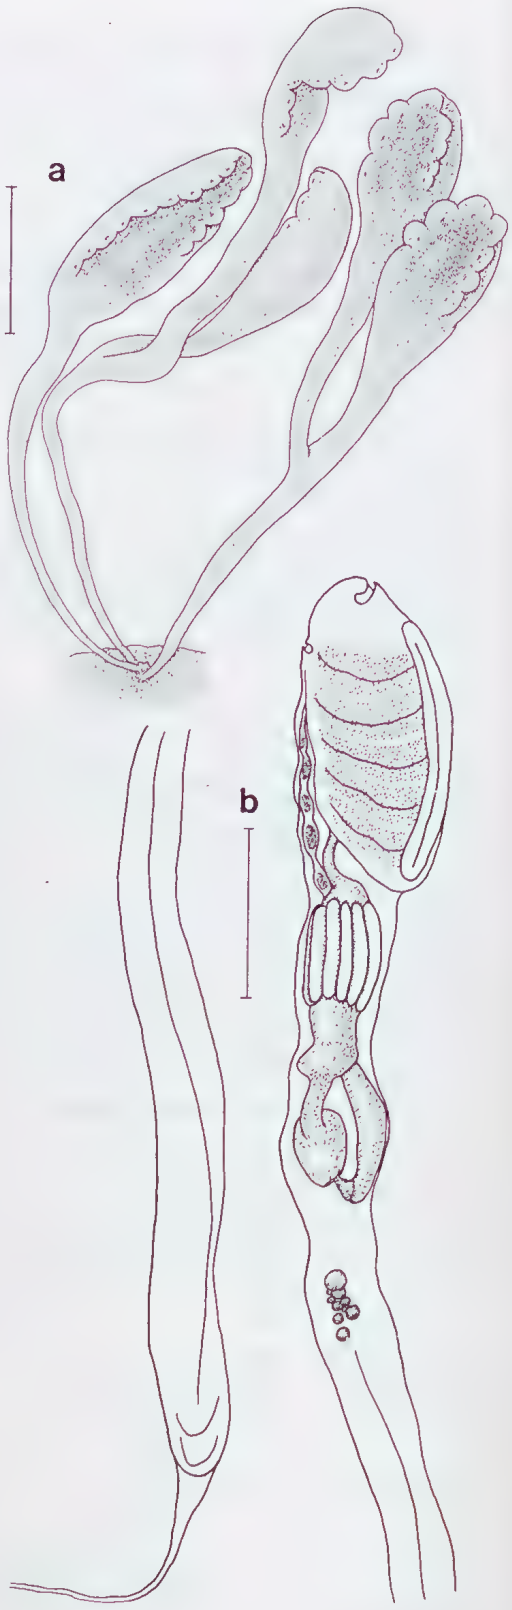

FIG. 4: *Ritterella asymmetrica* (MV F57792) — **a**, part of colony; **b**, zooid (posterior half of posterior abdomen shown separately). Scales: **a**, 1cm; **b**, 1mm.

are in a groove around the other (flat) side. Sand covers the outside of each stalk but is absent from the delicate internal test. In some of the preserved specimens the internal terminal expansion is spoon-shaped, its flat side slightly concave. In life it is probably slightly convex, presented to oncoming currents, deflecting the current past the branchial apertures that surround it.

The scalloped margin around the free end of each lobe is formed by the surface test swelling over the anterior end of each zooid. Each lobe of the colony contains up to 16 zooids, arranged parallel to one another in a single layer.

INTERNAL STRUCTURE: Zooids are about 1cm long, with thorax and abdomen of more or less equal length, and a longer, thread-like posterior abdomen. Both apertures are sessile, transversely elongated, and the 6 lobes around the rim of each opening are minute, sharply pointed and widely separated from one another, 3 on each facing lip. The branchial aperture is terminal and bent ventrally, the atrial sub-terminal and directed dorsally. A sphincter muscle is present around each aperture. A layer of fine transverse thoracic muscle fibres surrounds the slender longitudinal muscles which extend from the thorax onto the abdomen. Each of the 5 rows of about 20 long, narrow, parallel stigmata, is crossed by a conspicuous parastigmatic vessel. The transverse vessels are wide membranes projecting into the lumen. When contracted the edges of these membranes are drawn into tight frills that superficially resemble branchial papillae. However branchial papillae are not present. Triangular dorsal languets are on parastigmatic vessels as well as on primary transverse vessels.

The short, barrel-shaped stomach is in the anterior half of the abdomen. Twelve to 15 longitudinal folds are in its parietal wall, but the surface of the mesial wall is irregular. A long duodenal area, mid-gut and oval posterior stomach occupy the remainder of the descending limb of the gut loop. The rectum extends halfway up the thorax to open in a bilabiate anus just behind the atrial aperture. A small ovary with up to 12 small eggs is in the anterior part of the posterior abdomen. Mature testis are not present in any of the newly recorded South Australian and Victorian specimens (collected in April and June respectively), although they are present in the type specimen in 2 irregular longitudinal series (Millar 1966).

REMARKS

Millar (1966) believed that the branchial sac contained 10 rows of stigmata rather than 5, misinterpreting the parastigmatic vessels. These are true parastigmatic vessels, with the long stigmata continuous beneath them. The number of stigmata is difficult to determine in contracted specimens, but although at least 20 were counted there do not seem to be as many as the 35 Millar (1966) recorded.

Kott (1972a) discussed the possibility of this species being conspecific with *R. pedunculata*, suggesting that differences between the 2 species, viz. the size of colonies, zooids and branchial sacs, could be associated with growth. However, growth and maturity of *R. pedunculata* is not associated with increases of the order that could explain the differences. Although very large colonies of *R. pedunculata* have been examined, they all consist of the characteristically narrow lobes with not more than 12 zooids, and short stigmata without parastigmatic vessels. Further, the colonies are different, for atrial apertures of *R. asymmetrica* open around the convex sides of a club-shaped terminal expansion to form systems homologous with those of *Condominium areolatum* (see above); while those of *R. pedunculata* open in a row onto the concave side of a flat, fan-shaped expansion to form analogues of cloacal systems (see *R. cornuta* n.sp., below).

Transverse apertures with widely separated minute lobes on their rims are found in *Monniotus* spp., although, no phylogenetic relationship is implied by this. Rather the arrangement is an adaptation associated with the openings on opposite sides of the colony (see Kott 1989).

Ritterella compacta n.sp.
(Fig. 5. Plate 2a,b)

DISTRIBUTION

TYPE LOCALITY: South Australia (Investigator Group, Flinders I., in caves, coll. N. Holmes 10.4.83, holotype QM GH2399 *SAM E2094*; eastern side of Grindle I., 10-15m, coll. W.H. Sasse, 7.4.87 paratype, QM GH4172 *SAM E2095*; Price I., 15-20m, coll. N. Holmes 9.4.87, paratype QM GH4177 *SAM E2096*).
FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are compact, sessile, and hemispherical to almost spherical, with the surface either undivided or (QM GH4177) subdivided into tightly packed cylindrical lobes, each containing a single circular system of 6 to 8 zooids. The test is sandy throughout and the zooids are in rigid, vertical compartments. The branchial openings are in circular depres-

sions, around the periphery of the rigid sandy swellings or lobes (almost 5mm diameter) on the surface of the colony. Atrial openings are in a depression of varying depths in the centre of each lobe. Sometimes the central depression is deeper and forms a rudimentary cloacal cavity (QM GH2399 GH4172), opening to the surface through a central aperture and receiving the atrial openings of the zooids that surround it. A layer of sand continuous with the layer encrusting the outside of the colony lines the inside of the rudimentary cloacal cavity. It is homologous with the simple depression in the less compact colony (QM GH4177).

FIG. 5: *Ritterella compacta* n.sp. — **a**, diagrammatic cross section through a system (holotype QM GH2399); **b**, whole zooid (paratype QM GH4177); **c**, **d**, zooids (holotype QM GH2399); **e**, atrial siphon showing extended dorsal rim of aperture and dorsal median papilla (holotype QM GH2399). Scales: **b–d**, 1mm; **e**, 0.2mm.

INTERNAL STRUCTURE: The zooids are about 1cm long, they have a long thorax, a slightly shorter abdomen and a posterior abdomen that varies from about half to one third of the total zooid length. The 6-lobed branchial aperture is terminal, and the large atrial siphon subterminal. Often the anterior rim of the atrial siphon is produced into a lip of various lengths. The tip of the lip is divided into 3 pointed lobes, and the lower (posterior) half of the rim of the atrial aperture has another 3 widely separated small, pointed, lobes. In some zooids a pointed projection, or papilla projects from the dorsal mid-line on the posterior wall of the atrial siphon.

Circular muscles are present around the branchial and atrial apertures, curving out along the anterior atrial lip when one is present. About 12 longitudinal muscles extend down the thorax from each of the siphons. Posteriorly they extend along each side of the abdomen and posterior abdomen. Atrial lips are inserted into the rim of cloacal depressions or into the margin of cloacal apertures, so that the zooids in each system provide some muscular control around the rim of the opening.

Sixteen rows of about 20 stigmata are separated from one another by transverse vessels with about 14 rounded papillae on each. The stomach, with about 6 longitudinal folds on the parietal wall and irregular creases on the mesial wall, is about halfway down the abdomen. There is a duodenum and a mid-intestine in the descending gut loop. A distinct rectal valve is present at the proximal end of the ascending limb of the gut loop.

Gonads are in the upper half of the posterior abdomen, the 3 or 4 egg ovary anterior, and behind it almost spherical male follicles are bunched together.

REMARKS

Variations in length of atrial lip and the shape of the dorsal median papilla (on the posterior wall of the siphon) probably result from muscular action. With the exception of those variations, the zooids in the 3 available colonies of this species

have the same characters. However, the colonies are more variable. The compact colonies with rudimentary cloacal systems superficially look very different from the one with its upper surface divided into lobes and with cloacal depressions rather than cavities. Nevertheless, these seem to be differences of degree rather than definitive morphological differences.

The species demonstrates the close relationship between forms without, and others with, true cloacal systems. Despite the variations in the development of separate lobes, this species does not have the same capacity to respond to changes in prevailing currents as the stalked *Ritterella*.

The rudimentary cloacal system is a unique feature in this genus. It has not been observed in other *Ritterella* spp; although it parallels certain species of *Eudistoma* (e.g. *E. angolanum*, *E. carnosum*, *E. reginum*: see Kott 1990). The branchial sac with its branchial papillae and numerous rows of stigmata resembles that of *Ritterella cornuta* n.sp.

Ritterella cornuta n.sp.
(Fig. 6. Plate 2c)

DISTRIBUTION
TYPE LOCALITY: South Australia (Price I., coll. W.H. Sasse 9.4.87, holotype QM GH4176 *SAM E2098*).
FURTHER RECORDS:None.

DESCRIPTION
EXTERNAL APPEARANCE: The colony consists of narrow, sandy stalks about 2cm long and 0.4cm in diameter attached basally to branching stolons. Terminally they are divided into 2 or 3 flattened, fan-shaped expansions, and have 2 or 3 branches along their length. The terminal flattened part of each lobe has a median depression. This depression receives the atrial apertures of the zooids which are arranged in a row along each side of the depression. The branchial apertures are along the outside of the rounded rim along each side of the median depression. Sand forms a dense coat around the outside of the colony and there is some embedded in the internal test.

INTERNAL STRUCTURE: The zooids are about 1cm long. Thorax and abdomen together represent slightly more than half the length of the zooid. Each aperture has 6 pointed lobes. The branchial aperture is terminal, oriented slightly ventrally, and the atrial aperture, on a short siphon

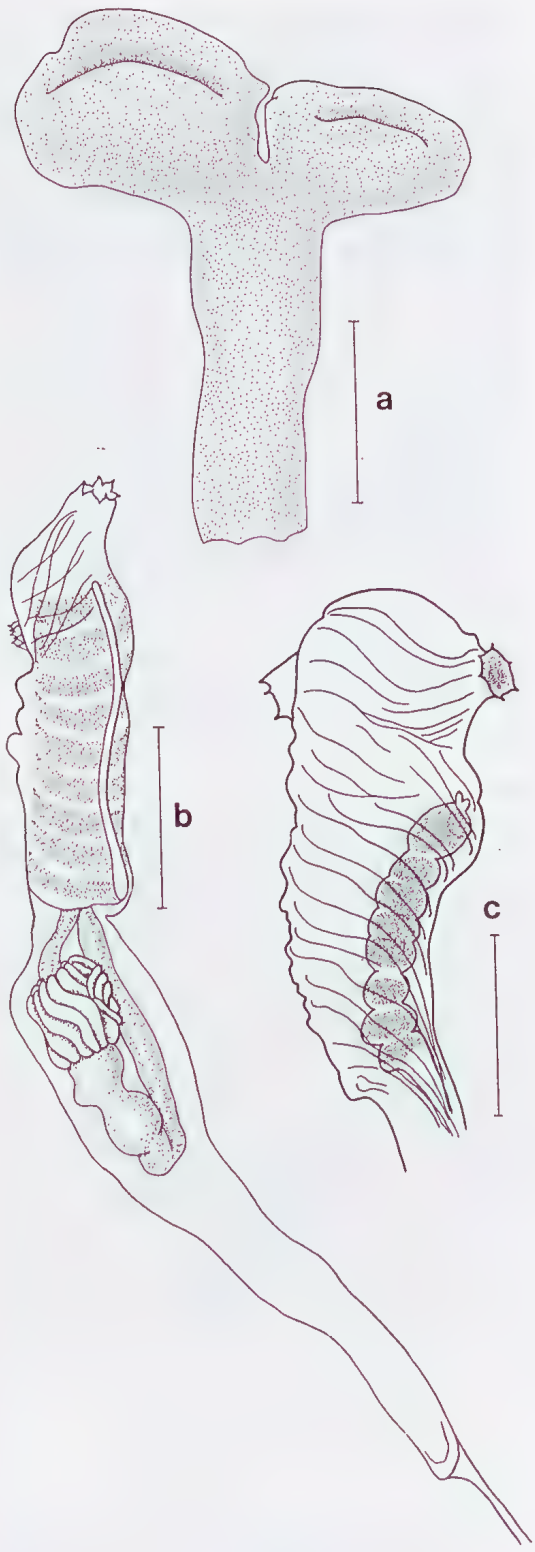

FIG. 6: *Ritterella cornuta* n.sp. (holotype QM GH4176) — **a**, part of colony; **b**, zooid; **c**, thorax. Scales: **a**, 5mm; **b**, **c**, 1mm.

directed at right angles to the long axis of the zooid, is about one quarter of the thorax length along the dorsal surface.

The body musculature is longitudinal and oblique, although in the examined zooids most bands extend transversely across each side to the dorsal surface before running the length of the zooid. About 5 bands are from the branchial siphon and a further 12 are from the endostyle. The muscles extend onto the abdomen and posterior abdomen from each side of the dorsal mid-line of the thorax. Stigmata are arranged in 9 rows of about 15 to 20. About 2 rounded papillae to every 3 stigmata are on the transverse vessels. There are no parastigmatic vessels.

The abdomen is relatively short, the stomach about halfway down, with about 6 indistinct oblique folds on the parietal surface, but with irregular creases on the side facing the ascending limb. A short duodenum and mid-intestine are in the descending limb distal to the stomach. The rectum extends about halfway up the thorax, terminating in a bilabiate anus. Gonads are not present in these specimens. The heart is present in the posterior end of the posterior abdomen.

Remarks

The species most closely resembles *Ritterella papillata* n.sp., which has similar although narrower colonies and forms rudimentary cloacal systems. The latter species has smaller zooids with only 5 rows of stigmata and is thus distinguished from the present species. The colonies of both resemble those of *R. pedunculata*, but the latter species lacks branchial papillae and has a bilaterally symmetrical concavity at one side, rather than a radially symmetrical one on the free end of the lobe surrounded by zooids, as it is in the present species and *R. papillata* n.sp. Nevertheless, these concavities in *R. cornuta*, *R. papillata* n.sp. and *R. pedunculata* all serve to concentrate the excurrent streams of water and separate them from the incurrent streams. *Ritterella asymmetrica* is different, the atrial openings being around the convex side of the terminal expansion (see *Condominium areolatum*, above).

(Fig. 7. Plate 2d)

Ritterella dispar Kott, 1957, p. 102; 1963, p. 78. Monniot and Monniot, 1976, p. 360.
Ritterella proliferus: Kott, 1972c, p. 245; 1981, p. 157 (part, specimen from Lord Howe I.).

Distribution

New Records: Queensland (Moreton I., QM GH4940; Noosa, QM G4969; Capricorn Group, QM G9468 GH881 GH4941–4 GH4947–8 GH4950–1).
Previously Recorded: New South Wales (Arrawarra QM GH5588). Queensland (Caloundra — AM U3897 Kott 1957; Currumbin — Kott 1963; Moreton Bay, Hervey Bay, Noosa Heads; Sarina — AM Y1116 Kott 1963). Lord Howe I. (QM G12001 Kott 1981). West Indian Ocean (Mauritius — Monniot and Monniot 1976).

The species is very common in the intertidal region on the mid-eastern coast of Australia and the southern part of the Great Barrier Reef. It has not been taken from the western Pacific — reexamination of the specimen from Fiji, which Kott (1981 QM GH102) assigned to *R. proliferus*, has shown it to be an *Aplidium* sp.

Description

External Appearance: Small flat-topped sessile cushions, sometimes lobed, and round to polygonal in outline, form mosaics on hard substrates. They are attached by the centre of the flat basal surface. The relatively thick, but fairly short evenly spaced zooids open on the flat upper surface. Colonies are one or 2cm in maximum extent, and never more than 1cm thick. When expanded, the crowded colonies appear to be continuous with one another, but when either contracted or preserved they are seen to be separate. In life they are a flesh colour, with white zooids showing through, or 'ochraceous buff' (Ridgeway 1886) with iridescent blue zooids.

Internal Structure: Zooids are relatively short (about 5mm) but quite thick, with a short posterior abdomen, and a wide thorax. Apertures are both anterior, each surrounded with 6 pronounced lobes. The lobes of the atrial aperture are particularly long, petal-like, and sometimes divided into 2, although those of the branchial aperture are shorter and triangular. Sphincter muscles are present around the base of each siphon. About 15 fine, parallel longitudinal muscles are on the thorax, and extend along the ventral side of the abdomen and posterior abdomen. Transverse muscles were not detected. There are 5 rows of 16 stigmata. Neither parastigmatic vessels nor branchial papillae are present. The oesophagus is short, and the stomach broad, with 15 parallel longitudinal folds. There is a broad duodenal region. An oval posterior stomach is in the bend of the gut loop. It is separated from duodenum and rectum by narrow mid-intestinal constrictions. A rectal valve is at the base of

the ascending limb. Both gonoducts and anus open in the anterior part of the atrial cavity, near the base of the atrial siphon. The anal border is bilabiate. Gonads are in the short, stumpy posterior abdomen, the testis follicles in a more or less spherical clump, surrounding the ovary.

Specimens taken in May and August from the Capricorn Group (QM GH4941 GH4947) and in May from Noosa (QM GH4969) contained embryos. Embryos were not present in specimens taken from the Capricorn Group in February and April.

Each zooid contains one (QM GH4969) to 3 (QM GH4947) embryos or infertile eggs serially arranged in the distal (thoracic) part of the oviduct. Only the most anterior egg appears to mature to a tailed larva, and it is possible that the other eggs may be infertile. In specimens from Noosa (QM GH4969) there is a single tailed larvae in the distal end of the oviduct with what appears to be an infertile egg just behind it.

In one colony, the larval trunk varies in length from 0.6 to 0.8mm. It has the tail wound three-quarters of the way around it. The 3 median adhesive organs have wide shallow cones of secretory cells, and narrow stalks. Seven to 9 large epidermal vesicles in a row on each side are scattered around the adhesive organs as the larva matures. An ocellus and an otolith are in the cerebral vesicle.

Remarks

These elegant transparent cushion-like colonies with independently opening zooids are significantly different from the colonies of other *Ritterella* spp. recorded from Australia, with their narrow sandy stalks and zooids arranged in colonial systems. There also are differences in the zooids, those of the present species being similar

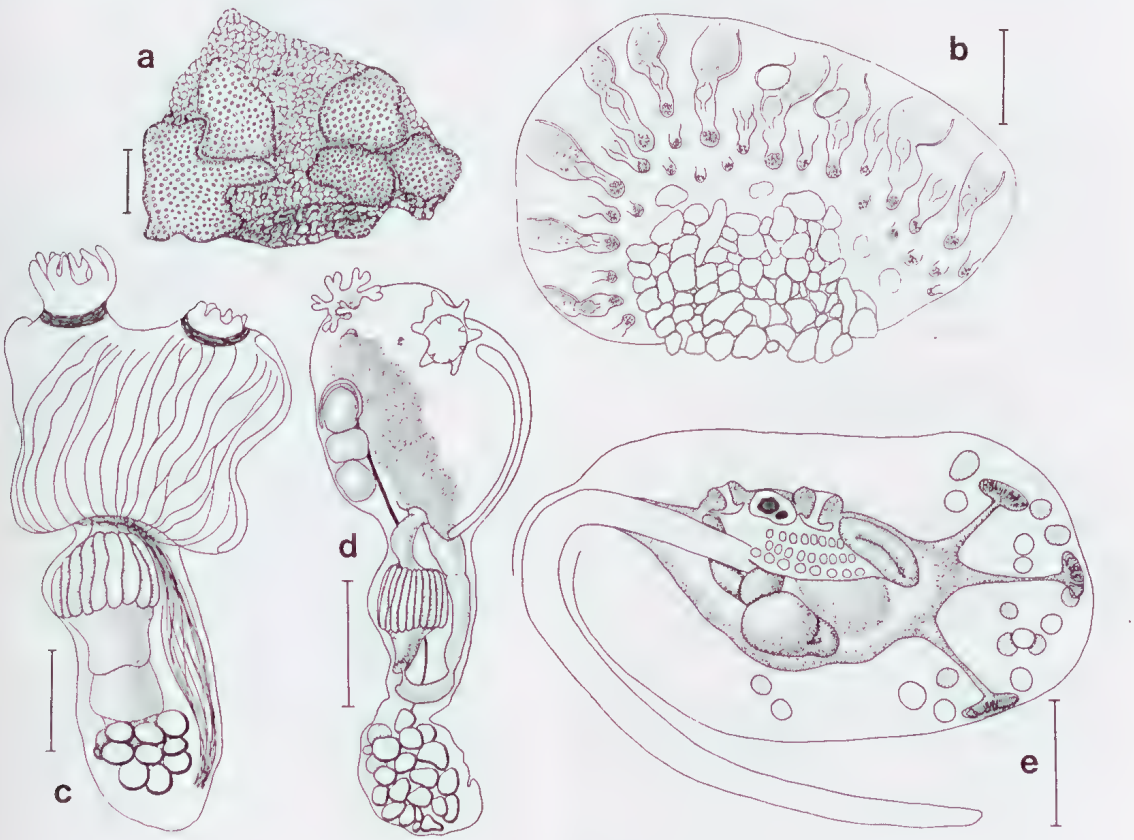

FIG. 7: *Ritterella dispar* — **a**, colonies viewed from above (QM GH4969); **b**, zooids seen in margin of colony viewed from below (QM GH4951); **c**, **d**, zooids (**c**, QM GH4951; **d**, QM GH4943); **e**, larva (holotype AM U3897). Scales: **a**, 1cm; **b**, 2mm; **c**, **d** 1.0mm; **e**, 0.2mm.

to others of the *aequisiphonalis* group, while zooids of other Australian species belong to the *pedunculata* group.

The relationship between *R. prolifera* (Oka, 1933) from Japan (see Tokioka 1953, Nishikawa and Tokioka 1976) and the present species is also very close, the only difference detected being the 6 rows of stigmata in the Japanese species as against 5 in *R. dispar*. Both species have deep, petal-shaped and sometimes bifid atrial lips, fine longitudinal body muscles, a short stomach with parallel folds, short posterior abdomen with bunched male follicles, up to 3 eggs in the distal end of the oviduct, and an identical larval trunk with a row of large, spherical ampullary vesicles each side of the adhesive organs, but no ectodermal ampullae. The colonies also are very similar, *R. prolifera* having the same flat, cushion-like, whitish, iridescent colonies that form mosaics on hard substrate and weed. On the basis of these similarities, Kott (1969, 1972d) proposed the synonymy of *R. dispar* and *R. prolifera*. They are presented here as separate species solely on the basis of the difference in the number of rows of stigmata.

The lack of continuity in the geographic range of the present species, with populations in Mauritius (Monniot and Monniot 1976) and on the sub-tropical coast of eastern Australia, is puzzling. There are no records from further north than Mackay, despite the fact that the species is common on the central coast. It is probable that the West Indian Ocean populations are isolated from the Australian ones.

Ritterella multistigmata n.sp.
(Fig. 8. Plate 2e)

DISTRIBUTION

TYPE LOCALITY: Western Australia (Sisters Reef, Murray Reef Warnbro Sound near Rockingham, 46°21.3S 115°41.3E, coll. AIMS Bioactivity Group 22.3.89, holoytpe QM GH5463).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The holotype colony is a large one, consisting of long (to 7cm), narrow (to 4mm diameter) sandy stalks, branched up to 3

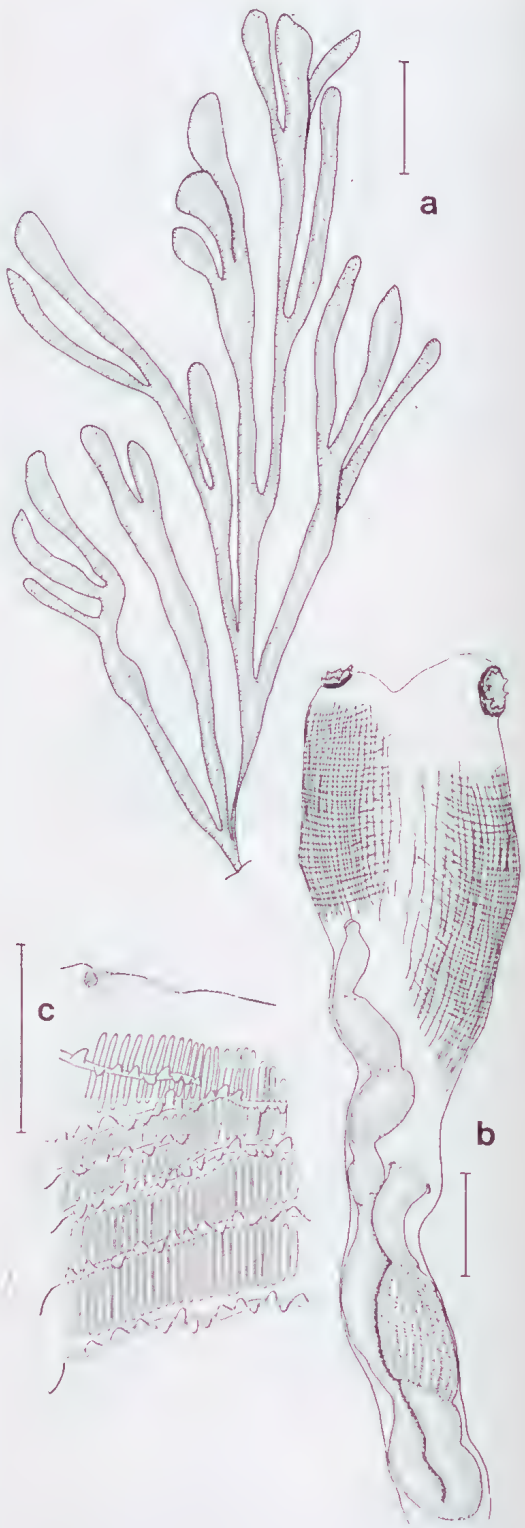

FIG. 8: *Ritterella multistigmata* n.sp. (holotype QM GH5463) — **a**, part of colony; **b**, thorax and abdomen; **c**, portion of branchial sac showing the neural gland and its opening, transverse and parastigmatic vessels, dorsal languets, and branchial papillae. Scales: **a**, 1cm; **b**, 1mm; **c**, 0.5mm.

times along their length. The terminal free ends are slightly expanded club-, or spoon- or fan-shaped. Each contains one to 3 zooids. Sand is crowded on the outer surface and is embedded in the surface layer of test making it brittle. However there is no sand internally, where zooids are in narrow longitudinal compartments in the transparent but tough test.

The long branching stalks of the colony are parallel to one another, and are crowded together to form compact masses.

INTERNAL STRUCTURE: Zooids are long and delicate, extending from the free end of a terminal lobe to the base of the colony. Most of that length is the narrow, thread-like posterior abdomen. The thorax and abdomen are together about 9mm long, with the abdomen about two-thirds the length of the thorax. The branchial aperture is turned ventrally, and the atrial aperture is directed anteriorly. Each of the apertures has 6 small points around the rim.

The thoracic body wall has an open meshwork of fine longitudinal and transverse muscle bands. Only the longitudinal bands extend to the posterior end of the zooid. The branchial sac has 10 rows of long, narrow stigmata each row crossed by a sturdy parastigmatic vessel which appears to be further subdividing the row of stigmata. Each transverse and parastigmatic vessel has about 12 large conspicuous rounded papillae evenly spaced along it. There are large triangular dorsal languets on parastigmatic as well as on primary transverse vessels. About 35 stigmata per row are in the rows about halfway down the pharynx, but fewer anteriorly, and even fewer posteriorly. Sixteen stigmata are in the most posterior row.

The long, oval stomach is halfway down the abdomen. The stomach wall is smooth externally but has fine longitudinal ridges internally. The post-pyloric part of the gut is wide, and has no marked divisions. The bilabiate anus opens about halfway up the branchial sac.

Gonads are not developed in this specimen.

REMARKS

Although they seem to branch more, the sandy stalks of this species with their asymmetrical tips most resemble those of *Ritterella pedunculata* and *R. asymmetrica*. Other *Ritterella* spp. have similar sandy stalks but radially symmetrical tips. Nevertheless *Ritterella cornuta* and *R. papillata* n.sp. are the only other stalked species that have numerous branchial papillae on the transverse vessels. However, both species lack parastigmatic vessels, *R. papillata* n.sp. has only 5 rows of stigmata, and although *R. cornuta* has a similar number of rows of stigmata (9) to the present species, it has a folded stomach wall rather than internal ridges. *Ritterella compacta* also has numerous rows of stigmata and branchial papillae, stomach folds, an atrial siphon with a long anterior lip adapted for circular colonial systems, and a compact colony, but it lacks parastigmatic vessels.

The unique characters of the present species are its branchial papillae, parastigmatic vessels, internally ridged stomach, and fine meshwork of longitudinal and transverse muscles on the thorax.

Ritterella papillata n.sp.
(Fig. 9)

DISTRIBUTION

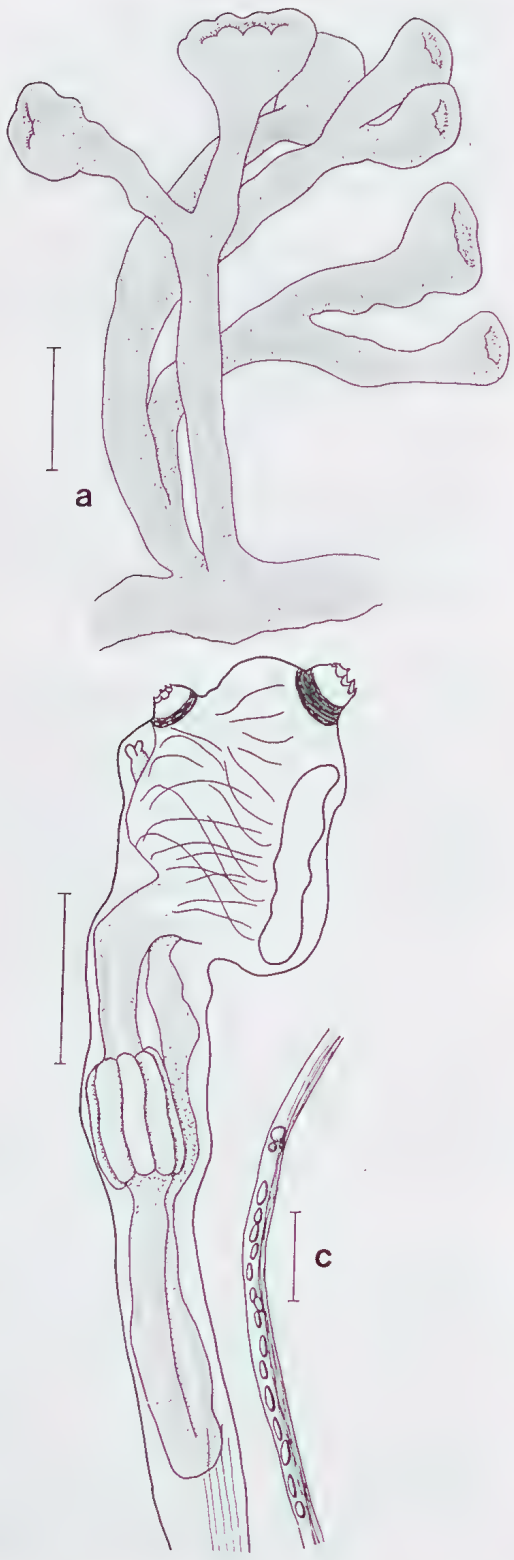
TYPE LOCALITY: South Australia (Price I., coll. W.H. Sasse 9.4.87, holotype QM GH4148 *SAM E2097*; Taylor I., coll. W.H. Sasse 6.4.87, paratype QM GH4217).
FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colonies consist of a tangle of narrow, sandy stalks up to 5cm long, with a terminal inverted conical expansion, concave on the free end. The atrial apertures open around the inside of the terminal concavity and the branchial apertures are in a single circle around the outside of its rounded margin. The sandy test is sometimes raised in rounded swellings over the anterior end of each zooid. Up to 10 zooids are in each lobe. The terminal concavities often are turned to the side, presumably facing away from the oncoming current, which, as it passes the colony, probably entrains the excurrent stream of water (see Kott 1989).

INTERNAL STRUCTURE: Zooids are long and thread-like, with a long posterior abdomen that is up to 3cm long — many times the length of the thorax and abdomen together (about 2mm). There are black pigment cells scattered in the body wall. Each aperture has 6 small sharply pointed lobes. The branchial aperture is terminal, turned slightly ventrally. The atrial aperture is about one-third of the distance down the dorsal surface of the thorax. About 20 thoracic muscles are oblique (from the branchial siphon to the dorsal surface) and transverse (from the ventral mid-line), joining into bands along each side of the abdomen and posterior abdomen.

In the branchial sac about 15 stigmata are present in each of 5 rows. The transverse vessels have flat, rounded papillae, containing dark black



pigment, about one to each stigma, along their edge. There are no parastigmatic vessels. The short stomach lies halfway down the abdomen. It has 6 broad but faint, oblique, parallel folds on the parietal wall, but its mesial wall is smooth. The bilabiate anus is halfway up the branchial sac. The gonads are in the posterior half of the posterior abdomen the small (about 3-egg) ovary anterior to a single longitudinal series of male follicles. In the type specimens, there are 4 or 5 embryos in the atrial cavity, but these do not include tailed larvae.

REMARKS

Although the colonies of *R. cornuta* are similar, those of the present species are narrower, and the terminal expansion is less flattened and not so wide. The zooids of the present species are smaller, with fewer rows of stigmata but much longer posterior abdomina. The accumulations of black pigment in the branchial papillae are not present in *R. cornuta*. *Ritterella pedunculata* and *R. asymmetrica* differ in not having branchial papillae. The terminal depressions containing the atrial openings are homologous with those of *R. cornuta* (see *R. cornuta* n.sp. REMARKS) and *R. compacta* n.sp. They are also radially symmetrical like those of *R. cornuta*, not bilaterally symmetrical like *R. pedunculata*.

New South Wales (Port Hacking, AM Y2170; North Solitary I., QM G9642; Arrawarra, QM GH5393).

FIG. 9: *Ritterella papillata* n.sp. (holotype QM GH4148) — **a**, part of colony; **b**, thorax and abdomen; **c**, part of posterior abdomen with gonads. Scales: **a**, 5mm; **b**, 0.5mm; **c**, 2mm.

PREVIOUSLY RECORDED: South Australia (Great Australian Bight — SAM E2105–10 QM G9292 Kott 1972b, 1975; St. Vincent Gulf — SAM E2450 Kott 1972a). New South Wales (Port Hacking, Newport — AM U3862 U4017 Y821 Y1131 Y2170 Kott 1957, 1963; Port Jackson — Herdman 1899).

Specimens are from depths to 12m, often in fast-flowing currents. The species is very common in Port Phillip Bay.

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are sometimes very large tangles of thin, sandy, branching stalks, one to 6cm long, attached to

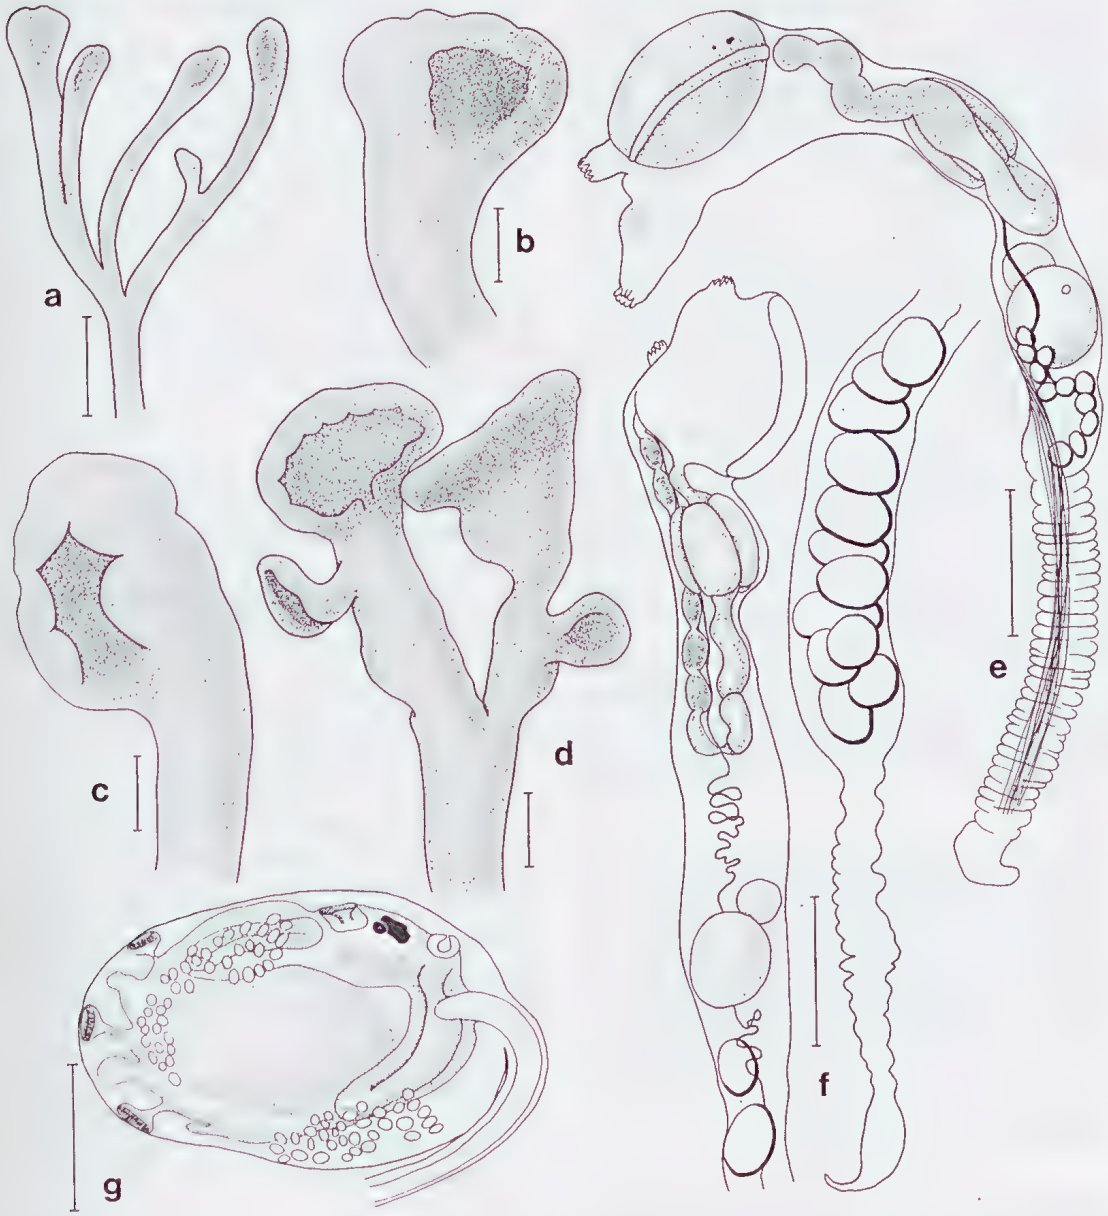

FIG. 10: *Ritterella pedunculata* — **a–d**, parts of colony and separate lobes (**a–c**, QM G9292; **d**, MV F57794); **e**, **f**, zooids (**e**, F57793; **f**, MV F57794); **g**, larva (MV F57793). Scales: **a**, 5mm; **b**, **c**, 1mm; **d**, 2mm; **e**, **f**, 0.5mm; **g**, 0.2mm.

basal stolons, and with flattened spatulate to fan-shaped tips which sometimes curve around to form a cornet, interrupted at one side. Up to 12 zooids are present in each lobe although usually there are fewer. The atrial openings are around the inside rim of the terminal, curved lamella and the branchial apertures around the outside of its rounded rim. Sand is thick externally but absent internally. Despite their outer layer of sand, collector's notes record specimens from St. Vincent Gulf (SAM E2450) to have been bright red.

INTERNAL STRUCTURE: The zooids are thread-like, the thorax and abdomen together up to 5mm long and with a much longer posterior abdomen. The apertures are almost sessile on short siphons, the rim of each with 8 small triangular lobes. Some fine circular muscle bands are on the thorax and the siphons. The longitudinal bands are delicate and extend the length of the zooid. There are 5 rows of about 12 stigmata. Neither parastigmatic vessels nor branchial papillae are present. Triangular dorsal languets are present over the dorsal sinus, on the transverse vessels.

The gut loop is slightly longer than the thorax, the oesophagus is short and the small stomach, smooth when distended but with 5 folds when collapsed, is not quite halfway down the abdomen. There is a distinct duodenal region and a posterior stomach in the descending limb of the gut loop. A rectal gland is at the junction of the mid-intestine and rectum.

The testis follicles are almost cylindrical, oriented longitudinally, and in a single series. When the posterior abdomen is contracted the male follicles are slightly bunched together. The small ovary is anterior to the testis, just behind the gut loop.

Up to 2 embryos, some developed to tailed larvae, are in the atrial cavity of specimens collected in February from Bruny I. (Tasmania) and Elliston Bay (S. Australia), in July from Portland (Victoria), and November (St. Vincent Gulf). The larval trunk is 0.6mm long. Single median ectodermal ampullae alternate with the adhesive organs. Ampullary vesicles are in bilateral clumps, about 3 deep postero-ventrally, antero-dorsally and around the anterior end of the trunk. Both otolith and ocellus are present.

REMARKS

Colonies from Green Pools (AM U3896, see below) assigned to this species by Kott (1957) are specimens of *Dumus*, having single zooids in each lobe, and 4 rows of stigmata.

Superficially, colonies of *R. pedunculata* resemble *R. cornuta*, *R. papillata*, and *R. asymmetrica* as well as *Monniotus* spp. and *Dumus* spp. However *Dumus* and *Monniotus* are distinguished by having only one zooid in each lobe; and the other *Ritterella* spp. have differently organised colonial systems, the shapes of the terminal free ends of each lobe being different (see *R. cornuta*, REMARKS). *Ritterella pedunculata* can also be distinguished from other *Ritterella* spp. by details of the branchial sac — from *R. asymmetrica* and *R. cornuta* by the 5 simple rows of stigmata, and from the latter and *R. papillata* by the absence of branchial papillae.

The specimens with both parastigmatic vessels and a branchial papillae on each transverse vessel reported from St. Vincent Gulf by Kott (1972a) are juveniles of *Monniotus australis*. There are neither branchial papillae nor parastigmatic vessels in *R. pedunculata*. Larvae from Elliston Bay (Kott 1975, Fig. 1) have a larval trunk 0.6mm long as do the newly recorded larvae from Bruny I. (MV F57793).

Genus **Dumus** Brewin, 1952

Type species: *Dumus areniferus* Brewin, 1952.

Only 2 species are known. Colonies are narrow, sandy, branched vertical lobes, the terminal branch containing only a single zooid, with 4 rows of stigmata, and a smooth or mulberry-like (but never folded) stomach wall. Possibly associated with the reduction in size of the branchial sac, there are no branchial papillae. Parastigmatic vessels sometimes are present. Testis follicles are in a single longitudinal series, relatively numerous eggs (to about 10) are present in the ovary and up to 12 embryos at a time are incubated in the atrial cavity. Many species of *Ritterella* (e.g. *R. pedunculata*) have similar colonies but otherwise are separated from *Dumus* by their more numerous rows of branchial stigmata, embedded zooids and longitudinal stomach ridges.

Nevertheless, the relatively large numbers of eggs in the ovary and the number of embryos incubated in *Dumus* suggest a more primitive condition than in *Ritterella* (in which not more than 3 embryos at a time are incubated in the atrial cavity).

The only species known are the type from New Zealand and temperate Australian waters, its northern limit in Moreton Bay), and *Dumus dumosus* (Monniot, 1987) from New Caledonia, a species originally assigned to the genus *Euherd-*

mania. It has neither the long oesophagus nor the folded stomach wall, nor the characteristic larval adhesive organs of *Euherdmania*. Its colonies are similar to those of *D. areniferus*, from which it differs in the presence of scattered circular swellings in the stomach wall and the parastigmatic vessels (as in *R. arenosa*, *R. asymmetrica*, *R. tokioka*, *R. yamazii*, and occasionally in *Condominium areolatum*, see above).

Dumus areniferus Brewin, 1952
(Fig. 11)

Dumus areniferus Brewin, 1952, p. 453. Kott, 1976, p. 58. Millar, 1982, p. 43.
Ritterella herdmania Kott, 1957, p. 102 (part, specimens from Green Pools).

DISTRIBUTION
NEW RECORDS: South Australia (Price I., QM GH4152). Victoria (Portland, QM GH92). New South Wales (South Ulladulla, QM G8585). Queensland (Moreton Bay QM G12725 GH3901 GH3903 GH4247).
PREVIOUSLY RECORDED: Western Australia (Green Pools — AM U3896). Victoria (Westernport — MV H286 QM G7509, AM Y1980 Kott 1976). New Zealand (Otago — Brewin 1952).

The range of this species, in Queensland and New Zealand, suggests a Gondwana component of the fauna.

DESCRIPTION
EXTERNAL APPEARANCE: Colonies are aggregations of long, narrow, sandy, branching vertical stalks up to 6cm long, joined to basal common stolons. The vertical stalks adhere to one another by the sand that covers them to form sandy platforms. The free ends of each terminal branch are expanded into a short bulb bent ventrally at right angles to the long axis of the stalk, onto which the zooids open. A single zooid is in each terminal branch of the colony. The branchial apertures face downwards from the front of the bulb and the atrial aperture upwards from the top. The thorax is slightly flattened dorso-ventrally. The stalks all taper slightly toward the base.

INTERNAL STRUCTURE: Zooids are up to 6mm long, and thread-like, at least half of the length being posterior abdomen. Six sharply pointed lobes surround each aperture. The body wall is muscular with 10 external longitudinal bands extending obliquely across the thorax from the branchial siphon to the postero-dorsal corner and then along the whole length of the zooid. From 10 to 16 stigmata are in each of 4 rows. Neither branchial papillae nor parastigmatic vessels are present. The smooth-walled almost cylindrical stomach occupies the middle third of the abdomen. The anal opening is halfway up the thorax. The ovary in the anterior part of the posterior abdomen has up to 10 eggs. Long and oval or, when compressed by contraction, circular to pear-shaped testis follicles are in a single series, although with contraction they tend to become bunched. Kott (1976) reported testis follicles confined to the posterior half of the posterior abdomen, but in the newly recorded specimens from South Australia and Queensland they occupy its whole length.

Up to 12 embryos are crowded in the atrial cavity of specimens collected in July (QM G8586) and August (QM GH3901 GH4247) from Moreton Bay, and November (AM Y3896 Y1980) from Green Pools and Westernport. The larval trunk is 0.4 to 0.5mm long. The 3 adhesive organs have narrow stalks and small, shallow cones of secretory cells. They alternate with median ampullae, each of which has a lateral ampulla near its base. On each side, there also are clumps of postero-ventral and antero-dorsal ampullary vesicles, the latter extending around the anterior end of the trunk, outside the lateral ampullae. The tail is wound about two-thirds of the way around the trunk. An otolith and ocellus are in the cerebral vesicle. The adhesive organs in this species are particularly small, and the robust ectodermal ampullae appear to be the most important structures at the anterior end of the trunk, and they have a cap of enlarged epidermal cells similar to those in *Polyclinum*.

REMARKS
The great geographic range of this species is not reflected in a variable morphology, for there is little variation, even between Australian and New Zealand populations. Although the larva is smaller, and lacks the lateral ampullae, it generally resembles the larva of *Ritterella pedunculata*.

Family EUHERDMANIIDAE Ritter, 1904
emend.

Zooids are either separate or embedded, with 6-lobed atrial openings directly to the surface. A long oesophagus opens into a small, longitudinally ridged stomach at the posterior end of the abdomen. The wide rows of stigmata (50 to 100 per row) vary in number from 5 to 20. Neither

parastigmatic vessels nor branchial papillae are present. The anus opens in the base of the atrial cavity. Gonads are bunched, in a relatively short abdomen. Fertilisation takes place at the proximal end of the oviduct and embryos are brooded in the oviduct. Larvae have long pycnoclavellid-type inverted tubular adhesive organs.

Usually longitudinal and oblique muscles from the branchial and atrial siphons cross the thoracic wall to join into a wide band along each side of the ventral border, and continue onto the abdomen and posterior abdomen in 2 wide bands. In *E. vitrea* Millar, 1961 a dorsal rather than ventral band of muscles is reported and in *E. morgani*

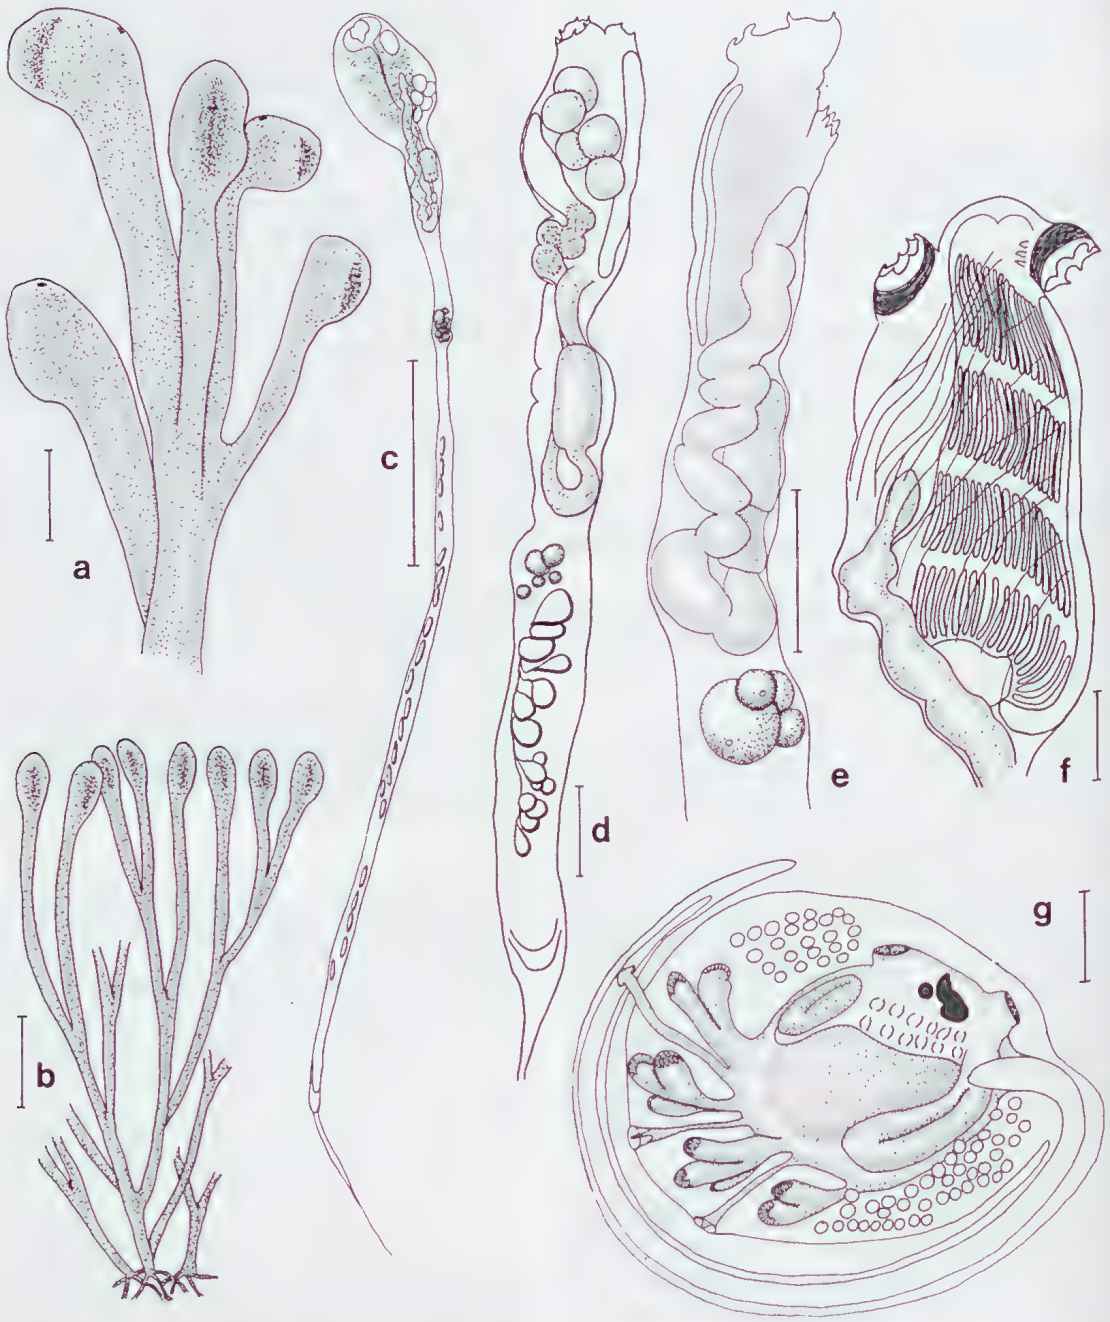

FIG. 11: *Dumus areniferus* — **a**, **b**, parts of colonies (**a**, QM GH4152; **b**, QM GH3901); **c–f**, zooids and parts of zooids (QM GH3901); **g**, larva (AM Y1980). Scales: **a**, 2mm; **b**, **c**, 5mm; **d–f**, 0.5mm; **g**, 0.1mm.

Millar and Goodbody, 1974 both ventral and dorsal bands are present. Transverse muscles have been reported only for *E. fasciculata* Monniot, 1983.

Pycnoclavellidae (see Kott 1990, p.66) have the same range in colony form as the present family, having zooids completely or partially embedded, or separate from one another for most of their length. Pycnoclavellidae also resemble the species of the present family in the position of the anal opening, the long oesophagus, fertilisation at the base of the oviduct and the same type of larval adhesive organs.

The principal characters distinguishing Euherdmaniidae from Pycnoclavellidae are the 6-lobed (rather than smooth) apertures, and the relatively large gonads sometimes located in a posterior abdomen (rather than in the gut loop). The relationship between the families seems to be closer than either has with other families.

Euherdmania is the only known genus of the family Euherdmaniidae.

When a posterior abdomen is not present (*Euherdmania dentatosiphonis*, *E. digitata* and *E. translucida* n.sp.), difficulties can arise in separating certain species of *Euherdmania* from *Polycitor*. Both have a long oesophagus and lobed apertures. The presence of larvae can resolve the difficulty as those of *Euherdmania* have long, inverted tubular (pycnoclavellid-type) adhesive organs. In the absence of larvae, reliance must be placed on the width of the thorax, position of the anal opening, and other details of the siphonal lobes to separate the genera.

Genus **Euherdmania** (Ritter, 1904)

Type species: *Euherdmania claviformis* (Ritter, 1903).

The genus is characterised by its separately opening zooids with long oesophagus and folded stomach wall.

In addition to the new species described below, the known species of *Euherdmania* are:

Euherdmania gigantea (Van Name, 1921) from Florida has embedded zooids and conspicuously serrated lobes around the apertures. Kott (1981) argued that the denticulate lobes of the apertures may indicate synonymy with *Stomozoa*. However, this is denied by the position of the gonads and the presence, in *E. gigantea*, of a series of embryos in the abdominal part of the oviduct (see Millar 1977) — as in *Euherdmania* but not in *Stomozoa*. The serrated lobes around the apertures probably occur in parallel in these taxa. Millar (1977) re-examined the holotype of *E. vitrea* Millar, 1961 from the Brazilian coast and thought that it may be conspecific with *E. gigantea*. A doubt remains, however, since the holotype zooids described (Millar 1961) have a dorsal rather than the ventral muscle bundle present in *E. gigantea*.

Euherdmania dentatosiphonis (Millar, 1975) from the western Pacific, was thought to be a synonym of *E. digitata* (see Kott 1981). However, it differs from *E. digitata* in having similar serrated lobes around the apertures to those in *E. gigantea*.

Euherdmania morgani Millar and Goodbody, 1974 differs from *E. gigantea* in its shallow and smooth (rather than serrated) oral and atrial lobes, its dorsal, as well as ventral, thoracic muscles, and zooids opening around a stalked, fan-shaped head rather than on top of a thick, sessile upright colony.

Euherdmania digitata Millar, 1963 from north-western Australia and the Western Pacific (Kott 1981, Tokioka 1967, Nishikawa 1984a) and southern Australia (see below) has separate zooids joined by basal stolons or common test. Occasionally its gonads are in the gut loop rather than in a posterior abdomen. It differs from *E. claviformis* in that the test is not sand-covered and the lobes of the colony are thicker. The larvae have the characteristic inverted tubular adhesive organs.

Euherdmania solida Millar, 1953 from the Gold Coast (Ghana) differs from *E. digitata* only in having partially embedded zooids. Its body musculature is like that of *E. digitata* and *E. vitrea*.

Euherdmania rodei Pérès, 1949 from the Gold Coast (Ghana) has fewer stomach folds than *E. solida* and completely embedded zooids.

Euherdmania claviformis (Ritter, 1903) from California has, like *Monniotus* spp. long, narrow, sandy lobes, each containing a single zooid, united basally. It is distinguished from zooids of the latter genus by the long oesophagus characteristic of *Euherdmania*. A related species from Senegal, *E. claviformis*: Pérès, 1949 has 15 to 16 rows of stigmata rather than 8 to 12 found in the Californian species. *Euherdmania claviformis*: Monniot, 1987 from New Caledonia with 18 rows of 40 stigmata is wrongly assigned (see *E. digitata* below).

Euherdmania fasciculata Monniot, 1983 from Guadaloupe has long, narrow branching stalks with the thoraces, at least, separate from one another. Sand is present only on the base of the colony. Longitudinal and transverse muscles form a meshwork and the

longitudinal ones go to the end of the posterior abdomen. There are 12 to 17 rows of up to 30 stigmata. The anterior row of stigmata curves anteriorly along dorsal line. The anus opens at the second-last row of stigmata. The oesophagus is long, and the stomach is in the posterior end of the long abdomen. The species is separated from *E. claviformis* by its more numerous stomach folds (10 rather than 6), and its naked test.

Euherdmania areolata Millar, 1978 from the western Atlantic (Guyana shelf), has long, narrow, sandy lobes, each of the terminal branches containing a single zooid. These colonies resemble *E. claviformis* but they have more branches. The stomach has internal folds which are not obvious externally and distinguish the species from *E. claviformis* and *E. fasciculata*.

Thus, there appear to be 3 groups of species in *Euherdmania*, viz.:

a.*Gigantea* group with separate or embedded zooids, and pronounced serrations on siphonal lobes (*E. gigantea*, *E. dentatosiphonis*, *E. translucida* n.sp. and possibly *E. vitrea*).

b.*Digitata* group with separate or embedded (partially or completely) zooids, gelatinous sand-free test, and shallow, smooth siphonal lobes (*E. digitata*, *E. solida*, *E. rodei*, and probably *E. morgani*). *Distoma pulchra* Ritter, 1901 (<*Sigillinaria pulchra*: Van Name, 1945) is a likely member of this group.

c.*Claviformis* group with separate zooids in long, narrow, sometimes sandy, sometimes branching stalks, and pronounced but not serrated siphonal lobes (*E. claviformis*, *E. areolata* and *E. fasciculata*). The colonies of this group of species resemble those of many Ritterellidae, and *Monniotus* spp.

Larvae are known for *E. vitrea* (see Millar, 1961), *E. claviformis* (see Trason 1957); *E. digitata* (see Millar 1963, Kott 1981 and below). The larvae of *E. gigantea*, *E. rodei*, *E. dentatosiphonis*, *E. translucida* n.sp., *E. areolata* and *E. solida* are not known.

Euherdmania australis Kott, 1963 is incorrectly assigned having a short oesophagus, branchial papillae on the transverse branchial vessels, parastigmatic vessels, a stomach wall areolated but not longitudinally ridged, and a polyclinid-like larva with ectodermal ampullae and vesicles, and stalked adhesive organs (see *Monniotus*). *Euherdmania dumosa* Monniot, 1987 is also incorrectly assigned (see *Dumus*).

Species of *Euherdmania* are known mainly from tropical oceans and generally they have relatively restricted ranges. *Euherdmania translucida* n.sp. from South Australia related to *E. dentatosiphonis*, and the eastern Pacific *E. claviformis* are the only records from temperate waters.

Key to species of *Euherdmania* recorded from Australia

1. Siphonal lobes serrated 2
   Siphonal lobes not serrated ..... *E. digitata*
2. Thoracic muscles not more than 3; colonial .... *E. dentatosiphonis*
   Thoracic muscles more than 3; solitary .... *E. translucida* n.sp.

Euherdmania dentatosiphonis (Millar, 1975) (Fig. 12)

Clavelina dentatosiphonis Millar, 1975, p. 211.

DISTRIBUTION

NEW RECORDS: None.

PREVIOUSLY RECORDED: Queensland (Coral Sea, Millar 1975).

The single small colony was taken at 100m.

DESCRIPTION (after Millar 1975)

EXTERNAL APPEARANCE: The single small colony consists of 4 narrow-stalked, club-shaped lobes attached to a basal stolon. Each lobe contains a single zooid, although in 2 they are degenerate or developing. The largest lobe is about 2cm high. The test is gelatinous and translucent, the thoracic part delicate and the stalk rather firm. The branchial aperture is terminal, but turned ventrally, and the atrial aperture is on the dorsal surface. Zooids are pink in preservative and can be seen through the test.

INTERNAL STRUCTURE: The larger zooid is 6mm when removed from the test. Each of the 6 lobes of each aperture is denticulate. The anterior lobe of the atrial aperture and the dorsal lobe of the branchial are broad. There is a half velum inside the 5 smaller lobes of each aperture which partly occludes the opening. The branchial tentacles, numbering about 45 are on the edge of a velum at the base of the branchial siphon. There are 3 wide oblique muscle bands on each side of the thorax, extending from the base of the atrial siphon to the postero-ventral corner of the thorax. These join into a single band running along the

ventral surface of the abdomen, one on each side of the mid-line. Millar (1975) found 16 rows of stigmata alternating with high transverse branchial vessels. Triangular, pointed dorsal languets are present on the dorsal sinus. The abdomen of Millar's specimen may have been mutilated, as there was no sign of either stomach or gonads, although there is an entire gut loop.

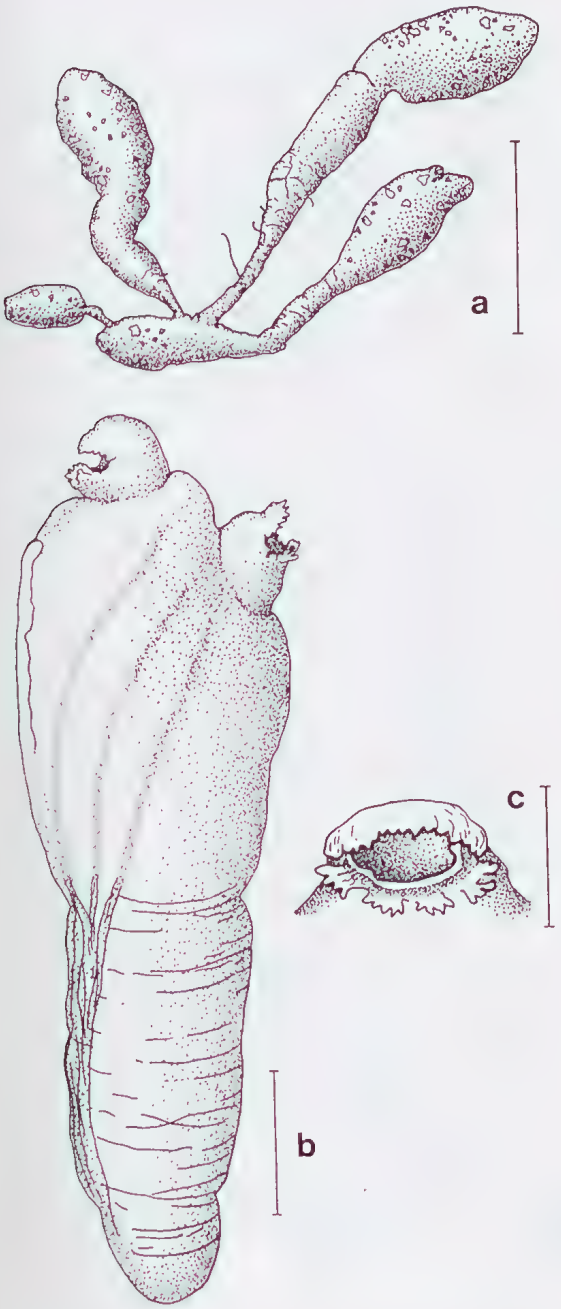

FIG. 12: *Euherdmania dentatosiphonis* (after Millar 1977) — **a**, part of colony; **b**, zooid contracted; **c**, lobes of branchial aperture. Scales: **a**, 1cm; **b**, **c**, 1mm.

REMARKS

Kott (1981) believed that this species was a junior synonym of *Euherdmania digitata* Millar, 1963, which is known from the Western Pacific (Tokioka 1967, Kott 1981), north western Australia (Millar 1963) and southern Australia (see below). However, as well as lacking the denticulate lobes of the present species, *E. digitata* differs in the arrangement of its body muscles, including the presence of transverse thoracic muscles. The present species has similar siphonal lobes to *Euherdmania translucida* n.sp. from southern Australia. However, *E. translucida* has a larger zooid, more numerous thoracic muscles, and a solitary habit, all of which distinguishes it from *E. dentatosiphonis*. Further, the different locations in which they have been found and the discontinuity in their ranges is a compelling argument in favour of separate species.

Euherdmania gigantea (Van Name, 1921), from the western Atlantic (see Millar, 1977), has similar denticulate lobes and half velum in the aperture. It differs from the present species mainly in the form of the colony with its embedded zooids, and its more numerous oblique thoracic muscles (joining the usual bands each side of the mid-ventral line).

Millar (1975) thought that the upper part of the corrugated tube in the abdomen of the type specimen of *E. dentatosiphonis* may be the stomach, and Kott (1981) thought that the presence of a stomach at more or less the same level in the abdomen of *Euherdmania digitata* confirmed Millar's view. However it seems more likely that the abdomen of the type of *E. dentatosiphonis* has been damaged, and that it will be found to have a longitudinally folded stomach in the posterior part of the abdomen, as in all known *Euherdmania* spp., including species such as *E. translucida* n.sp. and *E. gigantea* which have other characters in common.

DISTRIBUTION

NEW RECORDS: South Australia (Investigator Group, QM GH4920 GH4183). Queensland (Capricorn Group, QM GH2455 GH4919 GH4921–5; Lizard I., QM G9772 GH2442).

PREVIOUSLY RECORDED: Western Australia (Cape Boileau — Millar 1963). New Caledonia (Monniot 1987). Fiji (QM G12469–70 G12867–8 Kott 1981). Palau Is (Tokioka 1967). Ponape (Nishikawa 1984a). Moorea, Tahiti (Monniot and Monniot 1987).

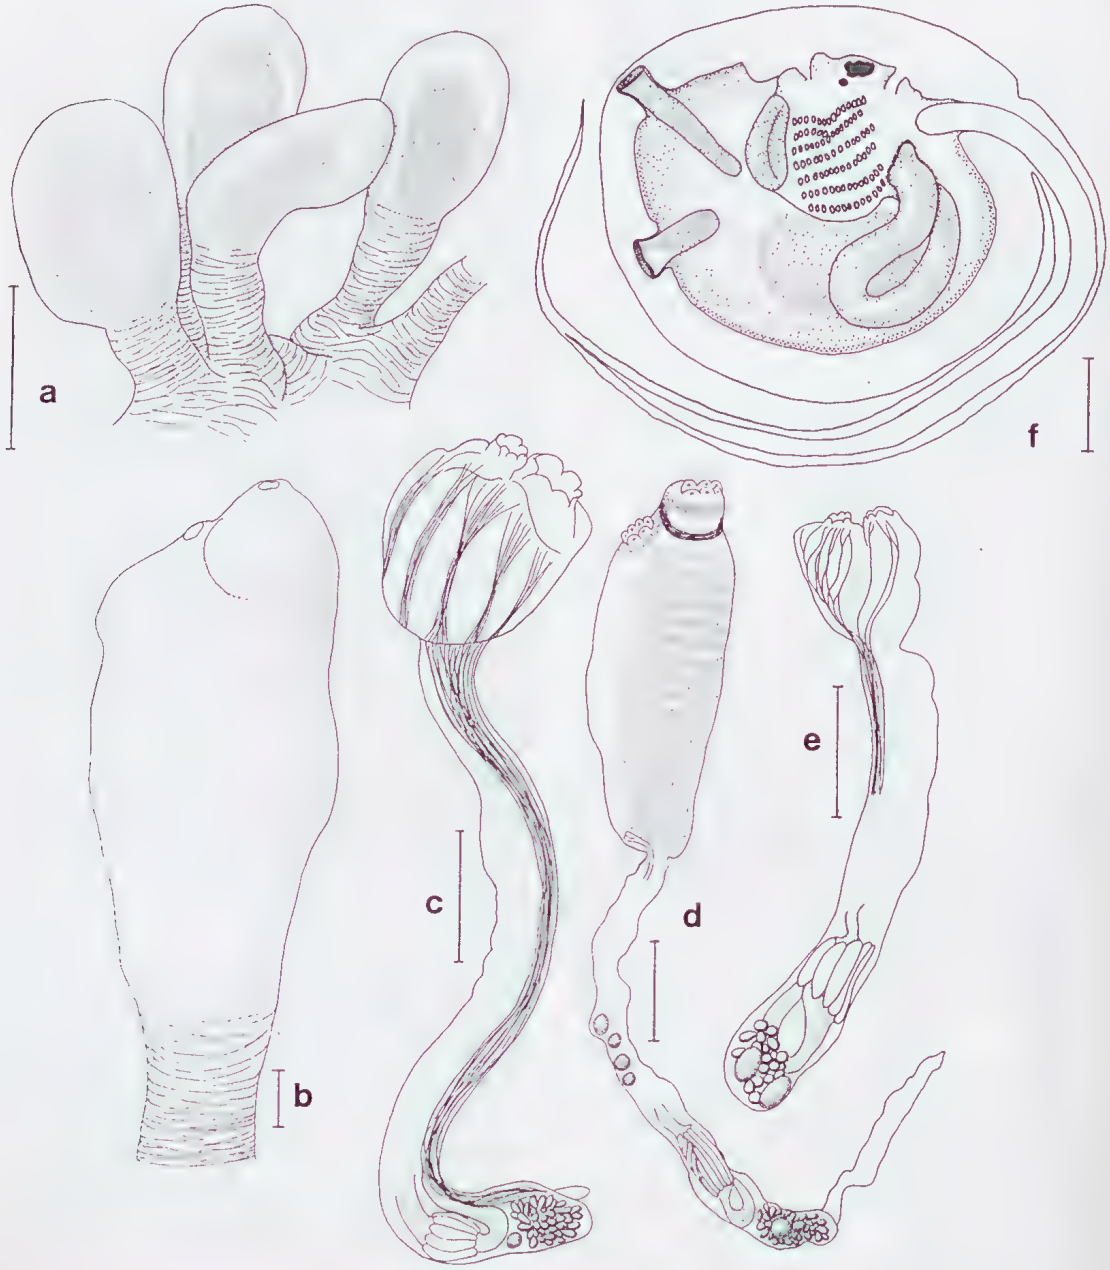

FIG. 13: *Euherdmania digitata* — **a**, part of colony (QM GH4920); **b**, single zooid in test (QM GH4183); **c–e**, zooids at various states of contraction (**c**, **d**, QM GH4920; **e**, QM GH4183); **f**, larva (QM G9772). Scales: **a**, 5mm; **b**, 1mm; **c–e**, 2mm; **f**, 0.2mm).

Description

EXTERNAL APPEARANCE: Colonies are up to 4cm in maximum extent, consisting of separate zooids up to 3cm high attached to a tangle of basal stolons or solid basal test. The lower one-third of each upright zooid is covered with very firm test, which becomes progressively softer and more transparent toward the upper (thoracic) part. The upright stalks sometimes branch along their length.

The thoracic test has a thickening each side of the terminal branchial aperture and another median one just postero-dorsal to the subterminal atrial opening.

The living specimens from the Capricorn Group are a clear, bright canary-yellow, and one of the zooids (from QM GH4925) had *Prochloron* symbionts evenly and densely distributed around, and in the lining of, the branchial siphon. Yellow pigment is especially dense in both siphon linings.

The rim of each of the apertures is divided into 6 shallow lobes, each lobe with a yellow (light sensitive ocellus?) pigment spot in the centre. The branchial aperture often is inclined ventrally, and the atrial aperture directed upwards.

INTERNAL STRUCTURE: Zooids are long (up to 3cm) and narrow. The thorax is about a quarter of the length of the abdomen. The posterior abdomen, only slightly shorter than the abdomen, terminates in several blunt vascular processes. Up to 20 fine parallel longitudinal thoracic muscles, which when contracted form 8 to 10 wide bands, cross the thorax obliquely from atrial and branchial apertures to the endostyle, and continue along each side of the mid-line on the abdomen and posterior abdomen in a pair of wide ventral bands. A layer of fine transverse muscles lies beneath the longitudinal muscles on the thorax. About 20 very slender branchial tentacles are in a circle at the base of the branchial siphon. About 16 to 18 rows of stigmata have approximately 50 to 60 stigmata per row in the anterior rows. Shorter rows with about 30 stigmata are at the posterior end of the branchial sac. Transverse vessels are broad, flat membranes projecting between the rows of stigmata. These expand into long, pointed dorsal languets over the dorsal sinus.

The gut loop is long and narrow, with a long oesophagus and a narrow stomach at the posterior end of the descending limb. The stomach wall has from 8 to 12 longitudinal irregular, or oblique and sometimes shallow folds. The anal opening has two smooth lips and opens in the base of the atrial cavity.

Gonads are in the anterior part of the posterior abdomen, just behind the stomach. They consist of a cluster of pyriform male follicles, surrounding 3 or 4 oocytes. In one of the specimens there are also orange eggs in the oviduct and in others a developmental series of embryos is in the oviduct from just distal to the stomach to the atrial cavity. Embryos are present in the oviduct in June from Lizard I. (QM G9772), but were not present in October at Heron I. Larvae have a long (1.0mm) trunk, with 2 long inverted tubular adhesive organs, an ocellus and an otolith. The tail is wound about halfway around the trunk. The postero-ventral part of the trunk is very yolky.

Remarks

The zooids and larvae of the north-western Australian (Millar 1963), and Palau Is (Tokioka 1967) specimens deviate from the present ones only to the extent that a lesser number of stigmata (15) was recorded for the Palau Is specimen. However, Tokioka was uncertain about the numbers he recorded and it is possible that he was misled by the narrow thorax.

Monniot (1987) assigned New Caledonian colonies (an unspecified number) to the indigenous Californian *E. claviformis*, which has fewer rows of stigmata and narrower thoraces. There is neither morphological nor geographic grounds for this assignation. Larvae are the same size as the other western Pacific specimens. It is presumed that the 2 adhesive organs recorded by Monniot are the usual inverted tubes characteristic of this genus.

Kott (1981) tried to establish a synonymy between the present species and *E. dentatosiphonis* Millar, 1975. She thought the denticulate siphonal lobes of *E. dentatosiphonis* were not essentially different from the smooth lobes of the Fijian specimens of *E. digitata*. However, comparison of the Fijian with the newly recorded Australian specimens shows them to be similar to one another, and distinct from *E. dentatosiphonis*. The larvae and embryos being incubated in the oviduct of Fijian and Australian specimens are also identical; and re-examination of the Fijian specimens has shown that although only 20 stigmata were recorded, at least twice that number is present.

Of concern to the interpretation of intrageneric phylogeny of these taxa is the variation in the position of the gonads, which are in the abdomen (in the Fijian specimens), or in a posterior abdo-

men. However, although the former have embryos in the oviduct, and tubular larval adhesive organs like *Pycnoclavella*, their siphonal lobes indicate that the specimens are members of the genus *Euherdmania*, and in view of their other characters, they appear to be specimens of *E. digitata*.

Variation in the number, orientation and depth of the stomach folds apparently is a characteristic of this species, Millar (1963) and Kott (1981) reporting 12 folds, Tokioka (1967) reporting 8, and Monniot (1987) 6 to 10 but mostly 8.

Euherdmania translucida n.sp.
(Fig. 14. Plate 3a)

DISTRIBUTION

TYPE LOCALITY: South Australia (Sir Joseph Banks Group, Marum I., N Point, offshore, in sand and root-mat of *Posidonia*, 8m, coll. W. Zeidler 11.1.84, holotype SAM E2092, paratype SAM E2056; Sir Joseph Banks Group, Reevesby I., NW Point 150–200m, coll. W. Zeidler, paratype SAM E2093).

FURTHER RECORDS: South Australia (Spencer Gulf, Banks and Investigator Groups, QM GH2310, SAM E2091; Yorke Peninsula, SAM E2455; Kangaroo I., SAM E2529).

DESCRIPTION

EXTERNAL APPEARANCE: Individuals are solitary, up to 4cm high. They have hard, long, narrow stalks with basal branching root-like extensions. Only 3 specimens (SAM E2056 E2092 E2455) are complete. The others have been cut off across the long oesphageal neck and the posterior end of the abdomen is missing. The base of the stalks of the holotype and one paratype (SAM E2056) expand into a holdfast amongst the *Posidonia* root mat. The firm stalk has whitish, translucent test internally, and is leathery externally. The terminal expanded balloon-shaped thoracic part, occupying about one-fifth of the total length, has thick, soft, and glassy test containing spherical test cells which are crowded together forming spots about 0.5mm apart. The branchial aperture is terminal and the atrial aperture subterminal. Each aperture is surrounded by 6 large, rounded petal-like lobes.

Photographs of living specimens show them to have very transparent thoraces, with bright spots which may be light sensitive at the tips of the siphonal lobes.

INTERNAL STRUCTURE: The zooid occupies the whole length of the stalk, with only a fine blood vessel extending into the basal holdfast.

Each aperture is surrounded by 6 flat lobes. A crescent-shaped half velum is around the ventral side of the lumen of the branchial aperture, and another is inside the dorsal side of the atrial aperture. The adjacent lobes of the respective apertures, viz., the dorsal lobe of the branchial and the ventral (or anterior) lobe of the atrial aperture are especially wide, each containing parallel longitudinal muscles and fringed with about 12 pointed tongues. The inner faces of these 2 large, fringed lobes are continuous with the lining of the pharyngeal and atrial cavities respectively. Continuity between the linings of these cavities and the inside surfaces of the slightly smaller lateral lobes (fringed with 6 to 8 points) on each side of the large median lobes is interrupted by the ends of the crescent-shaped vela. Outside the widest part of the vela, the tip of the opposite median and lateral lobes are divided into one or 2 long points.

A sphincter muscle in each velum seems to derive its fibres from the longitudinal thoracic muscles. Seen in section, the velum appears to be a fold of the body wall at the base of the siphons. The branchial velum in particular projects from just in front of the branchial tentacles, and its sphincter muscle may be homologous with that usually found beneath the tentacles. There are 12 strong longitudinal thoracic muscles, viz. 4 branchial contributing fibres to the branchial velum, 3 dorsal contributing fibres to the 2 large median siphonal lobes, and 3 atrial contributing fibres to the atrial velum. These muscles extend obliquely toward the postero-ventral corner of the thorax, and join into a wide band on each side of the long oesophageal neck, terminating at the posterior end of the abdomen. Transverse muscles were not detected.

About 40 relatively long, slender branchial tentacles are of various sizes. The dorsal gland is large, and a fleshy dorsal tubercle has a vertical opening in a V-shaped peritubercular area that projects into the pharynx so that the opening of the neural duct is directed forwards, toward the branchial aperture. There are 20 long rows of relatively short stigmata, with 100 or more stigmata in the anterior rows, although the rows become shorter posteriorly. The transverse vessels between the rows of stigmata are very wide, flat membranes. Over the dorsal sinus these expand into triangular languets with long points that coil over to the right side. Neither parastigmatic vessels, nor papillae are on the transverse vessels.

The oesophageal neck is long and straight, and the abdomen swells into an onion-shaped bulb

only at the posterior end. Both the oesophagus and rectum are transversely wrinkled. In the only 2 specimens with a complete abdomen, the stomach, and other parts of the gut loop, have very thin walls and are packed with trophocyte cells. The abdomen appears to be degenerating and possibly the body organs are being resorbed. The stomach is almost cylindrical with about 6 longitudinal folds. There is no apparent posterior abdomen. The pole of the gut loop curves around in the posterior end of the abdomen. The anal opening is at the posterior end of the atrial cavity. There were no gonads detected in these specimens; nor were larvae present.

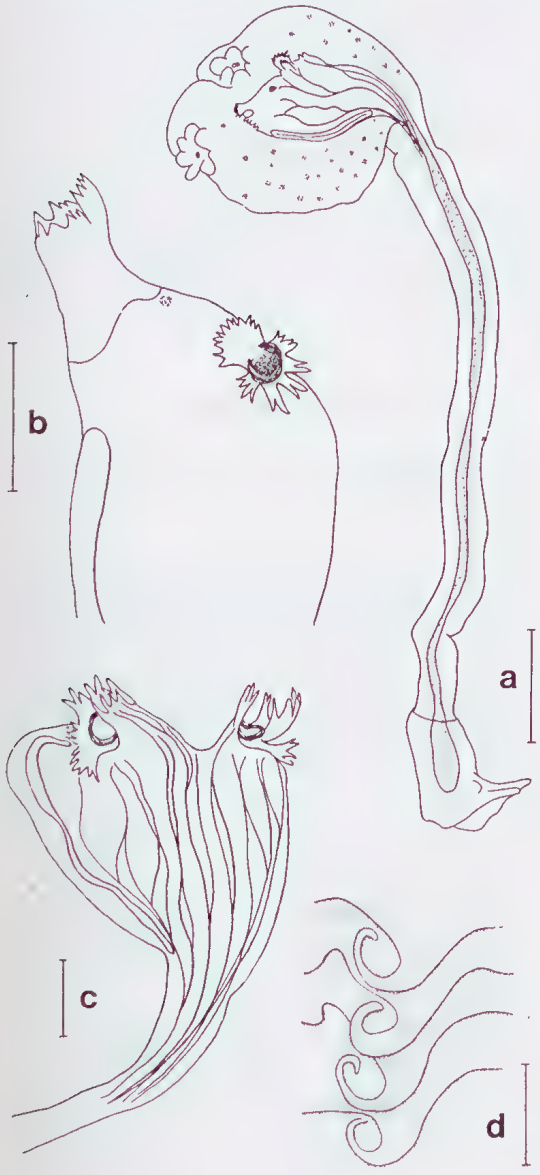

FIG. 14: *Euherdmania translucida* n.sp. — **a**, zooid in test (holotype SAM E2092); **b**, **c**, thoraces showing lobes of apertures and muscles (SAM E2093 E2091); **d**, part of dorsal lamina (SAM E2091). Scales: **a**, 5mm; **b**, **c**, 2mm; **d**, 0.5mm.

REMARKS

A number of characters can cause confusion in identifying this species. There are certain solitary *Clavelina* (e.g. *C. meridionalis*, *C. ostrearium*, *C. dagysa*) that superficially resemble the solitary individuals of *E. translucida*, but they have a characteristically conspicuous vascular stolon and plain-rimmed apertures (the present species has only a small inconspicuous vascular stolon and lobed apertures). The size of the pharynx, the number of stigmata as well as the number of rows, the absence of a posterior abdomen and the large siphonal lobes suggest *Stomozoa* but, in addition to their colonial habit, *Stomozoa* spp. have complete rather than partial siphonal vela, the so-called ocelli are on each side of the siphonal lobes rather than in the tips as they are in the present species, and the oesophagus is not as long as it is in the present species.

The long abdomen, long oesophagus and anus in the posterior end of the atrial cavity are characteristic of both *Pycnoclavella* and *Euherdmania*. Nevertheless, the species seems closer to *Euherdmania* than *Pycnoclavella* because of its large pharynx with numerous rows of stigmata, folded stomach, siphonal lobes, and muscular velum (which resembles that of *Euherdmania dentatosiphonis* Millar, 1975). Only its solitary habit, larger zooids and more numerous thoracic muscles distinguish the present species from *E. dentatosiphonis*. Thus, although the gonads are not always in a posterior abdomen, *Euherdmania* seems to be the most appropriate genus for this species.

Family PSEUDODISTOMIDAE n. fam.

The family is characterised by its colonies with embedded, separately opening zooids with 6 well defined lobes around the atrial and the branchial apertures, 3 rows of stigmata with the anterior row on each side continuing anteriorly along each side of the mid-dorsal line, fertilisation in the oviduct, and a generally smooth stomach wall with 4 broad longitudinal compartments or quadrilateral in outline. Generally the oesophagus is short and the stomach is in the middle third of the abdomen.

However, a group of species, viz. *P. arborescens*, *P. aureum*, *P. novaezelandiae*, *P. opacum* and *Anadistoma* n.gen. (see below) have a longer oesophagus, with the stomach two-thirds to three-quarters of the distance down the abdomen. The curved heart is in the posterior tip of the posterior abdomen. Gonads are in longitudinal series or bunched in the long posterior abdomen. The vascular processes from the tip of the posterior abdomen are moderately long (longer than those in the Polycitoridae) and longitudinal muscle fibres (from the muscle bands on each side of the abdomen) sometimes continue onto them. Larvae are large, with a trunk often exceeding 1.0mm in length. The adhesive organs are large, with a deep, wide, eversible axial platforms which, when everted, form large thin-walled balloon-like structures in the anterior mid-line. They appear to lack the tall columnar cells that comprise the axial elements of the adhesive organs of most taxa (see Cloney 1977, Turon 1991).

Apart from the presence of gonads in a posterior abdomen, zooids resemble those of *Sigillina* in having 3 rows of stigmata, a relatively short oesophagus, smooth stomach, a long vascular stolon sometimes with longitudinal muscle fibres on it, fertilisation and incubation of the especially large embryos in the oviduct or in a brood pouch, and wide platforms of adhesive cells in the deep epidermal cups of the large, eversible adhesive organs. Further, in *Anadistoma* n.gen. transverse muscles are present on the thorax as in *Sigillina*.

Zooids are smaller than those of *Sigillina*, and, like those of *Eudistoma* and *Pycnoclavella*, have the anterior row of stigmata deflected anteriorly. This could be the result of convergent evolution associated with size reduction and does not necessarily indicate a direct relationship with Pycnoclavellidae. Nevertheless an alternative hypothesis for the origin of the Pseudodistomidae is from a pycnoclavellid ancestor by shortening of the gut loop, leaving gonads and heart in the posterior abdomen, while the tubular larval adhesive organs reduce in length and partially evert. Evidence against the pycnoclavellid relationship is the position of the anus halfway up the short thorax (not at the posterior end of the atrial cavity as in *Pycnoclavella*), and the 6-lobed rather than smooth apertures.

The monotypic genus *Citorclinum* Monniot and Millar, 1988, containing a single species *Citorclinum laboutei* Monniot and Millar, 1988 known only from the New Caledonian lagoon, appears to belong to this family. It has 3 rows of stigmata, the anterior row inclined forward along the mid-dorsal line, a smooth-walled stomach halfway down the abdomen, and the testis follicles in a long series in the posterior end of the posterior abdomen. As in *Pseudodistoma* incubation is in the abdominal part of the oviduct. The large larva (trunk about 1mm long) has 2 elongate everting adhesive organs in the mid-line. These are hollow, without columnar cells, and are like those of *Pseudodistoma* rather than *Sigillina*, or other Holozoidae, Polycitoridae and most families of the Aplousobranchia. The genus is distinguished from *Pseudodistoma* by the withdrawal of the heart and ovary to the abdomen with the gut loop, leaving the testes in the posterior abdomen.

In addition to *Citorclinum* and *Pseudodistoma* the family contains the monotypic new genus *Anadistoma*. The latter has transverse thoracic muscles and a longer oesophagus than *Pseudodistoma*.

Genus **Pseudodistoma** Michaelsen, 1924

Type species: *Pseudodistoma cereum* Michaelsen, 1924

Brewin (1958) on the basis of what she called 'parallelism in classification' assigned species to genera solely on the presence or absence of stomach folds — those with stomach folds being in *Pseudodistoma*. This definition is based on the type species which has a quadrate stomach or one partially divided into 4 chambers. True stomach folds do not occur. Brewin's definition must also be amended to exclude *Ritterella* in which true stomach folds do occur, and which has other characters separating it from *Pseudodistoma*.

Species of this genus appear to be less prolific than most ascidians. Gonads apparently mature for only a short time, and were not seen in many of the examined specimens. Further, the ovaries are small, and in most species only a single ovum develops at a time. The testis follicles are confined to the posterior, middle, or anterior part of the posterior abdomen, and never occupy its full length. Fertilisation appears to be at the base of the oviduct, for embryos are found being incubated in the posterior abdomen in *P. oriens* n.sp. and *P. kanako*; and in the abdomen in *P. arborescens*, *P. aureum*, *P. opacum*, *P. cereum*, and *P. brieni*. In the last 2 species embryos are lined up in the abdominal part of the oviduct in a developmental sequence. In the new Australian species *P. acuatum* n.sp., *P. pulvinum* n.sp., and *P. grac-*

TABLE 4. Summary of characters of species of *Pseudodistoma* recorded from Australia

Species	Biogeographic Range[1]	Range anticlockwise around Australia	Colony	Sand (embedded)	Stomach position (thirds of abdomen)	Length vascular stolon	Stigmata: maximum number/ row	Gonads: ♂ position in posterior abd.; ♀ relative to ♂	Embryos: maximum number; site of incubation[2]	Larva: trunk length (mm); adhesive organs	Other

ilum n.sp. and in *P. australe*, *P. cyrnusense*, *P. kanoka* and *P. fragile*, incubation of embryos is completed in a brood pouch constricted from the top of the abdomen, near the postero-dorsal corner of the thorax.

Brewin (1958 p.444) refers to 'bud like masses' that lie beneath the zooids of *Pseudodistoma cereum*; and in the present collection *Pseudodistoma oriens* n.sp. has juvenile replicate zooids in the stalk of a developing colony lobe. It therefore seems possible that replication does not involve the abdomen. However at this stage it is not clear whether it involves strobilation of the posterior abdomen (as in *Aplidium* spp.), or the posterior vascular stolon (as in Holozoidae).

Colonies of *Pseudodistoma* often (though not always) are stalked, with the zooids regularly arranged, the atrial apertures opening toward the top of the colony or the centre of the upper surface, and the branchial apertures toward the stalk or the outer margin. Colonies thus have colonial, but not cloacal, systems.

The zooids of most species of *Pseudodistoma* are basically similar to one another and this has resulted in confusion in their taxonomy. The zooids are, moreover, very muscular and preserved specimens usually are so contracted that details of their morphology, such as the numbers of thoracic muscle bands and stigmata, are obscured. When relaxed the posterior abdomen is long and narrow, but it is short and thick when contracted. There often is a vascular stolon of appreciable length with some longitudinal muscle fibres on it. Male follicles, when present, are either clustered in the posterior, middle or anterior third of the posterior abdomen, or spread out in longitudinal series. Sometimes the small ovaries are surrounded by the clustered male follicles but in other species they are anterior to them. The gut loop is very conservative — the quadrate stomach and rectal valve being present in most species (*P. fragile* being the exception). However there is some variation in the length of the oesophagus (see family discussion, above). At this stage, the larvae (which vary in numbers of ampullae), the position of the gonads, and the form and colour of the colony constitute the principal characters distinguishing species of this genus from one another.

Only one known species, *Pseudodistoma aureum* has a character that implies a polyphyletic origin for the genus, viz. tufts of columnar cells in the adhesive organs of the unusually small larvae rather than the everting, balloon-like organs of other species.

The majority of species are known from either Mediterranean, Japanese or southern hemisphere temperate waters. The type species is recorded from New Zealand. The only tropical species known are *P. brieni* Pérès, 1949 from Senegal and *P. aureum* (Brewin, 1957) from the Western Pacific (see below).

Although only one species from Australia (*P. australe* Kott, 1957) was previously regarded as indigenous, revision of the material has shown that all Australian species are (Table 4). As in *Sigillina*, it is probable that gene flow for many species is inhibited by the relatively large and few larvae, longer incubation and shorter free-swimming life, and the probability that the relative size of the trunk and tail are unlikely to enhance a long free-swimming life.

Key to species of *Pseudodistoma* recorded from Australia

1. Test soft, mucus-like ..... *P. gracilum* n.sp.
   Test firm, not mucus-like 2

2. Colonies flat-topped mushrooms or sessile cushions, the surface sometimes raised into lobes or swellings 3
   Colonies not flat-topped lobes or sessile cushions, usually with branched stalks 5

3. Sand embedded in test ..... *P. inflatum* n.sp.
   Sand not embedded in test 4

4. Embryos incubated in a brood pouch ..... *P. pulvinum* n.sp.
   Embryos not incubated in a brood pouch ..... *P. aureum*

5. Sand crowded in central or sub-surface test... 6
   Sand not crowded in central or sub-surface test 7

6. Sand in central test; head not pointed ..... *P. pilatum n.*sp.
   Sand in layer beneath surface; head pointed ..... *P. acuatum* n.sp.

7. Embryos in a brood pouch; stalk soft, fleshy ..... *P. australe*
   Embyros not in a brood pouch; stalk not soft, fleshy 8

8. Ovary anterior to testis follicles . *P. oriens* n.sp.
   Ovary surrounded by testis follicles ..... *P. candens* n.sp.

Species recorded from regions adjacent to Australia

Stalked species

Pseudodistoma africanum Millar, 1954 (see also Millar 1962) from Cape Province, South Africa, has a variety of colonies, probably not all conspecific, assigned to it. The Walker Bay (type) specimens have stalks tapering to the base, and resemble *P. oriens* n.sp. (see below) except for the sand embedded in the central test, and the spherical shape of the head of the South African species. The specimen from Natal (Millar 1962) with long tapering stalk has a smaller larval trunk than *P. oriens*.

Pseudodistoma antinboja Tokioka, 1949, from Japan (see also Nishikawa 1990, Rho 1971), has conical heads on short, thick, wrinkled cylindrical stalks and resembles the New Zealand *P. cereum*, differing in having only 8 to 9 stigmata per row (rather than 20 to 24). The Australian *P. australe* also is similar (see below).

Pseudodistoma arborescens Millar, 1967 from Madagascar, New Caledonia (Monniot 1987) and the Philippines (new records: QM GH456 GH471–3) has distinctive colonies of narrow, branching stalks with embedded sand, and soft, rounded or conical heads. Zooids have up to 15 stigmata per row, and a relatively long, narrow oesophagus, with the stomach in the posterior half to one-third of the abdomen. Larvae have a trunk 0.6mm long, deep pseudodistomid-like adhesive organs, and lateral ampullae.

Pseudodistoma cereum Michaelsen, 1924 (see also Brewin 1958) from New Zealand resembles *P. australe*, especially in its colour, it has similar wide, thick, short, stalks, 20–24 stigmata per row, and similar but smaller larvae with the trunk about 1.0mm long. It also differs in having a developmental sequence of up to 8 embryos in the top of the oviduct (Brewin, 1958) rather than the single one being incubated in the thoracic brood pouch in the Australia species (see below). It resembles, but is larger than, an undescribed tropical species from the Philippines (see *P. aureum* remarks, below).

Pseudodistoma novaezelandiae (Brewin, 1950), from New Zealand, has colonies with pointed lobes on short, thick stalks that resemble those of *P. cereum*, differing in the relatively long oesophagus with the stomach in the posterior third of the abdomen.

Pseudodistoma opacum (Brewin, 1950) from New Zealand has flat-topped, sessile lobes attached to basal test. These differ from the stalked lobes of *P. antinboja* Tokioka, which similarly has few stigmata per row. Like *P. novaezelandiae*, *P. opacum* has relatively long oesophagus.

Sessile species

Pseudodistoma brieni Pérès, 1949, from Senegal, forms massive, sessile lobes, rose-yellow or brown in life, with cartilaginous test. Zooids are numerous, irregularly placed. Twelve to 14 stigmata are in each row. A developmental sequence of up to 4 embryos are in the top part of the oviduct (as in *P. cereum*) which distinguishes the species from the Australian *P. pulvinum* n.sp. (see below) which has similar colonies. The larval trunk is probably about 1.0mm long and the larvae look like those of *P. australe*.

Pseudodistoma cyrnusense Pérès, 1952, from Corsica is yellow in life, with an orange pigment patch each side of the cerebral ganglion and one at the anterior end of the endostyle which distinguish the species from others (see *P. australe* n.sp., below).

Pseudodistoma fragile Tokioka, 1958, from Japan has soft mucus-like test that readily disintegrates as in *P. gracilum* n.sp. The Japanese species has up to 5 embryos being incubated in a brood pouch rather than only the one found in the Australian species.

Pseudodistoma kanoko Tokioka and Nishikawa, 1975, from Okinawa has massive sessile colonies, with translucent, firm test, red with white patches around zooid openings. Zooids have weak longitudinal muscles on the thorax, and 10 stigmata per row. Embryos are incubated in the posterior abdomen, sometimes projecting from it, and larvae have a trunk 2.1mm long with the tail and atrial siphon apparently displaced. Zooids of *P. australe* have lighter yellow patches anteriorly, but these are at the top of endostyle and between the apertures rather than surrounding them. A specimen with a leathery tapering stalk was assigned to *P. kanoko* (see Nishikawa and Tokioka 1976), but there is insufficient information to establish whether it is a normal variation in colony form or a different species related to *P. africanum* or *P. oriens* n.sp.

Pseudodistoma acuatum n.sp.
(Fig. 15. Plate 3b)

DISTRIBUTION

TYPE LOCALITY: South Australia (Ward I., 20-25m, coll. S. Shepherd 31.3.82, holotype SAM E2120 *QM GH923*; Ward I., on undercuts and ledges, 8m, coll. N. Holmes 12.4.83, photo 0064 R893, paratype QM GH2323).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colonies, up to 10cm high, consist of a basal primary trunk, secondary, and tertiary branches (the terminal pointed lobes), each of about the same length (3cm). The colonies are firm throughout, and have a layer of sand embedded beneath the surface of the colony. The branches are crowded and vertical. Sand is absent from the central test. Zooids are crowded and project through the sand to open around the sides of the terminal lobes of the colony. Living colonies are white.

INTERNAL STRUCTURE: The zooids are very long, extending down through the stalk to the base of the colony. Fine longitudinal muscles extend the whole length of the zooid, and terminate each side of the tip of the posterior abdomen. The pharynx is narrow, with only about 8 stigmata per row. The oesophagus is relatively long, the stomach being in the middle of the posterior half rather than in the middle third of the abdomen. It is smooth walled, and quadrate in section. the male follicles are in the posterior end of the posterior abdomen.

A single embryo is incubated in a brood pouch projecting from the zooid at the top of the abdomen in specimens collected in January.

REMARKS

These stalked colonies have a superficial resemblance to *P. cereum*, however they have longer and more pointed heads and branching, rather than simple cylindrical stalks. The sympatric species *Pseudodistoma pilatum* n.sp. has sand throughout the centre of the colony (rather than confined to a layer beneath the surface as it is in the present species), its stalks are thicker, shorter and not as long as those of the present species, the terminal expanded head has a more or less flat upper surface (where the zooids open) rather than being long and pointed, and it has more numerous stigmata.

Pseudodistoma aureum (Brewin, 1957)

Pseudodistoma aurea: Kott, 1981, p.157. Nishikawa, 1984a, p.114. Monniot and Monniot, 1987, p.81.

FIG. 15: *Pseudodistoma acuatum* n.sp. — **a**, part of colony (holotype SAM E2120); **b**, zooid (paratype QM GH2323). Scales: **a**, 1cm; **b**, 0.5mm.

DISTRIBUTION

NEW RECORDS: Queensland (Capricorn Group, QM GH4958 –73 GH5103 GH5177 GH5199 GH5206 GH5259 GH5502 GH5691).

PREVIOUSLY RECORDED: New Zealand (North I. — Brewin 1957). Fiji (Dravuni — QM GH106 Kott 1981). Majuro Atoll (Nishikawa 1984a). French Polynesia (Monniot and Monniot 1987).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are sessile, flat-topped pillow-, or mushroom-shaped, to 2cm high and 3cm diameter, sometimes narrowing to a short stalk from the lower surface. The test is firm, transparent in preservative with zooids evenly distributed in it. Each zooid opens (on the upper surface only) by 2 apertures. In living colonies the test is transparent, 'orange buff', 'ochraceous buff', 'tawny ochraceous', 'buff yellow', 'maize yellow', 'Indian yellow', 'deep chrome', 'chrome yellow', 'orpiment orange', 'cadmium orange', 'vinaceous pink', or 'saturn red' (Ridgeway 1886). Occasionally there is a honeycomb pattern, of 'orange ochraceous' (blood?) around the zooids. Zooids are opaque, and usually a darker shade of the same colour as the test. One collector (PK) has referred to the appearance of these colonies as 'orange ice' or 'soft orange look'.

INTERNAL STRUCTURE: Zooids are long (about 8mm) and slender. Anteriorly they project slightly from the upper surface and posteriorly they extend into the base of the colony and into the stalk (when one is present). The thorax and abdomen together are only about 2mm long, the remainder of the length consisting of posterior abdomen. Only very short vascular stolons are present at the posterior end of the zooid. The atrial siphon is sometimes longer than the branchial one. About 12 longitudinal muscles extend along each side of the thorax and along the abdomen and posterior abdomen which, when muscles are contracted, may be drawn up behind the abdomen in a short, blunt appendage no longer than the abdomen. About 25 stigmata are in the anterior rows, the dorsal end of each row extending anteriorly along each side of the dorsal mid-line. The posterior and middle rows each have 20 stigmata.

The oesophagus is relatively long, and the short, smooth-walled stomach with the usual 4 compartments is two-thirds to three-quarters of the distance down the abdomen. The duodenal area is relatively short. An oval posterior stomach is in the pole of the gut loop. The testis follicles are in a single series in the middle of the posterior third of the posterior abdomen, and the small ovary is just anterior to the male follicles. Up to 4 embryos are present in a developmental series in the distal part of the oviduct (in the thorax and at the top of the abdomen) in specimens collected in May, October and November, but not in January, April, August, or September. Gonads were not present in the small colonies taken in April

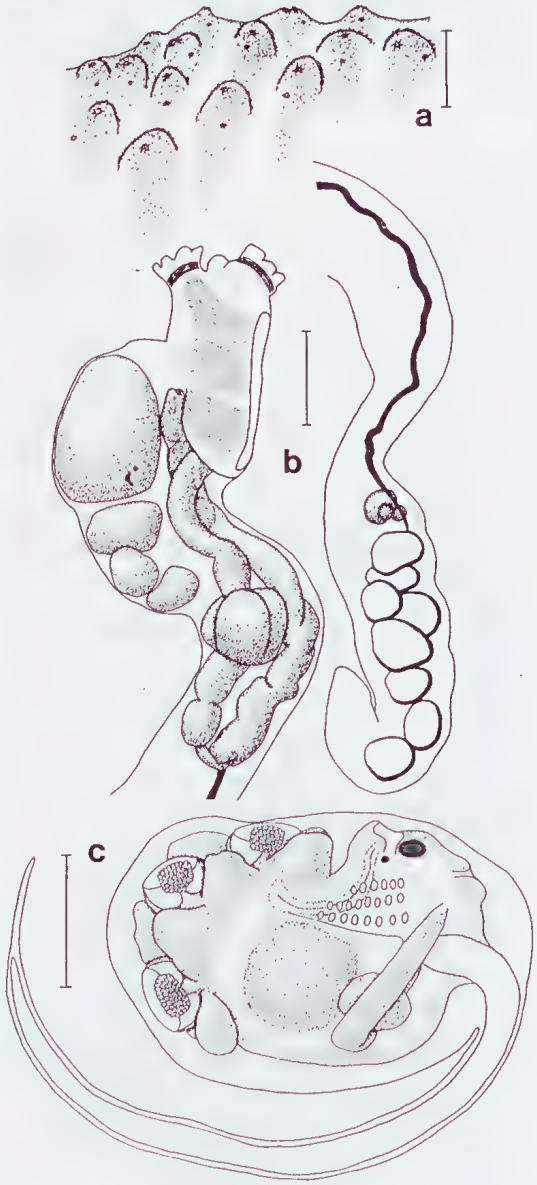

FIG. 16: *Pseudodistoma aureum* — **a**, part of colony surface (QM GH4958); **b**, zooid (QM GH4970); **c**, larva (QM GH4970). Scales: **a**, 2mm; **b**, 0.5mm; **c**, 0.2mm.

and August. A colony taken in September has male follicles but no ovary, and it is possible that the species is protandrous.

Larvae are relatively large, the trunk being 0.6 to 0.65mm long. The tail is wound slightly more than halfway around it. The 3 median adhesive organs are on short thick stalks, and four rounded lateral ampullae are on each side of the anterior mid-line. The axial cone of adhesive cells has a narrow stalk attaching it to the base of the epidermal cup, and it has a tuft of what appear to be columnar cells diverging out from the base to a flat terminal platform.

REMARKS

Characteristic of the present species is the relatively clear, transparent test and the rounded cushion-like colonies. The oesophagus described for the New Zealand colonies (Brewin 1957) is longer than that in the present material, and the duodenal region between the stomach and mid-intestine appears to have been overlooked. In all other respects, however, zooids, colony and larvae from the type material are the same as those from Fiji (Kott 1981), French Polynesia (Monniot and Monniot 1987) and Heron I.

The firm, clear, golden colonies are readily distinguished from other species of *Pseudodistoma*. The zooids also differ from most other species in their relatively long oesophagus, short vascular stolons and small larvae with a tuft of columnar cells rather than the thin-walled everting balloon of other species. *Pseudodistoma cereum* has a similar larva of about the same size, but a short oesophagus (see Brewin 1958) and stalked colonies; *P. novaezelandiae* has a longer oesophagus, but also has stalked colonies; and *P. opacum* (Brewin, 1950) has a longer oesophagus, but lobed colonies and only 9 or 10 stigmata.

Of the known indigenous Australian species the oesophagus is a similar length in *P. inflatum* n.sp., which can be distinguished by its less regular, opaque orange colonies with sand in the base, and gonads in the anterior half of the posterior abdomen. *Pseudodistoma arborescens* Millar, 1967 from Malagasy, New Caledonia and the Philippines (new records: QM GH456 GH471–3) has a similar long oesophagus, and gonads in the posterior end of the posterior abdomen but is distinguished by its colony, with rounded to conical heads on long branched stalks.

(Fig. 17. Plate 3c,d)

Pseudodistoma australis Kott, 1957, p.101; 1963, p.78; 1972b, p.172 (part, not specimens from Waldegrave I. < *Sigillina grandissima* Kott).
Pseudodistoma cereum: Kott 1972a, p.12.

DISTRIBUTION

NEW RECORDS: Western Australia (Exmouth Gulf, QM G9289 G9290 G9473; Shark Bay, WAM 867.83 *QM GH2133*, WAM 1018–9.83; Houtman's Abrolhos, WAM 764.82 814.83 950.83 1015.83 198.87 198.88 234.88 238.88; Cockburn Sound, WAM 152.75 928.89). South Australia (Great Australian Bight, QM GH4160; Cape Jaffa, SAM E2486). Victoria (Port Phillip Head, QM GH51).

PREVIOUSLY RECORDED: Western Australia (Rottnest I.— holotype AM Y0919, AM U3982–3 Y1314 Kott 1957 1963). South Australia (Elliston Bay — SAM E2549 Kott 1972b; Nora Creina Bay — SAM E2440 Kott 1972a).

DESCRIPTION

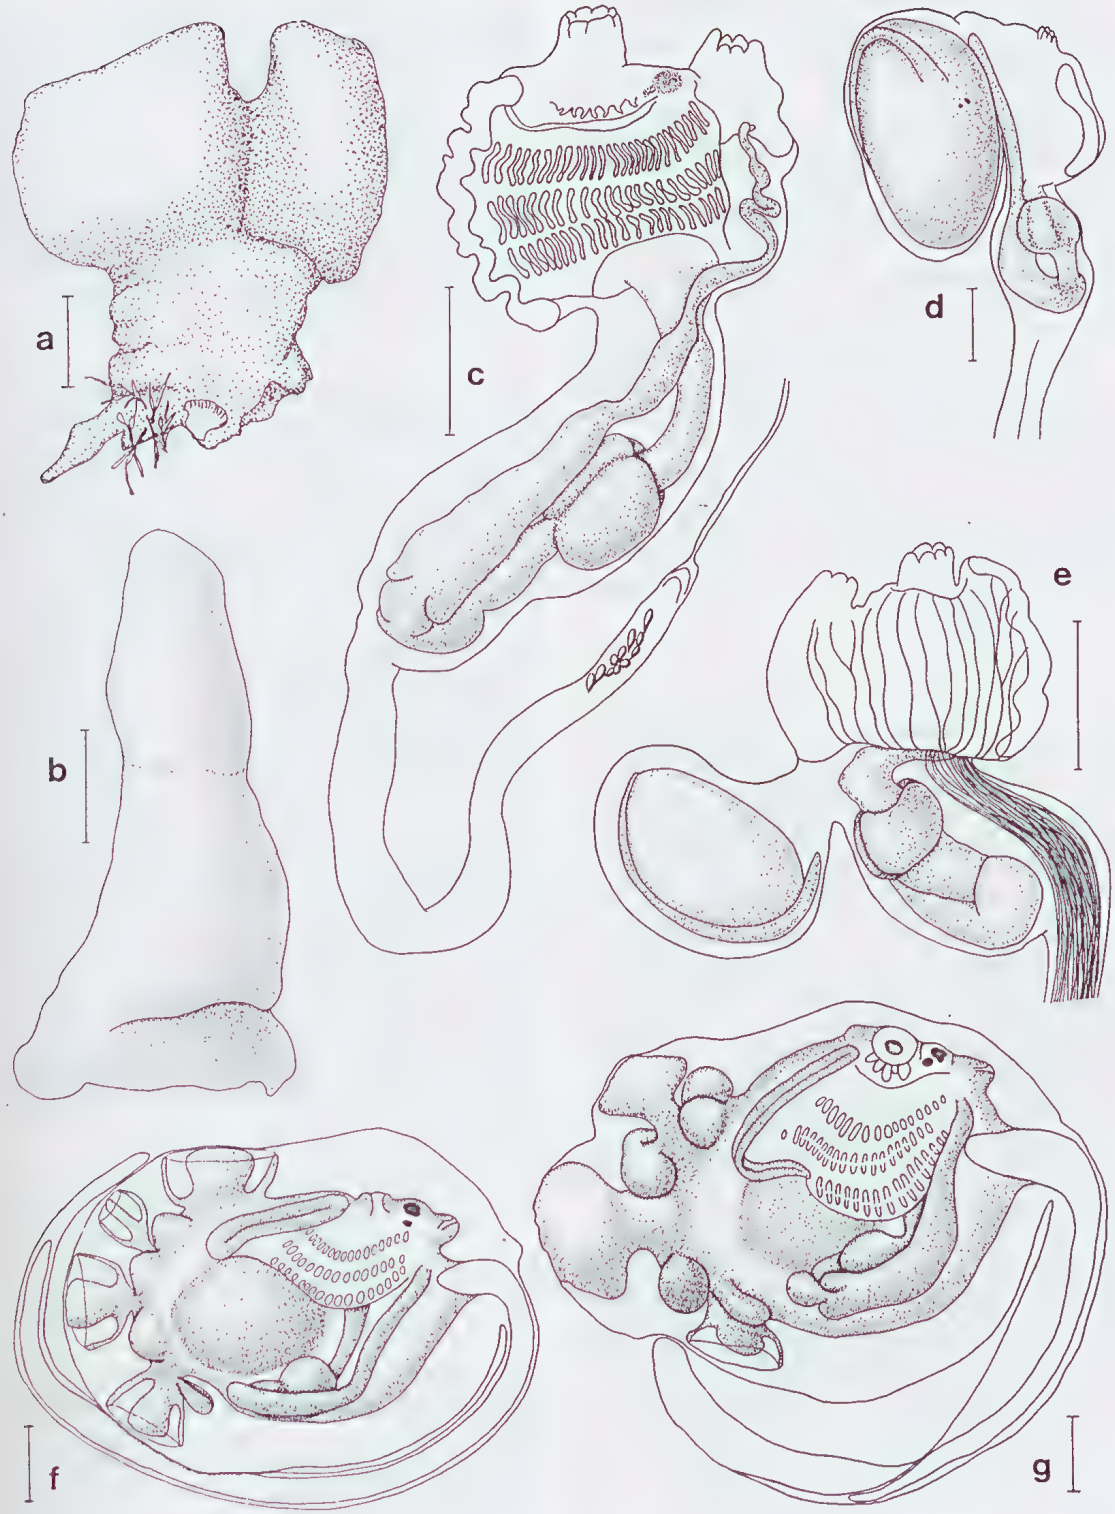
EXTERNAL APPEARANCE: The colonies are stalked or sessile, conical to rounded fleshy lobes or stalked heads arising from a common basal test mass or upright fleshy stalk. The zooids open all around the lobes but not on the common base or stalk.

The smaller conical heads (about 1.5cm long) on relatively long (to 2.5cm) narrow stalks (WAM 1015.83) probably are younger colonies than those in which the almost sessile heads, up to 5cm, are on a fleshy basal test mass to 1.5cm high (WAM 867.83). The test is very soft but fibrous, and firmer in the stalk than the head. The stalk contains scattered sand grains. In preservative the colonies are often very squashed.

In life, the head is rose-pink to red-orange, with the outer layer of test translucent and a white to yellow opaque ring around the rim of each aperture. The stalk is brown. Zooids are orange in preservative, fading to whitish-beige. The white particles that form the opaque ring around the apertures persist in the surface test around the apertures.

The laterally flattened specimens from South Australia (SAM E2486) have a patch of yellow or brown pigment over the dorsal tubercle. The faded, preserved zooids of the holotype colony have an opaque, white, circular patch in the same

FIG. 17: *Pseudodistoma australe* — **a**, **b**, colonies (**a**, QM G9473; **b**, WAM 859.83); **c–e**, zooid and parts of zooids (**c**, **e**, holotype AM Y919; **d**, WAM 152.75); **f**, **g**, larvae (holotype AM Y919). Scales: **a**, **b**, 1cm; **c–e**, 0.5mm; **f**, **g**, 0.2mm.



a
b
c
d
e
f
g

position over the dorsal tubercle. Similarly, there are yellow spots over the dorsal tubercles of the orange lobed colony photographed at Exmouth Gulf (AMPI 76, Plate 3c).

INTERNAL STRUCTURE: Contracted, the thorax and abdomen together are sometimes only about 1.5mm long. The posterior abdomen is straplike, and about the same length. However, in less contracted zooids the posterior abdomen and delicate vascular stolon extend down into the stalk of the colony and zooids are long and threadlike, most of their length being posterior abdomen. Longitudinal muscle bands (from 12 to 20 on each side) extend along the length of the zooid, half from the atrial and branchial siphons and about half from the anterior part of the ventral border (across the endostyle). They terminate at the end of the posterior abdomen. The branchial tentacles are in about 4 rows, the 6 largest ones in the posterior circle. The branchial sac is wide, with 22 stigmata in the second and third rows, and about 25 in the anterior row, which is deflected anteriorly along the dorsal midline.

The oesophagus is moderately long. The stomach, divided into 4 longitudinal quarters by shallow grooves in its otherwise smooth wall, is about halfway down the abdomen. The duodenal area is long, an oval posterior stomach interrupts the narrow mid-intestine in the pole of the gut loop. A rectal valve at the proximal end of the ascending limb of the gut loop separates the mid-intestine from the rectum. The anus, with a bilabiate border, opens halfway up the branchial sac.

A short double series of small male follicles were observed in the posterior end of the posterior abdomen in the holotype, although they are half to three quarters of the way down the posterior abdomen in the South Australian specimens (SAM E2486).

A single series of about 8 mature male follicles are present about two-thirds of the way down the contracted posterior abdomen in a mature colony from Exmouth Gulf collected in August (QM G9473). They are flattened against one another into discs, but this may not be their shape when the zooid is extended. Zooids in a colony off Rottnest have a single embryo being incubated in the oviduct at the top of the abdomen, just behind the postero-dorsal corner of the thorax. The large embryo protrudes from the zooid, distorts the thorax, and is partially constricted off from it.

The larval trunk is 1.0mm long and the tail wound halfway around it. It has 3 large, stalked adhesive organs in the anterior mid-line, each consisting of an ectodermal cup around a large hollow eversible axial cone or platform, all on a long narrow stalk. Four wide ampullae alternate with the adhesive organs. These are flattened antero-posteriorly and are produced laterally on each side into rounded lobes that curve ventrally, forming a cushion around the stalks of the adhesive organs. There is an ocellus and an otolith. In some zooids of colonies collected in November and December (AM Y919, U3982) a single embryo is present in a brood pouch, partially constricted off from the top of the abdomen. Ova were not detected in any of the other colonies.

REMARKS

The type colony, although mutilated, appears to have been stalked rather than the investing cushion which Kott (1957) thought it to be.

The species resembles *P. cereum* from New Zealand, which has similar stalked colonies although the heads are regular and rounded; and although its larvae are also similar they are smaller (trunk 1mm long). Some of the colonies resemble some of those of *P. africanum* Millar, 1954 which are also said to be pink in life (see Millar 1962). However the head and stalk of South African material remain distinct, in even the largest colonies, and the long sessile lobes found in the present species do not develop. Two sessile colonies from Western Australia differ from the present species in having sand in the stalk, and larger larvae without ampullae around the sessile adhesive organs; and in lacking a distinct brood pouch constricted off from the abdomen. They have been assigned to *Pseudodistoma oriens* n.sp. (WAM 859.83 923.83).

Pseudodistoma cyrnusense from Corsica is a sessile species with pigment patches in a similar position to the present species. However the Corsican species has 2 (one each side of the dorsal tubercle) rather than the single median one of *P. australe*.

Pseudodistoma candens n.sp.
(Fig. 18. Plate 3e,f)

Pseudodistoma cereum: Kott, 1975, p.4.

DISTRIBUTION

TYPE LOCALITY: South Australia (Pearson I., coll. S.A. Shepherd 28.3.82, holotype QM GH977, paratype SAM E2118).

FURTHER RECORDS: Western Australia (Cervantes, WAM 197.87; Dongara; Cockburn Sound, WAM 70.75 .841.83 *QM GH2132*, WAM 1014.83 QM GH5462). South Australia (Cape Jaffa, SAM E2117

E2119 E2446 E2526, QM G9286 Kott 1975); Ward I., QM GH1295; Topgallant I., QM GH972; Hotspot, QM GH2421; Nuyts Archipelago, SAM E2408); Victoria (Cape Nelson, SAM E2407).

Description

External Appearance: Colonies are long (to 5cm) and oval (to 2cm diameter), to short and rounded (to 3cm diameter) or conical and sometimes laterally flattened heads, usually on a thick (1cm diameter) stalk of variable length (to 5cm), sometimes tapering to the base. It is always tough, leathery and transversely wrinkled. The head sometimes overlaps the top of the stalk. On the head the test is tough, in larger specimens almost opaque, and more or less smooth on the surface with cloudy brown pigment cells.

The stalked heads often appear to be solitary, but occasionally the stalk is branched. Replicated zooids with small abdomina sometimes are present in the stalk and appear to move up into the head as it develops. The zooids open all around the outer surface of the head. Living specimens are said to be wine red, although the colour appears to be in the zooid, and the test is translucent. In photographs of a living specimen (Pl. 3e,f) fine red bands are present around each aperture. In preservative the zooids are yellow but subsequently fade to white.

Internal Structure: The zooids are up to 2cm or more, although most of their length is taken up by the posterior abdomen, and the thorax and abdomen are together only about one to 2mm. There is a long (up to 2cm) vascular stolon extending posteriorly from the end of the posterior abdomen. Twenty to 40 longitudinal muscles extend the length of the zooid and some of these extend along the length of the vascular stolon. The branchial and atrial lobes are especially conspicuous. Up to 20 long, rectangular stigmata are in each of the second and third rows, and in the anterior row additional stigmata extend forward along each side of the mid-dorsal line. The stomach has the usual 4 longitudinal compartments. A long, duodenal area and oval posterior stomach are in the distal part of the descending limb of the gut loop. The heart is a U-shaped tube at the end of the posterior abdomen.

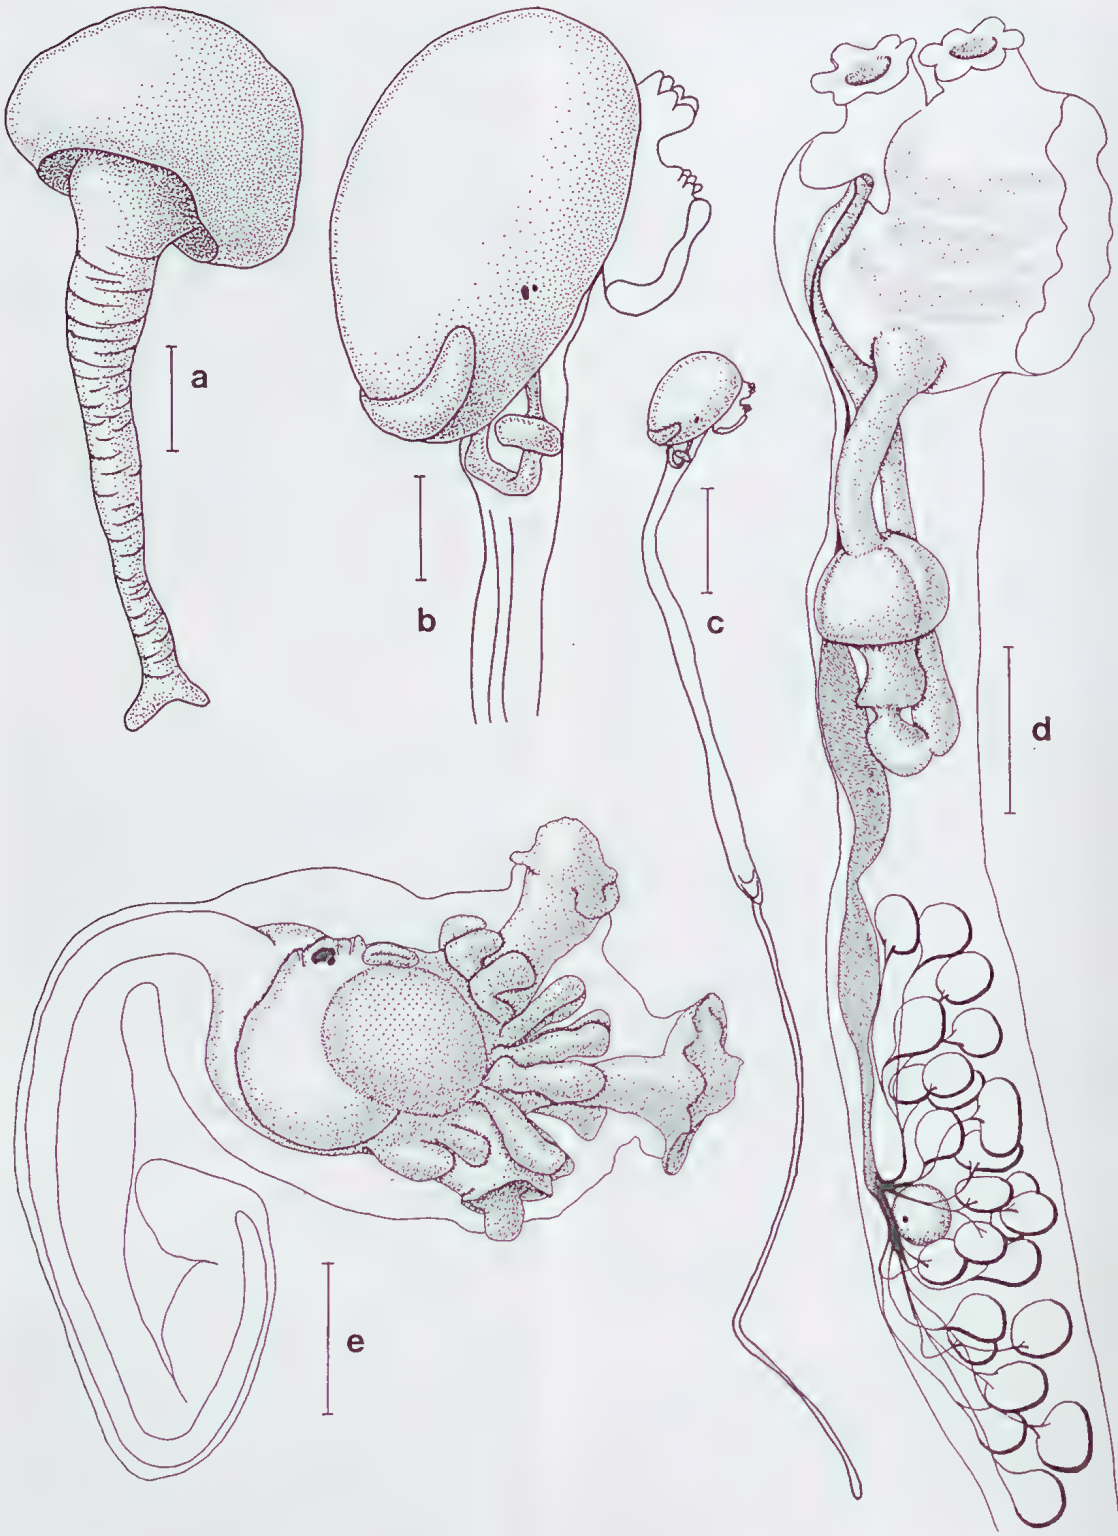
The gonads are in the anterior part of the posterior abdomen just behind the gut loop. The testis follicles are large and pear-shaped and are in a long, loose or a tightly bunched cluster around the small ovary. The vas deferens is long, extending from halfway down the side of the male follicles to a point level with the ovary, where it is joined by the vasa efferentia from the follicles. The length of the testis probably depends on the state of contraction of the posterior abdomen. A single large embryo is found in the oviduct at the top of abdomen in the holotype. Some specimens (QM GH972) collected in March from South Australia have a conspicuous egg in the posterior abdomen but male follicles are not developed. Mature male follicles are in specimens from Point Peron (WAM 70.75) collected in April and from Cervantes I. (WAM 189.75) collected in May. Large larvae (1.5mm trunk) project from the side of the zooid along the length of the oesophagus to just behind the atrial cavity in specimens collected from Pearson I. in March (QM GH977). Larvae have 3 large, stalked eversible adhesive organs in the midline anteriorly. The axial protrusions are rounded and the everted organs seem to expand into thin-walled balloon-shapes. About 8 long, digitiform ectodermal ampullae per side bend anteriorly at right angles to lie parallel to the stalks of the adhesive organs. The tail winds three-quarters of the way around the trunk. An ocellus and otolith are present.

Remarks

Pseudodistoma africanum Millar, 1954 (also Millar 1962) from South Africa, has rounded heads on stalks tapering toward the base, as in the present species. With the exception of one specimen from Natal which is 8cm long and may be a different species (Millar 1962), the African species has smaller colonies, softer stalks without an outer leathery cuticle, and less muscular zooids with only about 8 longitudinal bands. The large specimen from Natal more closely resembles *P. candens*, having about 20 longitudinal muscles. However its larva is smaller (1mm long trunk).

Pseudodistoma cereum Michaelsen, 1924 from New Zealand, has shorter, fleshy and cylindrical stalks (see Brewin 1958) rather than the long ones of *P. candens*.

The present species does not have sand included in its test, and thus is distinguished from other Australian stalked species (e.g. *Pseudodistoma pilatum* n.sp., *P. acuatum*). The species most readily confused with the present one is the sympatric *Pseudodistoma oriens* n.sp., which sometimes has long tapering, leathery, wrinkled stalks like the present species. *Pseudodistoma oriens* has pointed conical heads rather than rounded ones, softer more transparent test on the head, and slightly larger zooids. It also has larger larvae with sessile (rather than stalked) adhesive organs, a long irregular series of testis follicles in



a
b
c
d
e

the posterior half of the posterior abdomen and separated from the ovary (rather than being bunched around the ovary in the anterior half as they are in *P. candens*), and a wide band of strong muscles on the vascular stolon. Colonies of *P. candens* from off Cape Jaffa may be found to be a separate species. However they differ from the type only in their darkly pigmented zooids, thick fleshy stalks, and large opaque flattened heads, and for the present they have been assigned to *P. candens*.

DISTRIBUTION

TYPE LOCALITY: South Australia (Top Gallant I. 10m, coll. S. Shepherd March 1982, holotype SAM E2413 *QM GH971*; Grindal I., coll. W.H. Sasse 6.4.87, paratype QM GH4167).

FURTHER RECORDS: South Australia (Top Gallant I., QM GH973; Investigator Group, QM GH2422; Elliston Bay — SAM E2414 Kott 1972b; Beachport, SAM E2412; Kangaroo I., QM G11989; Cathedral Rock, QM GH4158). Victoria (Western Port —MV F57789 Kott 1976). New South Wales (Jervis Bay, QM G10092; Port Jackson AMY2263). Queensland (Heron I. QM GH4954; Lizard I., QM GH3808; Lihou Reef, QM GH4955; northern Great Barrier Reef, QM GH5334).

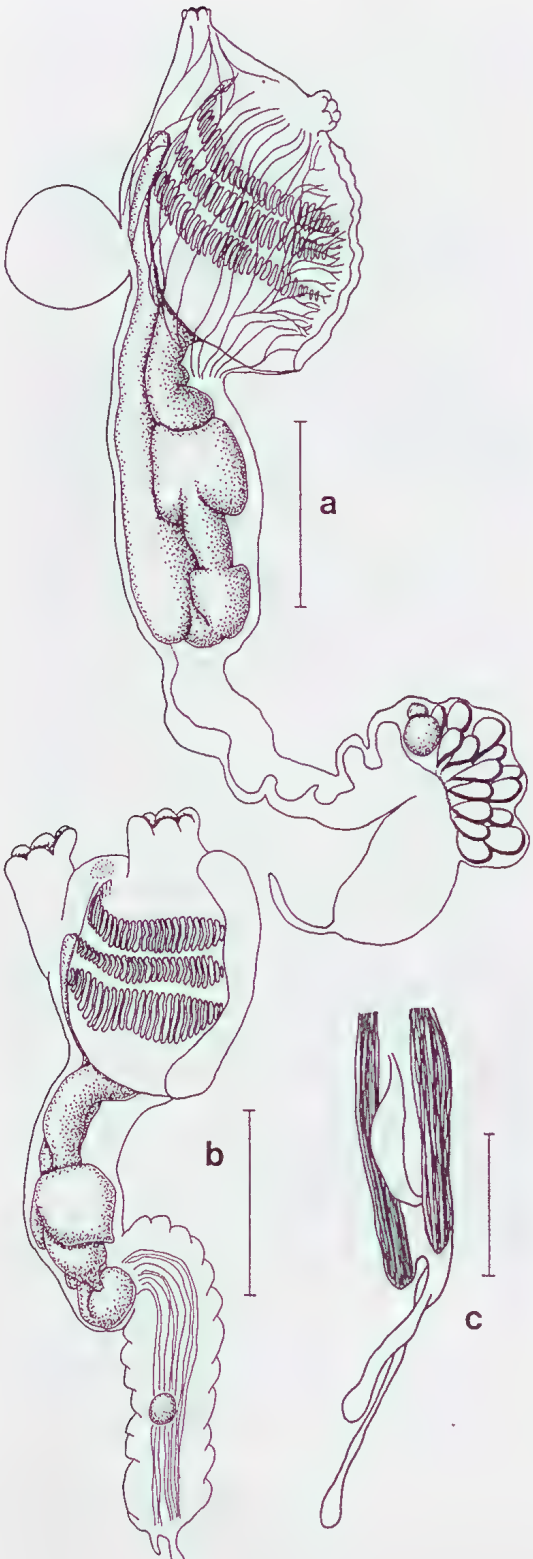
DESCRIPTION

EXTERNAL APPEARANCE: The test is mucus-like and disintegrating in preservative, often with the zooids lying free and the colonies so soft and flaccid their shape cannot be seen. In preservative all colonies are pale cream with beige zooids and contain evenly distributed cloudy morula cells in the test.

In photographs of some living specimens (QM GH4167 GH5334) the test is colourless and the extended zooids show as white streaks converging into the centre of the colony. The collectors notes record the holotype specimen to have had a 'colourless matrix with cream zooids'. However a colony (QM GH973) taken from the holotype location at the same time (March 1982) but at a greater depth (20m rather than 10m) is said to have been 'dark green with blue zooids'. One colony is recorded by the collector to have been a 'white jelly-like ascidian', but the photograph of the specimen (QM G11989) *in situ* has pale violet zooids, and a photograph from the same location shows white streak-like zooids in a colourless test (AMPI 223). The specimen from Cathedral Rock (QM GH4158) appears from its photograph to be bluish-purple like the Kangaroo I. specimen (QM G11989). Other collectors report living colonies with 'black-purple zooids' (QM G10092), and white zooids in 'a very fluid pale brown gel' test (QM GH3803). One living colony is reported to have been a 'fragile gelatinous mass about 50cm square and 3cm thick under a large rock' (QM G10092). The colony from Lihou Reef is saucer-shaped (QM GH4955). Only one bluish colony from South Australia (QM GH4158), in which zooids are in a vegetative condition, has relatively firm test and the colony entire in preservative. From photographs, colonies vary from spherical to extensive masses with the surface produced into lobes.

INTERNAL STRUCTURE: Zooids are robust up to 3cm long, most of the length being a narrow thread-like posterior abdomen. Thorax and abdomen are together about 3mm long, the thorax slightly longer than the abdomen when relaxed. The atrial siphon is sometimes longer than the branchial siphon, but sometimes the whole dorsal surface of the zooid swells out behind the atrial aperture forming a conical projection. Each aperture has 6 well-defined, evenly rounded lobes around its rim. From 12 to about 20 longitudinal muscles are on the thorax, and extend along each side of the abdomen and posterior abdomen. Fine transverse branches from the ventral longitudinal muscles terminate along each side of the endostyle. The longitudinal muscles terminate posteriorly in well-defined horns each side of the heart at the end of the posterior abdomen. Muscles do not extend onto the one to 4 fine vascular stolons, which vary from short to moderately long. Stigmata are from 0.4mm to twice that length, depending on the state of contraction of the thorax. They reduce in length at the ventral end of each row. From 20 to 25 stigmata are in the second and third rows and about 25 to 30 in the anterior row (which deflects anteriorly along the mid-dorsal line).

FIG. 18: *Pseudodistoma candens* n.sp. — **a**, colony (holotype QM GH977); **b–d**, zooids and parts of zooids showing embryos being incubated, proportions of zooids, relatively long vascular stolon, bunched testis follicles surrounding ovary, and distended vas deferens (**b–c**, holotype QM GH977; **d**, QM GH5462); **e**, larva (holotype QM GH977). Scales: **a**, 1cm; **b**, **d**, 0.5mm; **c**, 2mm; **e**, 0.4mm.



The smooth-walled stomach halfway down the abdomen is partially divided into 4 broad, shallow longitudinal compartments. An oval posterior stomach is in the pole of the gut loop. A distinct rectal valve is at the proximal end of the ascending limb of the gut loop. A bunch of pyriform male follicles is about three-quarters of the way down the posterior abdomen or sometimes in the posterior quarter. A small ovary is anterior to the male follicles in a specimen collected in April (SAM E2412 from South Australia) and from Lihou Reef (QM GH4955: unknown date). These colonies have a single round embryo in the brood pouch constricted off from the top of the abdomen. Embryos were not in other examined material.

The single larva in each brood pouch of specimens from New Caledonia (Monniot 1987) has the tail wound halfway around the 1.75mm long trunk, and, like larvae of *P. aureum*, has deep conical adhesive organs, 2 lateral ampullae and median dorsal and ventral ampullae.

REMARKS

A specimen of this species (QM G10092) analysed for vanadium was found to have 800–1600 ppm (Paul Fredrickson *pers. comm.*).

The species has a range in the number of stigmata but neither this nor any other morphological or geographical feature has been identified to correlate with colony appearance in photographs. However, it is not known what the colonies with zooids fully extended and appearing as white streaks would look like when contracted. Further, the zooids of colonies appearing as blue-purple in photographs always are contracted (in one case they also are in their vegetative phase). Possibly when extended they would appear as characteristic white streaks in colourless test.

Pseudodistoma fragile: Monniot 1987 seems not to be distinct from the present species. Monniot has recorded about 40 stigmata, although in the figured specimen (Monniot 1987, Fig. 5A) they are not so numerous, being near the top of the range recorded for the Australian specimens (see QM GH4167 from South Australia and QM

FIG. 19: *Pseudodistoma gracilum* n.sp. — **a**, zooid showing fine transverse branches from ventral longitudinal muscles, bunched male follicles and ovary halfway down posterior abdomen, and brood pouch (QM GH4955); **b**, contracted zooid (QM G10092); **c**, posterior end of posterior abdomen showing heart, the insertion of the longitudinal muscles, and vascular appendices (QM G11989). Scales: **a**, **b**, 1.0mm; **c**, 0.5mm.

FIG. 20: *Pseudodistoma inflatum* n.sp. — zooid (QM G9636). Scale: 1mm.

GH4955 from Lihou Reef in the Coral Sea). The fact that one of the colonies with the maximum number of stigmata is from southern Australia and the other from the Coral Sea tends to support the view that the New Caledonian and Australian specimens are conspecific.

Pseudodistoma fragile Tokioka, 1958 (from Japan) has similar fragile colonies and similar zooids to the present species. However, the Japanese species has greenish-yellow (rather than blue or white) living zooids, the long curved brood pouch contains up to 5 embryos (rather than one), and the larvae have a trunk 2.3 to 2.6mm long (instead of 1.75mm in the New Caledonian specimen). Apart from the size difference, the larvae of the Japanese species and the present one are similar. Larvae with a large trunk are not unusual in this genus, but the absence of median ampullae and the limited number of lateral ampullae is.

Pseudodistoma inflatum n.sp.
(Fig. 20. Plate 4f)

DISTRIBUTION

TYPE LOCALITY: New South Wales (South Solitary Is. rock faces 10m, coll. N. Coleman 27.9.76, AMPI 184, holotype QM G10157; Julian Rocks, Byron Bay, reef, 15m, coll. N. Coleman 29.3.75, AMPI 158, paratype QM G9472).

FURTHER RECORDS: New South Wales (Byron Bay, AM Y2002; Coffs Harbour, QM G9636). Queensland (Ngeering Reefs off Mooloolabah, QM GH5666–7).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies, to 3cm in maximum extent and 2cm high, are flat-topped and mushroom-like or sessile cushions with rounded margins, or wedge shaped narrowing to the upper free margin. The surface sometimes is raised into ridges and rounded to conical elevations, or divided into flat-topped lobes. Sand is present in the centre of the colony, just beneath the surface in the base, becoming less crowded and removed from the surface toward the top of the colony. Sand always is absent from the surface layer of test, which is opaque (in preservative) and contains a white cloudy suspension.

Living colonies are opaque, orange-red over each zooid and bright yellow between them. In preservative they are grey and firm.

INTERNAL STRUCTURE: Zooids are small and slender, often less than 1cm long when contracted. Atrial and branchial siphons are about the same size, and both apertures are bordered by 6

well defined rounded lobes. The longitudinal muscles extend in a wide band along each side of the abdomen and posterior abdomen. The heart is at the posterior and of the posterior abdomen the vascular stolon is relatively short.

There appear to be about 20 stigmata per row, however the exact number could not be determined owing to contraction of the thorax. The oesophagus is long, and the conspicuously 4-chambered stomach is in the anterior half of the posterior third of the abdomen. Gonads, when present, are in the anterior half of the posterior abdomen, the testis follicles in 2 clumps, one anterior and one posterior to a large ovum. Sometimes the anterior clump of testis follicles extends up into the abdomen alongside the gut loop. However in other specimens there is a gap between the anterior testis follicles and the posterior end of the abdomen. Larvae are not known.

REMARKS

This species appears to be indigenous to the southern (temperate) half of eastern Australia. Like the tropical species *P. aureum* and *P. arborescens* Millar, 1967, and *P. opacum* and *P. novaezelandiae* (from New Zealand), it has a long oesophagus. It most closely resembles *P. aureum* from which it is distinguished by its irregular opaque colonies with sand in the basal half, and the posterior position of its gonads.

Pseudodistoma oriens n.sp.
(Fig. 21. Plate 5a)

Pseudodistoma cereum: Kott, 1972b, p.173 (part, not specimens from Elliston Bay < *P. pilatum* n.sp.).

DISTRIBUTION

TYPE LOCALITY: Victoria (Port Phillip Heads Channel, 20m very fast current, on ledges, common, coll. J.E. Watson 25.11.76, holotype MV H306; paratypes QM GH4953).

FURTHER RECORDS: Western Australia (Rottnest I., WAM 859.83 *QM GH2134*; Geographe Bay, WAM 923.83). South Australia (Waldegrave I. — SAM E2115 E2116 Kott 1972b; off Cape Jaffa, SAM E2525; St. Vincent Gulf, QM G9287). Victoria (Port Phillip Heads, QM GH116).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies consist of stalked, pointed heads (up to 6cm long), the stalk usually longer than the head. Although most of the specimens in the examined material are solitary, the holotype has a number of stalked heads attached to a basal membrane. Stalks are up to 10cm long. Usually they are leathery and wrinkled with an outer hard cuticle, tapering to the base (MV H306, QM GH4953, SAM E2115 E2116). A few of the specimens have short, cylindrical stalks with some embedded sand (WAM 859.83 923.83). Zooids are conspicuous with the atrial openings toward the free end of the head. The branchial openings are closer to the stalk. The zooids bend at right angles so that, despite the orientation of the thoraces, the posterior ends extend down into the stalk, as is usual for most stalked aplousobranch species (Kott 1989).

Living colonies are said to be 'horizon red'. In preservative the test is translucent and the zooids pink to orange, subsequently fading to opaque cream.

INTERNAL STRUCTURE: Zooids are small, the thorax and abdomen (contracted) together are about 1mm long but about 3 times that length when partially relaxed (SAM E2115). About 20 longitudinal muscles extend along each side of thorax, abdomen and posterior abdomen. On the posterior abdomen the longitudinal muscles are in a wide, conspicuous band along each side and these continue onto the vascular stolon. Unperforated pharyngeal areas are anterior and posterior to the 3 rows of stigmata. The 2 posterior rows each have about 22 stigmata and the anterior row has an additional 5 or 6 perforations continuing anteriorly along the mid-dorsal line. The stomach, with the usual 4 longitudinal grooves, is halfway down the abdomen, and a long duodenal region and an oval posterior stomach are in its posterior half. A narrow mid-intestine is in the pole of the gut loop. A rectal valve is at the base of the ascending limb of the gut loop, which extends to about halfway up the thorax, ending in a bilabiate anus. Mature male follicles are in a long series in the posterior half of the posterior abdomen in specimens from Waldegrave I. collected in October (SAM E2116). The small (2 or 3 egg) ovary is anterior to the testis follicles and well separated from them. Immature follicles can

f

be seen irregularly branching off the vas deferens in the posterior half of the posterior abdomen in specimens from Hotspot collected in June (SAM E2115).

In the type material from Port Phillip Heads collected in November (MV H306; QM GH4953), and the specimen from Geographe Bay collected in January (WAM 923.83) there are one or 2 embryos being incubated in the distal part of the oviduct at top of the abdomen behind the postero-dorsal corner of the thorax. These embryos become very large, project from the side of the abdomen, and distort the zooid (the abdomen as well as the thorax). However there is no brood pouch constricted from the side of the zooid.

The larval trunk is variable, from 1.1 to 1.7mm long, and the tail winds three quarters of the way around it. A large, almost spherical yolk mass occupies a large part of the trunk, and the larval pharynx and gut are at the posterior end. An otolith and ocellus are present. The 3 median adhesive organs are large, sessile, consisting of an eversible, hollow axial cone depressed into the larval trunk. One mature larva from the specimen from Geographe Bay (WAM 923.83) has 5 adhesive organs, and 4 rounded ampullae from each lateral line. Other larvae examined from the same specimen lot lack the lateral ampulllae, and have the usual 3 adhesive organs.

Juvenile, presumably replicate, zooids are present in the stalk of a developing colony lobe.

REMARKS

Pseudodistoma oriens has long-stalked colonies like those of many specimens of *P. candens*, zooids have a similar long vascular stolon behind the posterior abdomen, and the species are sympatric for part of their range (viz. southern Australian waters). *Pseudodistoma oriens* is distinguished by its more robust zooids with wider bands of longitudinal muscles along each side of the posterior abdomen and vascular stolon, and the arrangement of its testis follicles in the posterior half of the posterior abdomen, its sessile larval adhesive organs, and its translucent test. Another sympatric species, *P. australe* is distinguished by its larvae, its lobed colonies and short vascular stolon.

The testis follicles branch off both sides of the vas deferens and when mature appear as a double or triple series in the posterior part of the posterior abdomen. This distinguishes the species from others with testes follicles in a single series posteriorly or bunched in the anterior part of the abdomen.

The large colonies of *P. africanum*: Millar, 1962 resemble those of the present species. However, all the specimens assigned to this South

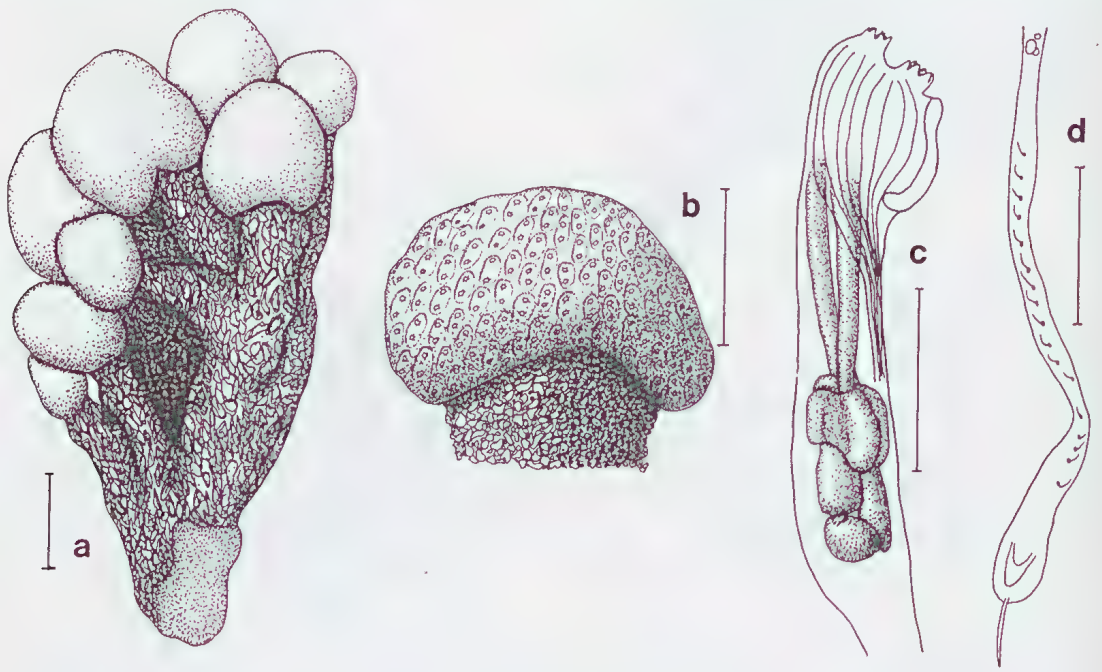

FIG. 22: *Pseudodistoma pilatum* n.sp. (paratype QM GH922) — **a**, colony; **b**, colony lobe, showing apertures (QM GH922); **c**, **d**, zooid. Scales: **a**, **b**, 1cm; **c**, 1mm; **d**, 2mm.

African species (Millar 1954, 1962) may not be conspecific. Larvae are known only for large colonies from Natal (Millar 1962), and these, although not fully developed, appear to have ampullae developing and resemble larvae of *P. candens* rather than those of the present species.

The short conical or spherical colonies from Western Australia (WAM 859.85) with sand in the basal half of the colony, but without the long tapering stalk, could be distinct, although their larvae are the same as those of the present species.

Pseudodistoma pilatum n.sp.
(Fig. 22. Plate 5b–d)

Pseudodistoma cereum: Kott 1972b, p.173 (part, not specimens from Waldegrave I < *P. oriens* n.sp.).

DISTRIBUTION

TYPE LOCALITY: South Australia (Ward I., 20–25m, coll. S.A. Shepherd 31.3.82, holotype SAM E2114 *QM GH921*, paratype QM GH922; 1–5m, paratype QM GH1296; Golden I., paratype QM GH4140; Cathedral Rock, paratype SAM E2409).

FURTHER RECORDS: South Australia (Elliston Bay — Kott 1972b SAM E2410; Nora Creina Bay SAM E2113).

DESCRIPTION

EXTERNAL APPEARANCE: The colony has solid branching, more or less cylindrical, stalks up to 1cm in diameter, and up to 2cm long, arising from a solid basal test mass. The upper free end of each stalk has a rather shallow, circular to elongate cap-like head, convex on its upper surface. In the stalk sand is present around the zooids, and the stalk and projects up into the centre of the head. The surface layer of test on the head is translucent, free of sand, and in preserved specimens contains small yellow pigment cells. Zooids open onto the upper surface of the head, each zooid with its 2 apertures close together in a small oval area. Living specimens are yellow to pink, with a sandy stalk.

INTERNAL STRUCTURE: Zooids are long, the thorax and abdomen together up to 3mm, of which the abdomen is about two-thirds. The posterior abdomen is often about 1.5cm long, with a fine sometimed forked vascular stolon from its posterior extremity. However, it is often contracted. About 20 distinct longitudinal muscles extend from the thorax to the tip of the posterior abdomen. There are about 20 stigmata in each of the 3 rows. The oesophagus is rather long, and the quadrilateral stomach is in the posterior half (rather than the middle) of the middle third of the abdomen. The small ovary is just anterior to the small male follicles which in extended zooids, are in a single series in the posterior half of the posterior abdomen although with contraction the follicles become bunched into 2 or 3 rows. A small ovary is anterior to follicles halfway down the posterior abdomen. The U-shaped heart is in the posterior tip of the posterior abdomen.

REMARKS

The species is distinguished from *Pseudodistoma acuatum* by its flat-topped (rather than pointed) lobes; the colour of the colonies ; the presence of sand in the central test; the number of stigmata per row (only 8 in *P. acuatum*). *Pseudodistoma opacum* (Brewin 1950), from New Zealand also has only 9 or 10 stigmata per row, its lobes are sessile rather than stalked, and it lacks the sand embedded in the present species.

Pseudodistoma pulvinum n.sp.
(Fig. 23. Plate 5e,f)

DISTRIBUTION

TYPE LOCALITY: South Australia (Ward I., in caves, 8m, coll. N. Holmes 12.4.83, holotype SAM E2411 *QM GH2396*, paratypes QM GH2397).

FURTHER RECORDS: South Australia (Flinders I., QM GH2300; Ward I., QM GH2423).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are sessile cushions about 1.5cm thick, fixed by most of the basal surface, and with rounded margins. The zooids open all over the more or less flattened upper surface. The test is soft and gelatinous. Living specimens are usually a translucent golden colour, although one specimen (QM GH2423) is pink. In preservative colonies are white to grey with minute black pigment cells throughout.

INTERNAL STRUCTURE: Zooids are threadlike. Extended, the thorax and abdomen are of equal length, together about 3mm long and the posterior abdomen about 1cm. One or two fine vascular processes of various lengths project from the posterior end of the zooid. About 15 longitudinal muscles extend along each side of the zooid, to the posterior end of the posterior abdomen (on each side of the heart), not extending onto the vascular processes. Sometimes the posterior abdomen is drawn up into a short, thick tapering mass behind the gut loop. Twenty-five stigmata are in the second and third rows, and at the dorsal

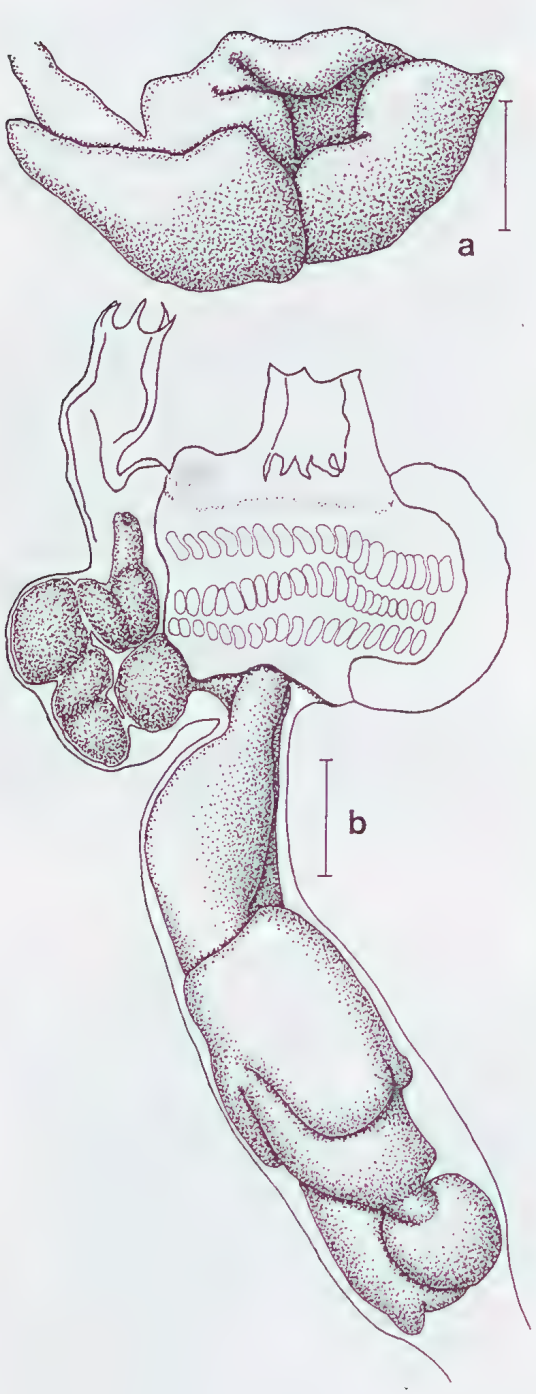

FIG. 23: *Pseudodistoma pulvinum* n.sp. — **a**, colony (QM GH2423); **b**, zooid, thorax contracted (QM GH2300). Scales: **a**, 1cm; **b**, 0.2mm.

end of the anterior row additional stigmata extend it along each side of the mid-dorsal line. The oesophagus is short, the stomach is halfway down the short abdomen, the duodenal area is relatively long, and an oval posterior stomach is in the pole of the gut loop. The rectal valve is conspicuous. A small ovary is present halfway down the posterior abdomen (see QM GH2300), but testis follicles have not been detected in any of the examined specimens.

REMARKS

The test is firmer than that of *Pseudodistoma gracilum*, the colonies are smaller, and their appearance in life with their golden translucent and slightly iridescent test is different. The dark pigment cells in the preserved material also helps to distinguish them.

Genus **Anadistoma** n.gen.

Type species: *Anadistoma attenuatum* n.sp.

The genus is erected to accommodate species with 3 rows of stigmata, transverse thoracic muscles as well as longitudinal ones, a smooth stomach, a long oesophagus with the stomach more than three-quarters of the distance down the abdomen, and gonads in the posterior abdomen. These muscular zooids with their long oesophageal neck suggest a relationship with the genus *Eudistoma* (Polycitoridae) rather than *Sigillina* (Holozoidae; see Kott 1985). The possession of these eudistomid characters together with the relatively large zooids, may mean that the relationship of this genus with *Pseudodistoma* is not as close as the presence of 3 rows of stigmata and the position of gonads in the posterior abdomen suggest.

It is unfortunate that only one specimen lot of this monotypic genus is available, and that it has no larvae which could help to confirm its relationships.

Anadistoma attenuatum n.sp.
(Fig. 24)

Pseudodistoma cereum: Kott, 1963, p.77.

DISTRIBUTION

TYPE LOCALITY: New South Wales (Montague South, near Eden, 94m, coll. CSIRO cruise CC/34 1938C, holotype AM Y1315, paratypes AM Y2212).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The living colonies appear to have been spherical up to 5cm in diameter. The lower half is impregnated with sand, which becomes more sparse toward the upper surface. Sand is absent from the upper part of the colony, where the test is very soft and delicate. The zooids open around the upper half of the colony and converge toward the centre of the base.

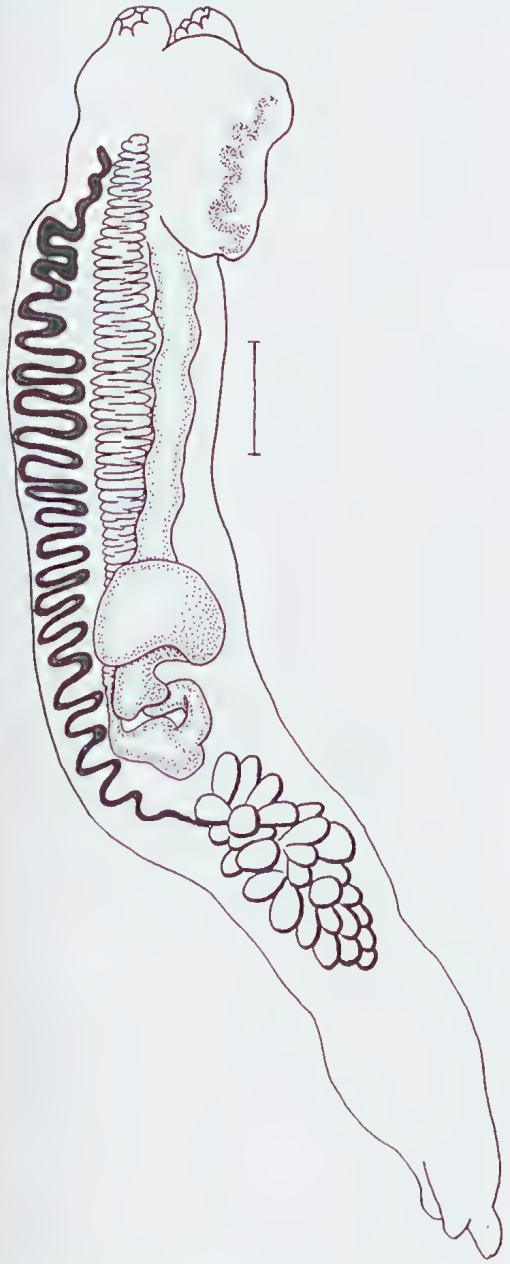

FIG. 24: *Anadistoma attenuatum* n.gen. n.sp. (holotype AM Y1315) — contracted zooid showing bunched male follicles. Scale: 0.5mm.

INTERNAL STRUCTURE: The zooids are large, and robust, up to 1cm even when contracted, and probably about 3 times that length in extended condition. The thorax and abdomen together are at least two-thirds of the total length of the zooids. The vascular stolons are very short. Both siphons are well developed with distinct lobes around the apertures and sphincter muscles. The 20 strong longitudinal muscles on the thorax extend in wide bands along each side of the abdomen and posterior abdomen. Beneath the longitudinal muscles on the thorax is an almost continuous coat of about 50 horizontal, circular muscles. About 25 long, narrow stigmata are in the second and third rows. The first row of stigmata has more perforations, and is longer, extending forward along each side of the mid-line at its dorsal end. The oesophagus is long and wrinkled in these contracted specimens. The relatively large smooth-walled stomach is in the posterior fifth or sixth of the abdomen. A wide duodenal region, and a narrow mid intestine are at the end of the descending limb of the gut loop, and an oval posterior stomach is in its pole. A rectal valve is at the proximal end of the ascending limb of the gut loop. The rectum, convoluted and pleated in these specimens, accompanies the vas deferens and the oesophagus up the long oesophageal neck to about halfway up the pharynx.

Gonads are in the anterior half of the posterior abdomen, the large, pyriform male follicles crowded together, around a small ovary.

REMARKS

There is no other taxon that displays the unique combination of characters that distinguish this monotypic species from the genus *Pseudodistoma*. It is the only species of the family in which the abdomen and thorax together are longer than the posterior abdomen.

Family POLYCLINIDAE Milne Edwards, 1842 *emend.*

The family (type genus *Polyclinum* Savigny, 1816) originally was established for genera with the gonads in a posterior abdomen. In the present more restricted sense, the family is further defined by the presence of cloacal systems, new families being erected to accommodate the genera with separately opening atrial apertures formerly comprising the subfamily Euherdmaniinae (see above).

Polyclinidae Milne Edwards, 1842 has priority over Synoicidae Hartmeyer, 1908 (type genus *Synoicum* Phipps, 1774) which Hartmeyer erroneously had proposed as the senior synonym because *Synoicum* was the earliest described genus of the family.

In the family Polyclinidae, the branchial aperture has a regularly lobed rim, but the atrial aperture is not lobed. The latter opens into the common cloaca, guided by an anterior lip that either is a projection from the body wall anterior to the opening, or is produced from the anterior border of the opening. Minute branchial papillae that may be relicts of internal longitudinal vessels are present in one genus only (*Polyclinum*). The oesophagus is short, with the stomach halfway down the abdomen. Gonads are in the posterior abdomen. These consist of a small ovary and numerous male follicles, either bunched or in longitudinal series. Larvae are small (the trunk usually less than 1mm). They have an otolith and ocellus, 3 small median adhesive organs, ectodermal ampullae and vesicles. Fertilisation is in the atrial cavity and incubation is either in the atrial cavity, or in a thoracic brood pouch constricted from the body wall.

In the Ascidiacea prolific replication results in fast growth rates and rapid responses to environmental pressures, large sized colonies, strengthening of the test allowing for greater diversity in shape than would otherwise be possible, and a high level of colony integration, organisation and the evolution of cloacal systems.

Evolutionary experiments with colonial systems occur in Polyzoinae (Stolidobranchia), and in Polycitoridae, Ritterellidae and Pseudodistomidae (Aplousobranchia), but only in exceptional cases (*Exostoma* and *Hypodistoma* see Kott 1990) are cloacal systems developed in these taxa. Nevertheless cloacal systems have evolved in a number of lineages in the Ascidiacea, viz. in some Holozoidae and all Polyclinidae and Didemnidae (in Aplousobranchia), and all Botryllinae (in Stolidobranchia).

In all these taxa the replicative process is prolific. However Polyclinidae may have particular advantages (possibly shared with Didemnidae) in flexibility and colony size and form that derive from the strength of the test, the amount of test in relation to zooid size and the use of embedded sand and other material to strengthen it. Some of the largest ascidians and the greatest diversity in shape and form of colonies occurs in this family (e.g. the three-dimensional reticulum of *Aplidium acroporum* n.sp., the large vertical buttresses of *Aplidium arboratum*. As well as extensive investing sheets and upright branched, lobed and convoluted colonies). Morphological structures of the test, independent of the overall colony habit, also occur to moderate interactions with the environment, and to insulate and protect the zooids and their apertures and enhance the advantages of the cloacal systems. Examples of this may be seen in *Synoicum castellatum* n.sp., *Aplidium craterif-erum*, and *A. lobatum* colonies with surface ridges and depressions (that protect the incurrent apertures), and upstanding cloacal apertures (that elevate the excurrent water high above the rest of the colony). It may be these morphological characteristics of the colony that have enabled Polyclinidae to adapt to a wide diversity of habitats resulting in the remarkable radiation of genera, especially *Aplidium*.

The relationships of most genera of Polyclinidae (*Polyclinum*, *Aplidiopsis*, *Sidneioides*) appear to be with Protopolyclinidae through *Polyclinum*. Branchial papillae, such as those in *Polyclinum* occur in *Monniotus*, and the stomach is similarly inclined and dorsally shorted. A curved oesophagus, smooth and obliquely or horizontally oriented stomach such as those found in *Polyclinum* are also in Holozoidae, but the larvae and the branchial sacs of Holozoidae are completely different.

However, Ritterellidae also has a claim to a close phylogenetic relationship with some (but not all) species of *Polyclinum*, *Aplidiopsis*, *Sidneioides*, and *Synoicum*, through the presence of a median dorsal papilla which protrudes from the body wall just posterior to the atrial siphon as in *Ritterella compacta*. Certain *Ritterella* species (e.g. *R. compacta*, *R. cornuta*, *R. multistigmata*, and *R. papillata*) also have papillae on the transverse branchial vessels as in *Polyclinum*. *Aplidium* with its vertical barrel-shaped and longitudinally folded stomach also may be related to the Ritterellidae.

Thus, it is possible that even the newly defined family Polyclinidae is polyphyletic, the evolution of cloacal cavities proceeding in parallel in several evolutionary lines, viz. from both Protopolyclinidae and Ritterellidae. Convergence, rather than a phylogenetic relationship, may also be the reason for similarities in the cloacal cavities and atrial apertures of many species of *Synoicum* (e.g. *S. suarenum* n.sp.) and those in the *angolanum* species group of *Eudistoma* (Polycitoridae; see Kott 1990).

The 6 genera of the family Polyclinidae are *Polyclinum*, *Aplidiopsis*, *Synoicum*, *Sidneioides*,

Aplidium and *Morchellium*. The last 2 are separated from the others by their vertical barrel-shaped stomachs, which in *Aplidium* have a longitudinally folded wall. *Morchellium* has a mulberry-like stomach and 8 branchial lobes. Eight branchial lobes also occur in some species of *Aplidium* that were formerly assigned to the genus *Sidnyum*, which here is regarded as a synonym of *Aplidium*. Branchial papillae are present only in *Polyclinum*. The position of the ovary (in the thorax) distinguishes *Sidneioides* from the other genera. *Polyclinum*, *Aplidiopsis* and *Sidneioides* are distinguished from the other genera by a constriction between abdomen and posterior abdomen. Embryos are known to develop in a brood pouch in some species of *Polyclinum*, *Synoicum* and *Aplidium*. The brood pouch (when it occurs) of the former is at mid-thoracic level, while that of the last 2 is at the postero-dorsal corner of the thorax.

The differences between *Polyclinum* and *Aplidiopsis* are often obscured. There is a particular problem in assigning those species of *Polyclinum* in which the branchial papillae are ephemeral (e.g. *P. vasculosum*). In *Polyclinum* the longitudinal muscles do not continue past the thorax to form ventral abdominal and posterior abdominal bands as they do in some species of *Aplidiopsis*, but there also are species of *Aplidiopsis* with longitudinal muscles present only on the anterior part of the zooid. The small usually horizontal, and twisted gut loop of *Polyclinum* as opposed to the large vertical one of *Aplidiopsis*, is the only reliable difference, but sometimes it is difficult to interpret.

The larvae of *Aplidium* differ from those of the other genera in that they have ectodermal vesicles that separate directly from the larval ectoderm around the anterior end of the trunk. In all the other genera the ectodermal vesicles branch off a dorsal and a ventral pair of tissue strands that trail posteriorly through the larval test, one strand on each side of the dorsal and ventral mid-lines, respectively.

Aplidium is the most diverse of the genera, and is common in tropical and temperate waters of all the oceans. *Synoicum* is moderately diverse and commonly encountered in Australian waters. Both *Aplidiopsis* and *Polyclinum* are cosmopolitan. *Polyclinum* contains species with wide geographical ranges, but *Aplidiopsis* and *Morchellium* species are seldom recorded and most are known from restricted locations in temperate waters (see below). *Sidneioides* is known only from two species, one from Japanese and the other from Australian waters.

Key to genera of Polyclinidae

1. Stomach wall longitudinally folded .. *Aplidium*
   Stomach wall not longitudinally folded 2
2. Branchial lobes 8 ..... *Morchellium*
   Branchial lobes 6 3
3. Ovary in the thorax ..... *Sidneioides*
   Ovary not in the thorax 4
4. Constriction present between abdomen and posterior abdomen 5
   Constriction not present between abdomen and posterior abdomen ..... *Synoicum*
5. Gut loop voluminous, not twisted and always vertical; branchial papillae never present ..... *Aplidiopsis*
   Gut loop small, twisted and usually horizontal; branchial papillae usually present ..... *Polyclinum*

Genus **Polyclinum** Savigny, 1816

Type species: *Polyclinum constellatum* Savigny, 1816

The test is usually soft in preservative. Sand, though embedded in the surface layer in some species, is seldom present internally. The atrial lip is often long and muscular. It usually arises separately from the body wall anterior to the anteriorly directed opening which has a distinct sphincter muscle. However, in some species the lip is produced from the anterior rim of the aperture. The body musculature consists of fine longitudinal bands that fade out on the posterior half of the thorax and do not extend onto the abdomen and posterior abdomen. Transverse muscle bands are in the transverse branchial vessels between the rows of stigmata, but no other transverse muscles are present. Branchial papillae are present on the transverse vessels, although in a few species they are present only in juvenile zooids. The thorax is always longer than the abdomen, usually with from 10 to 20 rows of stigmata, and the atrial cavity is relatively large. The oesophagus curves ventrally to enter the smooth-walled stomach along its short dorsal margin. The whole gut loop is bent horizontally from the oesophagus, and at the same time twisted so that the descending limb

is anterior (or ventral) and the ascending limb posterior (or dorsal). The distal tip of the loop is also curved to the left and dorsally. The stomach is small and smooth-walled.

The gonads are in a sac-like posterior abdomen constricted off from the abdomen by a narrow neck. The vas deferens has a complicated course, joining the abdomen in the concavity on the left side of the centre of the pole of the gut loop. It then curves around the ventral border of the descending limb of the gut loop (the mid-intestine) and continues around on the right side of the gut, following its bend at the pole before extending anteriorly on the inside of the rectum to the atrial cavity. The male opening is at about mid-thoracic level near the bilabiate anus. The small ovary is usually surrounded by male follicles. The course of the oviduct has not been determined.

In many species there is degree of polymorphism in the shape of the posterior abdomen which is related to the reproductive condition of the zooid. In zooids reproducing sexually it is short and sac-like, joined to the left side of the gut loop by a narrow neck. It contains bunched testis follicles, a small ovary, and (in the posterior end) the V-shaped heart. In zooids in the vegetative phase the posterior abdomen is long and strap-like. It is horizontally divided into buds that develop into replicated zooids. These long posterior abdomina often occur on zooids around the outer margin of colonies where growth is taking place, while in other parts of the same colony the posterior abdomina are short sacs. One or 2 moderately long, narrow vascular stolons extend out into the test behind the posterior abdomen.

Embryos are incubated either in the peribranchial cavity, or in a brood pouch constricted off from it at mid-thoracic level, near the anus. Larvae are small (the trunk length usually 0.6mm or less — only *P. glabrum* has a trunk more than 1mm long). They are unusually conservative throughout the genus, with 4 pairs of lateral ampullae, usually 4 median ampullae alternating with the 3 median adhesive organs, and clusters of epidermal vesicles along each side of the dorsal and ventral mid-lines. On each side, the dorsal vesicles are on terminal branches of a long strand of epidermal tissue extending back through the test from a point near the dorsal ampulla. Clusters of vesicles on each side of the trunk near the base of the tail are on the terminal branches of similar strands extending posteriorly on each side of the mid-ventral line, from about halfway along the ventral surface. Columnar epidermal cells form a cap on the tip of the ampullae, and sometimes on the outer wall of the epidermal vesicles (see *P. vasculosum*). The adhesive organs in this genus have long, narrow stalks and shallow epidermal cups and axial cones.

The branchial papillae are said to be the relicts of the papillae that support internal longitudinal vessels in the Cionidae, Diazonidae, and Phlebobranchia. Sometimes they are present in the younger zooids of a species but are not present in the larger, older ones (see *P. vasculosum* below).

Systems are either large with complex branching canals or they are simple and circular. Generally in this genus, sand (when it is present) is either embedded throughout the test, or it forms a sandy coating in the surface layer of test completely enveloping the colony. Naked areas on the upper surface over the zooid systems, such as occur in many *Aplidium* species, are known only in a few species (e.g. *P. festum* Hartmeyer, 1905 from Mauritius and *P. solum* nom.nov.).

Problems in defining the species of this genus result from a high degree of intrageneric conservatism in both larval and zooid morphology, as well as changes that occur with growth such as polymorphism in the posterior abdomen and changes (e.g. loss of papillae) in the branchial sac. The present studies suggest that wrong assignation of specimens on the basis of zooid similarities has resulted in apparent intraspecific variability in the presence of sand in the colony. The presence or absence of sand, and the form of the systems, together with the number of rows of stigmata and the number per row, and occasionally the shape of the posterior abdomen, constitute the principal means of distinguishing species.

The colonies of species of this genus often grow large, forming gelatinous masses up to 20cm long, and this may also contribute to confusion in species definitions.

Species of *Polyclinum* usually have a wide geographic range. The genus is well represented in Australia being especially diverse in temperate waters where there are some common indigenous species (Table 5).

Key to species of *Polyclinum* recorded from Australia

1. Sand embedded in surface test 2
   Sand not embedded in surface test 10

2. Branchial sac wide with 18 or more stigmata per row 3
   Branchial sac narrow with fewer than 18 stigmata per row 5

3. Stigmata in more than 15 rows 4
Stigmata in not more than 15 rows .... *P. saturnium*

4. Zooids in a single circular system per colony lobe; brood pouch not present .... *P. orbitum* n.sp.
Zooids not in a single circular system per colony lobe; brood pouch present ..... *P. tsutsuii*

5. Atrial lip from upper border of the aperture. 6
Atrial lip from body wall anterior to the aperture 7

6. Colony with thin keel-like base .... *P. terranum* n.sp.
Colony without thin keel-like base .... *P. tenuatum* n.sp.

7. Systems conspicuously circular .... *P. incrustatum*
Systems not conspicuously circular 8

8. Stigmata up to 17 per row; with brood pouch .... *P. marsupiale*
Stigmata up to 12 per row; without brood pouch 9

9. Stigmata in 14 or more rows .... *P. solum* nom. nov.
Stigmata in fewer than 14 rows ..... *P. fungosum*

10. Atrial lip from upper border of the opening ..... *P. nudum* n.sp.
Atrial lip from the body wall anterior to the opening 11

11. Living colonies with translucent test; branchial papillae present ..... *P. glabrum*
Living colonies with opaque test; branchial papillae not present ..... *P. vasculosum*

Species recorded from waters adjacent to Australia

Polyclinum circulatum Sluiter, 1909 from Indonesia is a flat, circular plate, sometimes with a short stalk. Three to 5 circular systems, each with 5 to 8 zooids are in each colony. Zooids have about 10 rows of 10 stigmata. Branchial papillae are not recorded. Stalks sometimes have sand but heads are naked.

Polyclinum complanatum Herdman, 1899 (> *P. depressum* Herdman, 1899) appears not properly assigned. It has a long abdomen distinguishing it from genera of Polyclinidae. It is said to have incubatory pouches packed with embryos (Herdman, 1899). It could be a species of *Pseudodistoma*, no other known genus having a brood pouch as well as both a long abdomen and a posterior abdomen, although brood pouches of *Pseudodistoma* cannot be said to be 'packed with embryos'. The number of rows of stigmata is not known.

Polyclinum constellatum Savigny, 1816 from Mauritius, has flat-topped colonies attached by a small part of the basal surface. They are without sand, and have branching double rows of zooids radiating from circular common cloacal apertures. *Polyclinum festum*: Kott and Goodbody, 1982, from Hong Kong, with large potato-shaped colonies, blue-green when living, and crowded stellate systems of zooids, may be a synonym of *P. constellatum*. The loaf-like *P. constellatum*; Michaelsen, 1923 from Hong Kong and other specimens from Hong Kong, Mozambique and St. Helena, all with radiating rows of zooids are probably also conspecific with *P. constellatum*, as Michaelsen (1923) thought them to be. The branchial sacs are relatively wide with 18 to 22 (16 to 18: Kott and Goodbody 1982) stigmata. Small papillae are present on the transverse vessels. Further probably conspecific populations are from the Atlantic (Florida, the West Indies and possibly south to Rio de Janiero), and the West Indian Ocean to Ceylon (Michaelsen 1923).

Polyclinum constellatum: Tokioka, 1967 has indistinct systems. Although the zooids, like those of *P. constellatum*, have 14 to 18 rows of stigmata with 15 to 20 stigmata per row (more in specimens from the Palau Is), and distinct branchial papillae, the sandy coating on all Tokioka's examined specimens suggests they are not *P. constellatum*.

Polyclinum crater Sluiter, 1909 has simple circular systems, each with the branchial apertures surrounding a central cloacal aperture in a surface depression. The body wall has strong muscles. About 9 rows of 6 to 8 stigmata are present. The outer surface of the test is smooth and slippery.

Polyclinum festum Hartmeyer, 1905 (see also Millar 1975) from Mauritius has flat-topped colonies with circular systems. Sand is present externally (around the base and outer border, and sometimes along radii across the upper surface) as in *Aplidiopsis amoyensis* and related species (see below).

Polyclinum hospitale Sluiter, 1895, from Thursday I. is smooth on the upper surface, with debris and sand on the under surface. Sluiter did not see either cloacal openings or systems, but both are likely to be present — the atrial opening having the usual pointed lip associated with a cloacal system. The body wall is muscular — an unusual condition for *Polyclinum*. The gut loop (including the oesophagus) is shorter than usual for this genus, and is not twisted. There are no branchial papillae. It is probable that the colony is an *Aplidium* species.

Polyclinum gelidus (Monniot, 1987) from New Caledonia, with a brownish-yellow colony resembles *P. vasculosum*, having no branchial papillae. Monniot (1987) assigned the species to the genus *Aplidiopsis*,

TABLE 5. Summary of characters of species of *Polyclinum* recorded from Australia

Species	Biogeographic range[1]	Range anticlockwise around Australia	Surface	Systems	Atrial lip[2]	Stigmata: no. rows; max no./row	Branchial papillae	Larval trunk median length (mm)	Other

however its abdomen is characteristic of the genus *Polyclinum*.

? *Polyclinum nigrum* Herdman, 1906, from Sri Lanka, has a smooth shiny surface, and circular depressions in the surface, which may have contained zooids, although these are not present. There is no evidence of the genus of this colony.
The type specimen of this species from Port Jackson (AM U33, *Polyclinum nigrum* Herdman, 1899) and another (MV F59436) from the same locality have been re-examined and found to be *Sigillina* (see *S. nigra*: Kott 1990). The zooids are contracted, possibly causing Herdman to misinterpret the length of the oesophagus.

Polyclinum sundaicum (Sluiter, 1909), from the western Pacific (Fiji, Indonesia and Hong Kong: see Kott 1981, Kott and Goodbody 1982) are small stalked or sessile sandy colonies each containing one or more circular systems. They are distinguished from *P. fungosum* and *P. solum* nom. nov. by their large branchial papillae.

Polyclinum tralatica Sluiter, 1913 from Aru I. is an irregularly lobed, cylindrical, gelatinous mass along a bryozoan or gorgonian stalk. Its outer surface grey with a pale violet hue. The body wall is moderately muscular. The species resembles *P. vasculosum* in the absence of branchial papillae and in its 10 rows of about 10 to 12 stigmata

Polyclinum fungosum Herdman, 1886
(Fig. 25)

Polyclinum fungosum Herdman, 1886, p.190.
Polyclinum marsupiale: Kott, 1976, p.60.
Synoicum hypurgon: Kott, 1976, p.62.

DISTRIBUTION
NEW RECORD: Victoria (Bass Strait, QM G12748).
PREVIOUSLY RECORDED: Victoria (Westernport — MV F59365 F59431–2 Kott 1976). New South Wales (Port Jackson — Herdman 1886).

DESCRIPTION
EXTERNAL APPEARANCE: The small (about 5mm diameter) newly recorded specimen from Bass Strait is mutilated, possibly stalked, mushroom-shaped, with a firm, translucent test, an external layer of sand, and some sand internally. The zooids are crowded, obscuring the form of the systems. Larger (to 4cm diameter) colonies (MV F59431) are soft, mushroom-shaped, fixed by a small part of base or with a small stalk. In preservative they are collapsed, with a wrinkled, furrowed surface. Sand encrusts the sides and under surface, is in patches on the upper surface, and is sparse internally.

INTERNAL STRUCTURE: Zooids are about 3 to 4mm long, with a narrow thorax, small horizontal

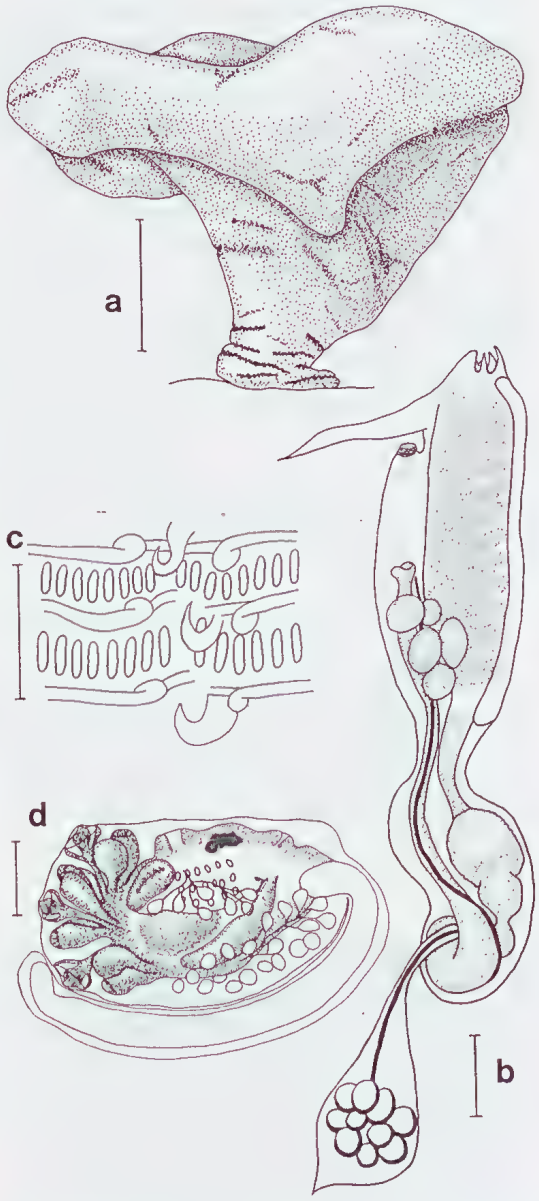

FIG. 25: *Polyclinum fungosum* — **a**, colony (MV F59431); **b**, zooid with embryos in atrial cavity (MV F59431); **c**, dorsal part of portion of branchial sac showing kink in transverse vessels (MV F59431); **d**, larva (QM G12748). Scales: **a**, 1cm; **b**, 0.5mm; **c**, 0.2mm; **d**, 0.1mm.

gut loop, and sac-like posterior abdomen. The branchial lobes are triangular and pointed, and the atrial lip is long and narrow. Six to 10 fine longitudinal muscles are present on the anterior half of the thorax. Fine circular muscles are present in the transverse vessels between the rows of stigmata. The branchial sac is narrow, with 12 or 13 rows of 12 to 14 short oval stigmata. A short expansion of the transverse vessels on each side of the dorsal languets in some of the zooids could have resulted from contraction of the transverse muscle fibres in the vessels. The branchial papillae on the margin of the transverse vessels are small, shallow, triangular protrusions about one to every one and a half stigmata.

The gut forms the usual small, horizontal loop with a smooth-walled stomach, a long duodenal area and an oval posterior stomach. The sac-like posterior abdomen has a short neck and is pointed posteriorly. Male follicles are clustered behind and to the side of a relatively large ovary, which has up to 5 relatively large eggs and some small ones.

The Bass Strait specimen contains about 12 embryos in the right peribranchial cavity. Larvae have a row of median ampullae alternating with the adhesive organs and 4 lateral ampullae along each side. A ventral pair of rows of large epidermal vesicles expands into a postero-ventral cluster on each side beneath the tail. Corresponding rows are present on each side of the mid-dorsal line. The larval trunk is 0.4 to 0.5mm long, and the broad tail barely reaches its anterior end. Each of the ampullae has a terminal cap of columnar cells, although these are more conspicuous on the long, narrow median ampullae than on the rounded lateral ones.

Remarks

The type specimen of this species (Herdman 1886) is a circular, dome-shaped cushion, 1.6cm high, 3.3cm in maximum dimension. It has a hard sandy external coating. Zooids are crowded in the colony, and systems were not determined. Long, narrow stigmata are in 10 to 12 rows of about 12. Herdman did not observe any branchial papillae. The gut loop is small, with a smooth stomach, and although Herdman did not observe it to be horizontal, it has the short oesophagus and short mid-intestinal region that is characteristic of *Polyclinum*, and it also has a polyclinid, stalked, sac-like posterior abdomen with the ovary surrounded by male follicles. The species apparently is assigned to the correct genus rather than belonging to *Synoicum* as Millar (1982) suggested.

Some of the zooids of the holotype contained larvae. Although the exact number present is not recorded it appears that there were more than one or 2 and that they were in the atrial cavity, as a brood pouch is not mentioned.

The crowded zooids, the narrow thorax, the number of rows of stigmata, and the form of the colony of the holotype and the newly assigned and recorded specimens are all identical. The only point of difference is the presence of small inconspicuous branchial papillae in the Victorian specimen. Herdman may have overlooked these as they are difficult to detect.

Tropical sandy species such as *P. tsutsuii* and *P. saturnium* have broader branchial sacs with more stigmata per row. *Polyclinum incrustatum* n.sp. is distinguished from the present species by its slightly more stigmata per row (14) and more rows (15), and by its large tongue-like branchial papillae. The sympatric *P. marsupiale* also has larger branchial papillae, more rows of stigmata and more stigmata per row, and thinner more irregular colonies than the mushroom-like ones of the present species. It also has a brood pouch.

Polyclinum glabrum Sluiter, 1895
(Fig. 26)

Polyclinum glabrum Sluiter, 1895, p. 168; 1913, p. 71.

Distribution

New Records: Western Australia (Montebello Is, QM GH5507). Queensland (Capricorn Group, QM GH5038–41 GH5563; Townsville Harbour, QM GH2094; Lizard I, QM GH319 GH5024 GH5036–7 GH5042).

Previously Recorded: Indonesia (Sluiter 1895, 1913).

Description

External Appearance: The colonies from shallow reefal habitats are irregular cushions, or robust, spreading sheets, up to 1cm thick and 6cm in maximum dimension, with soft, transparent test entirely free of sand, and orange zooids. Collector's notes describe them as 'soft orange' and 'chinese orange' (Ridgeway 1886). In preservative these colonies are transparent and yellowish to a translucent, soft grey or beige colour. Common cloacal apertures are relatively crowded, especially around the borders of the colony. Some protrude from the surface on conical prominences, but others are sessile, irregular and extensive openings. Atrial lips of zooids are

in the test around the rim of the cloacal openings. In some preserved zooids, the tips of the atrial lips contain dark pigment. Cloacal systems are crowded, and zooids also are crowded along each side of the canals that radiate from the cloacal apertures.

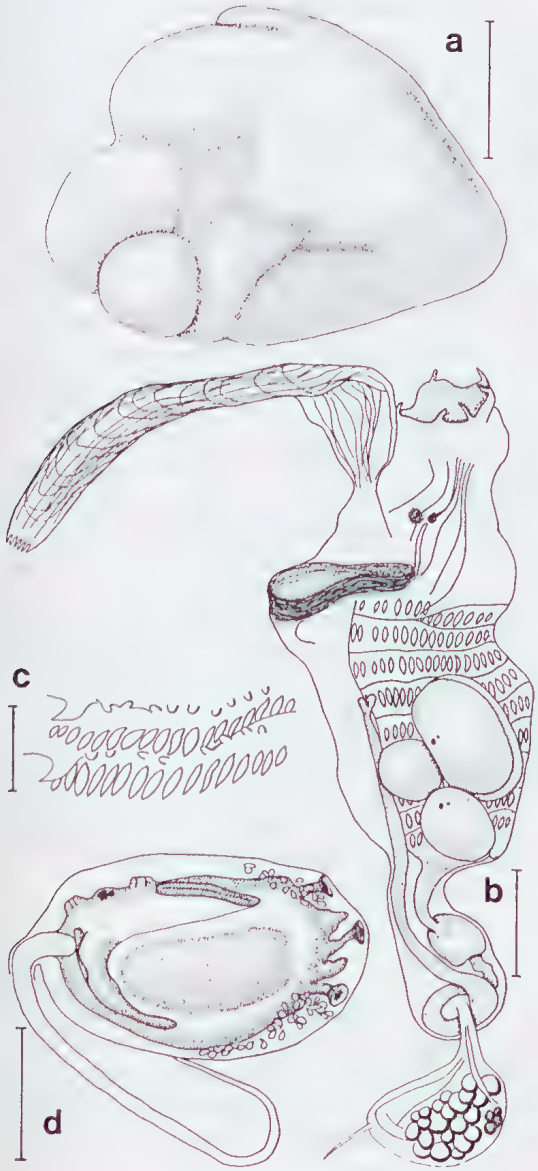

FIG. 26: *Polyclinum glabrum* — **a**, colony (QM GH319); **b**, zooid relaxed with embryos in atrial cavity, anterior rows of stigmata obscured (QM GH319); **c**, portion of branchial sac showing dorsal languets and branchial papillae on the transverse vessels (QM GH319); **d**, larva (QM GH5563). Scales: **a**, 2cm; **b**, 0.5mm; **c**, 0.2mm; **d**, 0.4mm.

The colony from the Montebello Is is a large (maximum dimension 4cm) flattened slab which, with a light coating of sand on one side, appears to have been lying on its side when collected. Originally it probably stood upright, attached to pebbles by its narrow base. Systems open on both sides of the colony, which has an irregularly subdivided surface.

INTERNAL STRUCTURE: The zooids are about 4mm long, with a large thorax, a small horizontal gut loop, and a spherical to tapering (QM GH2094) posterior abdomen. The atrial lip is long and moderately broad, and contains fine longitudinal muscles. It extends along the roof of the cloacal canal toward the cloacal aperture and ends in a single point or a fringe of up to 6 minute papillae. A small median papilla projects from the body wall just behind the atrial aperture. Fine longitudinal muscles are present over the anterior part of the thorax. There are 12 or 13 rows of up to 19 oval stigmata with the maximum number in rows 2 to 6. Rounded branchial papillae are on the transverse vessels, about one and a half per stigma. The gut loop is small and horizontal. The posterior abdomen is attached to it by a relatively long neck. The posterior abdomen is either sac-like or (sometimes) it tapers to a short vascular stolon that projects from its posterior end behind the heart.

Three embryos are in the posterior end of the atrial cavity of specimens from the Capricorn Group collected in December, Lizard I. specimens collected in July, and 6 in those from Montebello Is collected in August. Larvae have a long (1.2mm) trunk with median and lateral ampullae anteriorly, and dorsal and ventral clusters of ectodermal vesicles along each side of the mid-line.

REMARKS

Sluiter (1895) described the type specimen as a large naked cushion, less than 1cm thick, with a smooth surface, without conspicuous systems, and with conspicuous branchial papillae. Although he believed this colony to be juvenile, both male and female gonads are present. The cloacal systems in the present specimens are so crowded that they are hard to distinguish, and in view of the similarities in the branchial sac, and the smooth-surfaced colonies without sand, they seem to be conspecific with the Indonesian species.

The irregular shape and soft consistency of the colony distinguishes it from the more regular and robust *P. constellatum*. The branchial papillae, the more numerous stigmata per row, and the

transparent test of the living specimens distinguish it from *P. vasculosum*. The larval trunk is unusually long for this genus.

Sluiter's specimen from Ambon (1895) was grey in preservative with a reddish-violet glimmer, but this does not occur in other known colonies.

Polyclinum incrustatum Michaelsen, 1930
(Fig. 27. Plate 6a,b)

Polyclinum neptunium: Michaelsen, 1930, p.542 f. incrustatum. Kott, 1963, p.83 (part, South Australian specimen).

DISTRIBUTION

NEW RECORDS: South Australia (Golden I., SAM E2145 *QM GH4185*; Hopkins I., QM GH4192; Margaret Brock Reef, SAM E2531; Perforated I., QM GH4141; The Gap, QM GH4163; Cathedral Rock, QM GH4145 GH5209; Nuyts Arch., SAM E2528). Victoria (Portland Harbour, MV 59434 F59437).

PREVIOUSLY RECORDED: Western Australia (Bunbury, Albany — Michaelsen 1930). South Australia (Reevesby I. — Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are thick sheets, sometimes with swellings, high convoluted ridges and irregularities on the surface. The common cloacal apertures are sessile or on small raised prominences about 5mm apart. The zooids open all around the ridges and irregularities, as well as on the flat part of the colony. Sand is present in a single layer in the surface test. Sometimes it is interrupted by the prominences raising the cloacal apertures above the surface, but in other specimens these are also covered with sand. Embedded sand is only sparse in the internal test between the zooids, but the grains are moderately crowded between the zooid systems. Cloacal cavities are small, circular, and are confined to the area beneath the cloacal aperture. The zooids are arranged around these cavities. The atrial lip of each zooid in the system extends across the roof of the cavity and is inserted into the test around the rim of the cloacal aperture. The branchial apertures open in a small surface depression surrounding each cloacal prominence.

INTERNAL STRUCTURE: Zooids are about 8mm long, with the narrow thorax about three-quarters of the total length. A small horizontally oriented gut loop has an almost spherical to long, cylindrical posterior abdomen connected to it by a short narrow neck. There is a narrow vascular stolon from the posterior end of the posterior abdomen.

The atrial lip is long and narrow. It has denticulations on its free tip. The usual muscular atrial siphon projects forward to open into the base of the cloacal cavity around its outer margin.

The anterior part of the zooid, including the branchial lobes and atrial lip, contains black pigment. Fine longitudinal muscles (about 8) extend from the branchial siphon to about halfway down the thorax. Fifteen rows of 13 or 14 longish-oval stigmata have transverse vessels with flat tongue-shaped papillae along the margin, about one to every stigma. These are delicate and hard to see without staining.

The oesophagus is short, and curved ventrally to the small, smooth-walled, horizontal stomach. The distal end of the gut loop is bent to the left. The narrow neck connecting the posterior abdomen is attached in the pole of the gut loop in the concavity of this distal bend of the loop. It appears to have been drawn up onto this side of the gut loop, as the vas deferens moves to the outer curve of loop and follows the curve of the rectum where it lies adjacent to the duodenum, stomach and oesophagus. The rectum terminates in a 2-lipped anus halfway up the branchial sac.

Up to 20 male follicles surround the ovary in the sexual posterior abdomen. The long (3mm) vegetative posterior abdomen is in colonies collected in April from Perforated I. (QM GH4141) and in February from Franklin I. (SAM E2528).

Up to 7 embryos are clumped together in the atrial cavity of zooids from Portland Harbour (MV F59434) but the collection date is not recorded. Larvae have a trunk nearly 0.6mm long, with median and lateral ampullae, and postero-ventral and antero-dorsal vesicles.

REMARKS

Zooids of this species are relatively large and that, together with their distinct circular systems helps to distinguish them from other species.

Michaelsen (1930) believed specimens from Western Australia with embedded sand throughout to be a form of *P. neptunium* Hartmeyer, 1912 for which the type locality is South Africa. Hartmeyer's species has a more or less spherical stalked head, and, with the exception of one specimen (which has sand in the lower half of the colony), is without sand either on the surface or embedded (see also Millar 1962). The abdomen is clavate when mature, and long and cylindrical when immature, the zooids are in circular to double-row systems, and have conspicuous branchial

FIG. 27: *Polyclinum incrustatum* — **a**, general view of colony (QM GH4185); **b**, close-up view of surface of colony with common cloacal apertures surrounded by branchial apertures (MV F59434); **c**, zooid in colony showing atrial lip in test above cloacal cavity, and branchial aperture amongst sand adhering to outer surface (QM GH4185); **d**, abdomen and vegetative posterior abdomen (QM GH4141); **e**, portion of branchial sac showing branchial papillae (QM GH4141). Scales: **a**, 2cm; **b**, 2mm; **c–e**, 0.5mm.

papillae. Michaelsen (1930) and Kott (1963) assigned the western and southern Australian material to this species largely on the basis of the long vegetative abdomen, which now is known to occur in other species of this genus.

Michaelsen identified 2 forms, *Polyclinum neptunium* f. typicum being the form in which sand is absent altogether or present only in the basal layer; and *P. neptunium* f. incrustatum with sand throughout. The present sessile specimens from South Australia, with moderate amounts of embedded sand between the systems, with an almost continuous layer on the surface, and with strictly circular systems and raised cloacal apertures, appear to be conspecific with *P. neptunium*: Michaelsen, 1930 f. incrustatum recorded from Bunbury and Albany, but not with the stalked South African species. The stalked specimen from Western Australia (Kott 1963), does have characters in common with the South African species, but is distinguished by the flattened upper surface. It resembles *Polyclinum circulatum* Sluiter, 1909, and may be a synonym. There is insufficient data available for the Shark Bay specimens of *P. neptunium* f. typicum (see Michaelsen 1930) with double rows systems and sand in the lower half of the colony to assign it to a species.

Polyclinum marsupiale Kott, 1963

? *Polyclinum macrophyllum*: Kott, 1963, p. 82 (part, specimen from Rottnest I.).

DISTRIBUTION

NEW RECORDS: Western Australia (Albany, QM GH5059). South Australia (Kingston, QM G10138). Victoria (Deal I., QM G10175; Portland, MVF 59433).

PREVIOUSLY RECORDED: Western Australia (Rottnest I. — AM Y1330 Kott 1963). South Australia (Victor Harbour — Kott 1963); Tasmania (Hunter I. — Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are soft, rather irregular sheets, up to 4cm in maximum extent, investing weed; to upright structures to 1m high with vertical flattened ribs (QM G10175). The zooids are in circular systems. The branchial apertures open to the surface between the sand grains that form an otherwise continuous coat over the outer surface. Sand also is sparsely distributed in the soft, transparent internal test that forms thin partitions between the crowded zooids. Dark pigment in the anterior part of the zooid can be seen where the branchial apertures open to the surface. Common cloacal apertures protrude from the surface.

The colonies from Albany (sea grass beds) are small (less than 1cm in diameter) sessile and upright, covered with a layer of sand, and with characteristic zooids in circular systems.

INTERNAL STRUCTURE: The zooids are small, 3 to 4mm long, with a relatively large conspicuous thorax more than half the total length. Longitudinal muscles are fine and extend only over the anterior part of the thorax (about the first 3 rows of stigmata). The branchial lobes are triangular. The tongue-shaped, moderately muscular atrial lip, undivided to tridentate terminally, projects in front of the atrial aperture.

Stigmata are oval, and are in 12 or 13 rows with a maximum of 16 or 17 per row. The branchial papillae, on the transverse vessels are well-defined, tongue-shaped, and about one per stigma. The gut loop is small, horizontal with the pole of the loop curved to the left and the short neck of the posterior abdominal sac attached to the dorsal (concave) side of the gut loop.

The newly recorded specimen collected in September has 2 or 3 well developed embryos in the brood pouch which projects from the thorax about halfway up the thorax (opposite the sixth row of stigmata).

The larval trunk is 0.5mm long. It has the usual median and lateral ampullae and postero-ventral and antero-dorsal bunches of numerous ectodermal vesicles. The vesicles continue anteriorly in a row along each side of the median line. The tail is wound halfway around the trunk. The caps of columnar cells are more conspicuous on the narrow median ampullae than the rounded lateral ones.

REMARKS

Polyclinum marsupiale is a temperate species,

FIG. 28: *Polyclinum marsupiale* (QM G10138) — **a**, zooid with embryos in brood pouch; **b**, branchial sac showing papillae; **c**, larva. *Polyclinum nudum* — **d**, colony (QM GH5388); **e**, zooid with embryos in atrial cavity and ovary surrounded by male follicles in posterior abdomen (QM GH5387); **f**, thorax (holotype QM GH5391); **g**, atrial lip (holotype QM GH5391); **h**, larva (holotype QM GH5391). Scales: **a**, **f**, 0.5mm; **b**, 0.25mm; **c**, 0.2mm; **d**, 2cm; **e**, **g**, 1mm; **h**, 0.1mm.

characterised by the layer of sand in the surface test, black pigment in the zooids, soft internal test, and crowded circular systems of small zooids. The tropical *P. saturnium* also has small zooids, and they have a similar pharynx with 8 to 12 rows of 18 to 20 stigmata per row. However they lack the brood pouch of the present species.

The small colony from Rottnest I. assigned to *P. macrophyllum* : Kott, 1963 is similar to the newly recorded one from Albany and may be a specimen of the present species.

Kott (1963) reported an incipient brood pouch in a specimen from Heron I. she assigned to *P. marsupiale*. This has not been confirmed, and that specimen is possibly one of *P. saturnium*.

The other temperate sandy species with dark pigment in the zooids, *P. incrustatum*, has firmer colonies, larger zooids, more conspicuous circular systems, more rows of stigmata, and fewer per row.

Polyclinum nudum n.sp.
(Fig. 28d–f. Plate 6e–g)

DISTRIBUTION

TYPE LOCALITY: New South Wales (Coffs Harbour, old jetty piles, 0.5m, coll. AIMS Bioactivity Group 18.2.88, holotype QM GH5391; 16.2.88, paratype QM GH5387.

FURTHER RECORDS: New South Wales (Coffs Harbour, QM GH5388 GH5390).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are cushion- or dome-shaped, to about 9cm in diameter and up to 1.5cm thick. The test is soft and gelatinous, translucent internally, but with an opaque layer where the anterior ends of the zooids are crowded together at right angles to the surface.

Colonies are dark, black in preservative, and black immediately after removal from the substrate. The photograph of a colony *in situ*, however, shows it to be whitish green (QM GH5387) or yellow (QM GH5388), or brownish red with yellow zooids (QM GH5390). Zooids are in irregularly branching relatively short double rows, one row along each side of canals that converge to common cloacal apertures about 5mm apart. These apertures are sometimes sessile in the preserved colonies, but in the living colony they protrude from the surface on conical elevations. Occasionally there are a few patches of sand adhering to the surface test, but most of the surface is naked, and there is no embedded sand.

INTERNAL STRUCTURE: The zooids are large, about 1cm long, of which the thorax and abdomen together are about half, and the stalked posterior abdomen the other half. Only very fine longitudinal muscles extend over the anterior part of the thorax, including an extensive prestigmatal area.

The branchial siphon is long, with large lobes around the aperture and a long, prebranchial area. The atrial tongue is long, extending out from the upper rim of a large opening. Its tip is variable, sometimes being a single point, or with up to 12 minute papillae along a straight edge. The muscles in the atrial lip form a fine, irregular meshwork. A small, median dorsal papilla is present just posterior to the atrial opening.

There are 14 to 16 rows of up to 18 relatively short, oval stigmata. Small branchial papillae (about one per stigma) are on the transverse vessels. The gut forms the usual small, horizontal loop characteristic of this genus. The vas deferens also makes the characteristic loop around the outside of the bend of the gut loop before extending around onto the other side.

The long, club-shaped posterior abdomen has a long narrow neck, joining it to the abdomen. It contains up to 24, loosely bunched, large pear-shaped male follicles. A small ovary is from one third to half the distance down the posterior abdomen, surrounded by male follicles. A long vascular stolon extends back from the tip of the posterior abdomen.

Up to 7 embryos at a time are crowded in the posterior half of the right peribranchial cavity of the holoytpe. They are progressively advanced postero-ventrally in the postero-dorsal quarter of the atrial cavity, then anteriorly and dorsally in the postero-ventral quarter.

A tailed larva has a trunk 0.5mm long, with the tail wound about three-quarters of the way around it. A large otolith and ocellus are in the atrial cavity. A lateral ampulla is on each side of each of the 3 median adhesive organs. Also there is a median dorsal and a median ventral ampulla. Patches of epidermal vesicles are antero-dorsal and postero-ventral.

REMARKS

The present species is unusual in having the atrial tongue arising from the upper rim of the atrial aperture (as in *Polyclinum orbitum* n.sp. and *P. tenuatum* n.sp.). Like *P. orbitum* n.sp., the larvae lack median ampullae.

The long club-shaped posterior abdomen is unique. It differs from that of those *Polyclinum* spp. which have a long posterior abdomen only

in the vegetative phase. The long posterior abdomen of the present species has mature sexual organs in it, and in that it resembles *P. solum* nom. nov. However, although the latter species has similar colonies, it is distinguished from the present one by its smaller zooids, relatively small posterior abdomen with fewer and smaller male follicles, fewer stigmata in each row (i.e. a narrower thorax), and its lack of branchial papillae.

The colonies resemble some more fleshy ones of *P. vasculosum*. However, the cloacal canals of the present species do not branch as much, the atrial tongue is not separate from the opening, it has branchial papillae, and it has a long posterior abdomen in its sexual phase.

Polyclinum orbitum n.sp.
(Fig. 29)

DISTRIBUTION
TYPE LOCALITY: Victoria (Ninety Mile Beach, 10 km SW Seaspray, 560 m offshore calcenarite reef, 12m depth, fast currents, coll. J.E. Watson August 1977, holotype QM G12730, paratype QM G12731).
FURTHER RECORDS: None.

DESCRIPTION
EXTERNAL APPEARANCE: Colonies are a number of trumpet-shaped lobes up to 1cm diameter at the wide, free end, and 2cm long, narrowing basally to a common stalk. The outer surface is covered with sand, but there is no sand in the soft internal test. Zooids form a single circular system of up to 8 zooids in each lobe. Branchial apertures, around the outer rim of the upper free border are directed laterally. The test is raised into a rounded swelling over the anterior end of each zooid, around the margin of the upper, free end of each lobe. A protuberant cloacal aperture is in the centre of the upper surface.

INTERNAL STRUCTURE: Zooids are up to 1cm long, of which the thorax and abdomen together comprise less than half the length. The abdomen is small, and there is a particularly long, narrow neck, about half the length of the posterior abdominal sac, attaching it to the gut loop. Thus, posterior abdomina lie in the basal common stalk of the colony.

The branchial lobes are well defined. The atrial lip is large and pointed, rising from the anterior rim of the anteriorly directed atrial aperture. Eighteen to 20 rows of stigmata each have 22 to 24 stigmata. Transverse vessels have conspicuous rounded papillae (about one to every 1.5 stigmata).

The particularly small gut loop is horizontal. The ovary is surrounded by and mixed with male follicles in the tear-drop-shaped to long fusiform posterior abdomen.

One or two embryos are in the peribranchial cavity of the type specimens. The larval trunk is 0.45mm long, and the tail is wound three-quarters of the way around it. The 3 median adhesive organs are wide and shallow with thick stalks and wide, shallow axial cones. Four lateral ampullae with enlarged ectodermal cells over the tip of each are present along each side of the adhesive organs. Median ampullae are not present. A row of ectodermal vesicles are present along each side of the mid-ventral and mid-dorsal lines, but a postero-ventral clump was not detected. The otolith is larger than usual, and in one larva 3 otoliths are present (QM G12731).

REMARKS
The species is distinguished by its simple circular systems, the shape of the colonies, the long neck connecting the posterior abdomen to the gut loop, and the large branchial sac. Millar (1977) described a similar *Polyclinum* from the Brazilian Shelf which, however, has a narrow branchial sac with only half the stigmata of the present species.

The species is unusual in having the atrial lip continuous with the anterior rim of the opening. The larvae are unusual in the genus in the absence of median ampullae, and in having fewer ectodermal vesicles than usual. These larvae are also amongst the smallest known in this genus.

The colonies resemble those of *Synoicum stewartense* (Michaelsen, 1924) from New Zealand (see Millar 1982). Generic characters, including the absence of branchial papillae, as well as its purple colour, distinguish the New Zealand species.

DISTRIBUTION

NEW RECORDS: Western Australia (Dongara, WAM 280.83). Queensland (Heron I., QM GH5034–5 GH5260 GH5568).

PREVIOUSLY RECORDED: Suez, Red Sea (Savigny 1816, Hartmeyer 1915, Michaelsen 1920). Philippines (Baliwasan — USNM 11648 Tokioka 1967).

DESCRIPTION

EXTERNAL APPEARANCE: The re-examined colonies from the Philippines as well as the Heron I. colony are cushions up to 1.0cm in diameter, with a layer of sand externally. The internal test is soft and transparent. Zooids are arranged in circular systems, and the surface layer of sand is interrupted where they open to the surface. Sometimes the zooids extend along each side of short canals that radiate from the apertures to form stellate systems. The zooids are yellow in freshly preserved material with purple in the test above them. In the living specimens the zooids are 'burnt amber' or 'aster purple' and the test translucent. One juvenile colony is recorded as having bright red pigment in the zooids and the test.

INTERNAL STRUCTURE: Zooids are about 4mm long, with a moderately long neck joining the posterior abdomen to the abdomen. The atrial lip

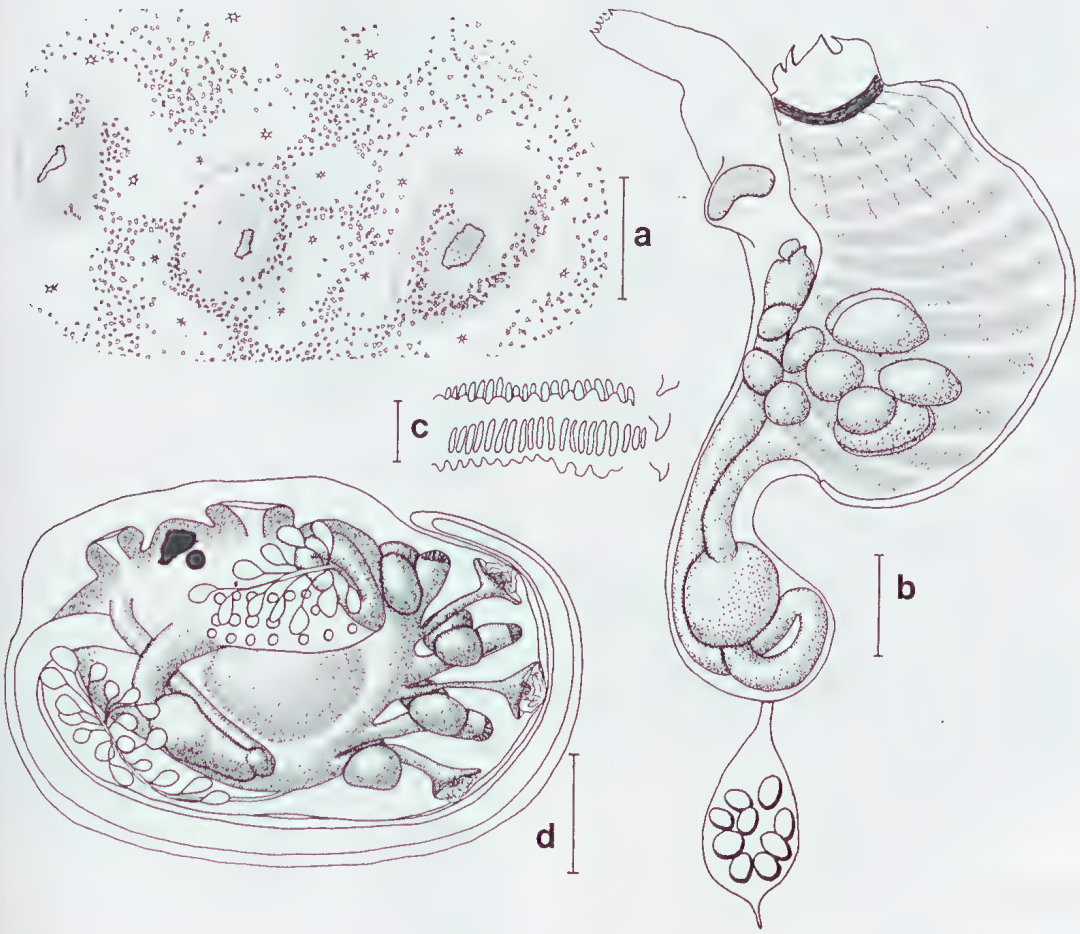

FIG. 30: *Polyclinum saturnium* — **a**, sandy surface of colony with large common cloacal apertures surrounded by branchial apertures (QM GH5034); **b**, zooid with 9 embryos in atrial cavity, abdomen twisted (QM GH5034); **c**, portion of branchial sac showing transverse vessels with papillae and dorsal languets (QM GH5035); **d**, larva (QM GH5035). Scales: **a**, 2mm; **b**, 0.5mm; **c**, 0.25mm; **d**, 0.1mm.

is moderately long and narrow with about 6 pointed denticulations on its terminal (straight) edge. Zooids have 8 to 12 rows of about 20 short, oval stigmata and about the same number of conspicuous, flat, tongue-shaped branchial papillae on the transverse vessels. These papillae are even more conspicuous anteriorly than posteriorly.

The gut forms the usual twisted loop. The bilabiate anus is halfway up the thorax. A group of about 8 large male follicles are clustered in a more or less spherical mass around the ova in the posterior end of the posterior abdomen.

About 5 embryos are scattered in the right peribranchial cavity of specimens collected from Bahiwasan (Philippines) in January (USNM 11540). Up to 10 embryos are present in the postero-dorsal quarter of the atrial cavity in specimens from Heron I. collected in May (QM GH5035). Tailed larvae have a trunk of 0.4 to 0.5mm, with the tail wound about three-quarters of the way around it. Median and lateral ectodermal ampullae have terminal caps of enlarged ectodermal cells. Paired rows of vesicles are antero-dorsal and postero-ventral.

REMARKS

The absence of the brood pouch distinguishes these specimens from *P. tsutsuii* (tropical) and *P. marsupiale* (temperate) which are also sandy, and have broad branchial sacs and circular or stellate systems. *Polyclinum incrustatum* and *P. solum* nom. nov. are also sandy species but they have narrower branchial sacs. The larvae have fewer ampullary vesicles than most other species of the genus.

The small specimen with only 8 rows of stigmata from Baliwasan assigned to *P. tsutsuii* by Tokioka (1967) seems more likely to be a specimen of the present species in which branchial sacs generally are shorter than in *P. tsutsuii*. The other small specimen (*P. vasculosum*: Tokioka, 1967 < *P. saturnium*) from Baliwasan has 10 to 12 rows of stigmata, as do the present colonies from Heron I. while *P. tsutsuii* has 14 to 16.

Polyclinum solum nom. nov.
(Fig. 31)

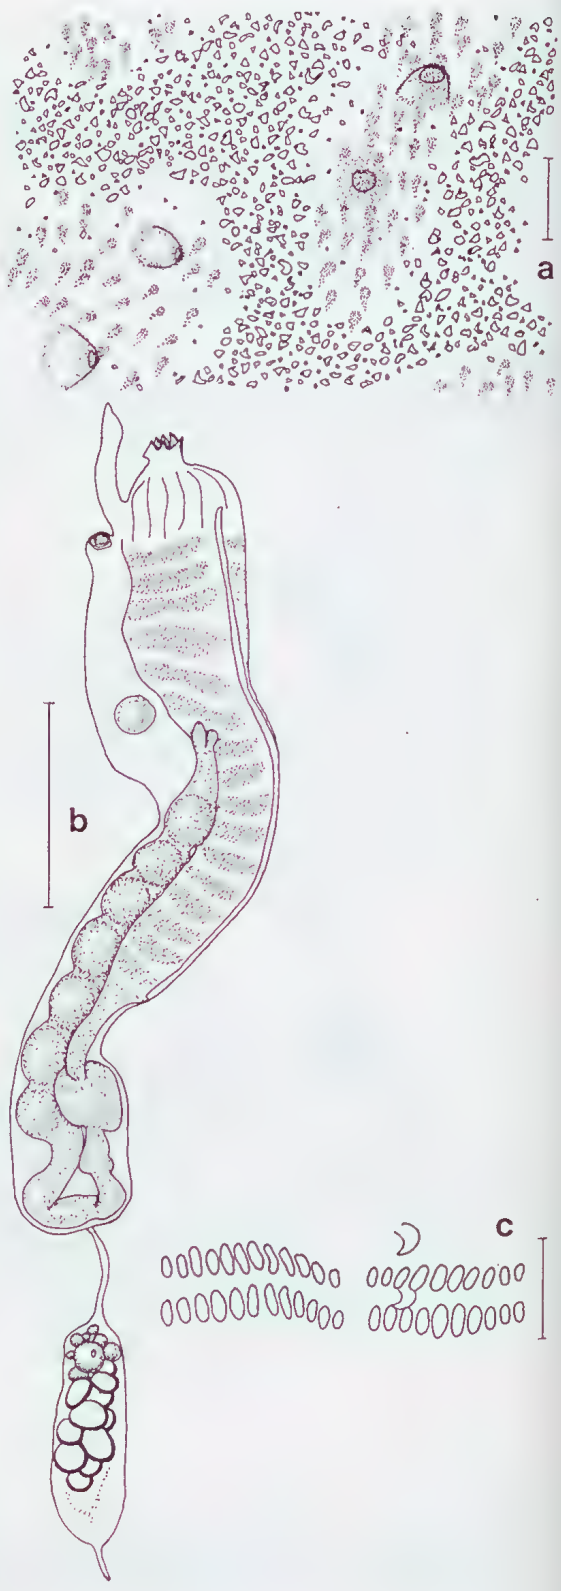

FIG. 31: *Polyclinum solum* nom. nov. — **a**, sandy surface of colony with protuberant common cloacal apertures surrounded by crowded branchial apertures (QM GH5023); **b**, zooid with single embryo in atrial cavity (QM G9293); **c**, portion of branchial sac (QM GH9293). Scales: **a**, 2mm; **b**, 1mm; **c**, 0.25mm.

DISTRIBUTION

NEW RECORDS: Queensland (Pt. Lookout, QM GH5273; Hervey Bay, QM G9293 G9295 GH4978–80; Tannum Sands S. of Gladstone, QM GH4977; Wistari Reef, QM GH5023; Heron I., QM GH5202 GH5273).

PREVIOUSLY RECORDED: Indonesia (Sluiter 1909).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are rounded cushions to 4cm in greatest extent and up to 1cm high. They have a single layer of sand grains adhering to the surface. Sometimes this is absent from the test over the systems, although it is present between and around them (QM GH5023). The internal test is very soft, transparent and free of sand. The cloacal apertures are on wart-like prominences about 3mm apart in the naked areas on the upper surface. Crowded zooids, some in short double rows, surround the cloacal apertures, and converge to them. Thoraces and abdomina are in the upper half of the colony and posterior abdomina in the lower half. There is no pigment in the test of the preserved specimens.

INTERNAL STRUCTURE: The zooids are slender, 6mm long, of which the thorax is about half. The abdomen is relatively short, but the loop is vertical rather than bending horizontally. The posterior abdomen is narrow and relatively long, more or less club-shaped, its posterior half slightly expanded. A fine vascular stolon extends from the tip of the posterior abdomen. Zooids contain minute dark pigment cells scattered through the body wall.

The 6 branchial lobes are triangular and pointed. A long, narrow atrial tongue extends from the body wall anterior to the muscular, forward-projecting atrial siphon. Six fine longitudinal muscles from the branchial siphon fade out on the anterior part of the thorax.

Fourteen to 18 rows of oval stigmata have 10 to 12 stigmata on the right and 12 to 14 on the left. There are some fine muscles in the branchial vessels, but there are no branchial papillae. The small smooth-walled stomach is halfway down the abdomen, with a moderately long duodenal area behind it. The vertical gut loop is twisted slightly so that the descending limb is ventral to the ascending limb, and the distal part of the loop is flexed slightly to the left. The rectum extends halfway up the thorax and the anal border is bilabiate.

Six to 10 male follicles are bunched or in an irregular double row in the posterior half of the long posterior abdomen, which is about twice the length of the abdomen. As they develop, they fill the whole of the posterior abdomen. The ovary is just anterior to them.

Colonies collected in November (QM GH4980) are in an active vegetative condition, those collected in May (QM GH4977) have mature male follicles.

REMARKS

Characteristics of the present species are the single layer of sand externally, the conical protuberant cloacal apertures, the narrow zooids with relatively few stigmata per row but numerous rows, the long narrow posterior abdomen with the gonads in its posterior half, testis follicles in an irregular double row, and the absence of branchial papillae. The holotype, from Indonesia, has a small tear-drop shaped posterior abdomen, like one of the juvenile colonies in the present collection (QM G9295). The Indonesian colony was stalked, and conical protruding cloacal apertures are not reported. However there is little else to separate the newly recorded specimens from it.

Polyclinum tenuatum n.sp. has similar (but smaller) crowded circular systems to the present species, but its zooids are smaller, branchial papillae are present, and the thorax is shorter. *Polyclinum constellatum*: Tokioka, 1967, has sand in the surface test, as does the present species. However, it has very numerous stigmata per row (15 to 20 and 40) and conspicuous branchial papillae. *Polyclinum saturnium* has similar colonies with prominent cloacal apertures and an external layer of sand. However it has a wide branchial sac with conspicuous papillae, relatively few rows of stigmata, and it lacks the narrow posterior abdomen of the present species.

Polyclinum solum nom. nov. replaces the name *P. sabulosum* Sluiter, 1909 for the present tropical species. The latter name is preoccupied by *Polyclinum sabulosum* (Lahille, 1890), which is a junior synonym of the northern hemisphere *Polyclinum aurantium* Milne Edwards, 1842.

Polyclinum tenuatum n.sp.
(Fig. 32. Plate 7a)

Synoicum papilliferum: Kott, 1963, p. 87.

DISTRIBUTION

TYPE LOCALITY: Western Australia (Shelly Beach, Nornalup, 29.1.39, holotype AM Y2261; paratypes AM Y1356).

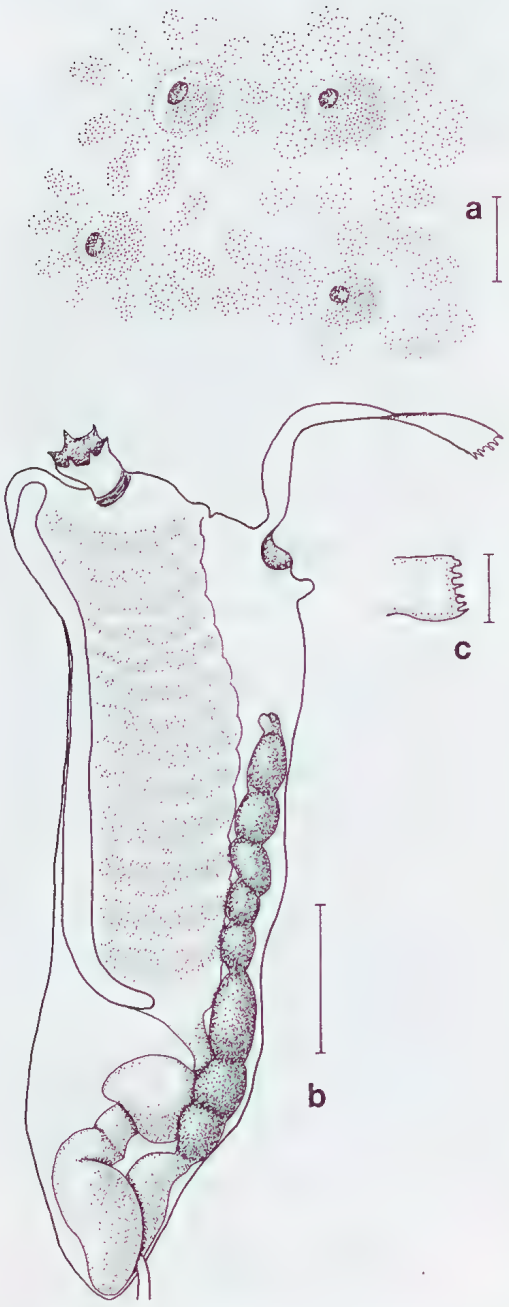

FIG. 32: *Polyclinum tenuatum* n.sp. — **a**, surface of colony showing zooids in circular systems with central common cloacal apertures (paratype AM Y1356); **b**, thorax and abdomen (QM GH5444); tip of atrial tongue (paratype AM Y1356). Scales: **a**, 1mm; **b**, 0.5mm; **c**, 0.1mm.

FURTHER RECORD: South Australia (Cape Jaffa, QM GH5444).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are fleshy sheets, up to 5mm thick, to 5cm in maximum extent, with an irregular outline, rounded borders, and a flat and even upper surface which has a light dusting of sand. The colonies are fixed to the substrate by irregular processes from the whole of the undersurface. Sand is sparse internally. Circular systems of 10 to 12 zooids have slightly protuberant common cloacal apertures in the centre of each system. Cloacal apertures are 2 to 3mm apart.

INTERNAL STRUCTURE: The thorax and abdomen are together about 3mm long. The posterior abdomen is short and sac-like or lengthened to a club-shape. Fine longitudinal muscles are confined to the anterior part of the zooid. The strap-like atrial tongue is produced forwards from the upper rim of the atrial siphon, which protrudes from the body wall. Five minute pointed papillae form a fringe along the straight tip of the atrial lip. A medial dorsal papilla projects from the body wall posterior to the base of the atrial siphon.

Thirteen rows of up to 12 relatively short, oval stigmata are separated by transverse vessels with about one conspicuous conical branchial papilla per stigma. The small, horizontal gut loop is twisted and the distal part of the loop curves forwards as is characteristic for the genus. The posterior abdomen, a short sac in its sexual phase, but long and club-shaped in the vegetative phase (QM GH5444), is attached by a narrow neck to the concavity of the distal curve of the gut loop.

REMARKS

Kott (1963), overlooking the branchial papillae and other characteristic polyclinid features (including the flexure of the gut loop and the constriction between abdomen and posterior abdomen), assigned these 3 colonies to *Synoicum papilliferum* on the basis of the dorsal papilla. This structure has since been found in many *Polyclinum* as well as *Synoicum* species.

The present species has a layer of sand on the upper surface, crowded circular systems, and the atrial lip from the upper rim of the aperture like *P. solum* from the central Queensland coast. However *P. solum* has a longer thorax with more rows of fewer stigmata, and lacks branchial papillae altogether. *Polyclinum terranum* n.sp. has similar branchial papillae and atrial lip, but its

zooids are larger, and its colonies have a keel-like structure anchoring them to the substrate.

Polyclinum terranum n.sp.
(Fig. 33. Plate 7b,c)

DISTRIBUTION
TYPE LOCALITY: Western Australia (Rockingham, 32°15.7S 115°37.1E, 15m, coll. AIMS Bioactivity Group 21.3.89, holotype QM GH5460).
FURTHER RECORDS: None.

DESCRIPTION
EXTERNAL APPEARANCE: The colony consists of extensive hard, robust zooid-bearing lamellae up to 1cm thick, 3cm across the upper surface and 6cm along its length, standing vertically above the substrate. Along the upper edge the thick zooid-bearing part curves over to form a round margin. Along the underside of the zooid bearing part, the colony abruptly changes to a keel-like flange (up to 0.5cm thick, 5cm deep) which is hard, brittle and stiff with embedded sand. This flange appears to have been embedded in sand, although here and there it suddenly increases in thickness to accommodate zooids, and it may have been above the surface of the substrate in those places.

The colony is complex, branched and folded so that lamellae lie in parallel against one other. Sometimes there are 2 basal keels attached to the one zooid-bearing part of the colony. Zooids are arranged in circular systems, about 3mm diameter, opening on the upper surface of the zooid-bearing part of the colony. Common cloacal apertures protrude from the surface. Patches of sand are present on the upper surface of the zooid-bearing part of the colony, and some is present internally, but it is sparse. The test is tough and zooids, tightly enclosed in it, are hard to remove. The atrial lip is inserted into the rim of the cloacal aperture and is particularly difficult to remove entire. In preservative the test is transparent, purple, but living specimens are a dark purple-brown, and opaque.

INTERNAL STRUCTURE: The thorax and abdomen together are about 4mm long, of which the abdomen is only about one quarter. Body wall musculature consists of about 6 fine longitudinal bands extending halfway down the thorax. Branchial apertures are small, with 6 pointed lobes. The atrial lip is long, moderately muscular with dorsal muscle bands extending along each side and transversely across the lip. The tip usually is pointed, terminating in 2 or 3 small papillae. The anterior part of the circular sphincter muscle of the atrial aperture is in the base of the atrial lip, and the lip is thus associated with the anterior rim of the aperture. A median dorsal papilla is behind the atrial aperture.

Sixteen rows of oval to rectangular stigmata with 15 in the middle rows are separated by transverse vessels containing the usual groups of transverse muscles. An extensive imperforate area of branchial wall is along each side of the endostyle. The transverse vessels have conspicuous, almost triangular branchial papillae, about one per stigma. The dorsal languets are small, only about twice the length of the branchial papillae.

The small gut loop has the usual twist distally, a smooth-walled stomach, long duodenum, and complicated course for the vas deferens. The bilabiate anus is halfway up the branchial sac. The posterior abdomen is tear-drop-shaped with a narrow neck attaching it to the abdomen. It contains mature gonads in the holoytpe colony, consisting of about 15 male follicles and 2 or 3 large eggs. Up to 2 embryos are in a brood pouch attached to the thorax by a narrow stalk, at the level of the anus.

Larvae have a trunk 0.7mm long with 2 median ampullae in each interspace between adjacent adhesive organs, 4 lateral epidermal ampullae on each side, and large postero-ventral and antero-dorsal clusters of epidermal vesicles on each side. Conspicuous caps of enlarged ectodermal cells are on the tips of the ampullae.

REMARKS
The present species, known only from its type locality off Rockhampton, resembles the southern Australian *P. incrustatum* and *P. tenuatum* in its circular systems. The latter species also has large branchial papillae and its atrial lip directly associated with the aperture.

Quite apart from the unique colony with its flat, brittle, keel-like extension projecting down into the substrate, *P. terranum* has more rows of stigmata and more stigmata per row than *P. tenuatum*. Although it has a similar number of stigmata to *P. incrustatum*, the latter species does not have a brood pouch. The brood pouch in the present species resembles that of *P. marsupiale* which, however, does not have the regular circular systems of the present species, and has fewer rows of stigmata and a slightly smaller (0.5mm trunk) larva.

? *Polyclinum laxum* Van Name, 1945, p.71.

DISTRIBUTION
NEW RECORDS: Western Australia (W. of Cervantes, WAM475.91 476.91. Queensland (Heron I., QM GH5609).
PREVIOUSLY RECORDED: Moorea, Tahiti (Monniot and Monniot 1987). New Caledonia (Monniot 1987). Japan (Tokhara Is — Tokioka 1954a; Osaka, Sagami Bay — Tokioka 1962). Marianas Is (USNM 11540 Tokioka, 1967). Korea (Rho 1971, 1975). ? Eastern Pacific (Gulf of California — Van Name 1945).

The species has a wide longitudinal as well as latitudinal range in the Pacific Ocean.

DESCRIPTION
EXTERNAL APPEARANCE: Some colonies (WAM475.91) are sessile, rounded to wedge-shaped lobes, the borders sometimes spreading out in sheets over the substrate, other colonies are sheet-like and investing (USNM 11540). The external sandy coating often is light and interrupted on the upper surface leaving bare patches. Sand grains are sparse in the internal test. The zooids are in a crowded layer around the outside of the colony. The external layer of sand is interrupted where the zooids open to the surface, and the darkly pigmented anterior ends of the zooids are seen, evenly spaced over the surface. Zooids are difficult to remove from the test.

The actual arrangement of zooids is difficult to determine in some colonies, but in others they are seen to be arranged in crowded circular systems with the atrial lip inserted around the rim of the central common cloaca. However, it is possible that some cloacal canals with zooids along each side, radiate from the apertures.

INTERNAL STRUCTURE: Zooids are about 3mm long, including the short, tear-drop shaped posterior abdomen with a short neck attaching it to the abdomen. There is a posterior vascular stolon from the posterior end of the posterior abdomen.

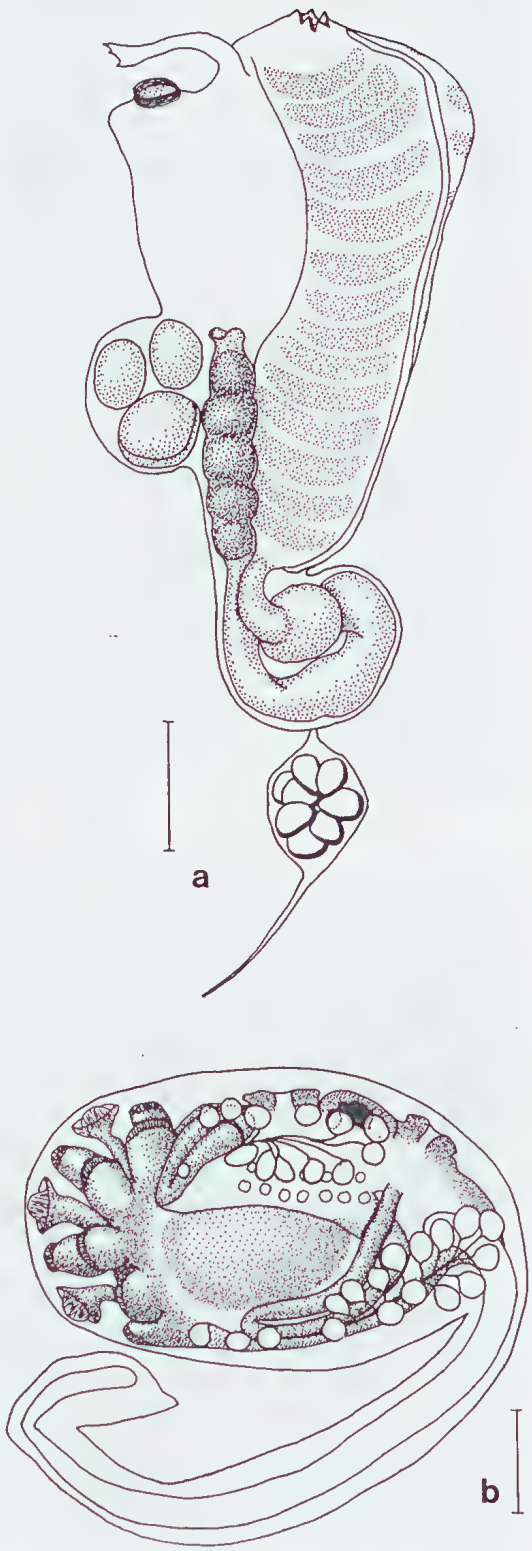

FIG. 34: *Polyclinum tsutsuii* — **a**, zooid with 3 embryos in atrial cavity (WAM 475.91); **b**, larva (WAM 476.91). Scales: **a**, 0.5mm; **b**, 0.1mm.

The atrial aperture is well anterior and the body wall projects dorsally so that the aperture is directed anteriorly. The atrial tongue is moderately long and fleshy, and sometimes has a serrated tip. Eight short, fine muscle bands on each side radiate from the branchial aperture over the anterior part of the body but they become finer posteriorly and only occasionally can be distinguished extending the whole length of the thorax. The branchial sac has 14 to 16 rows of about 18 to 20 stigmata per row. The transverse vessels have about one tongue-shaped papilla per stigma.

The gut loop is horizontal, lying close behind the thorax, with the distal part of the loop turned to the left. About 8 relatively large male follicles surround the ovary in the posterior abdomen.

Colonies taken in April have 3 embryos are in a brood pouch which projects from the dorsal part of the peribranchial cavity at about the level of the sixth row of stigmata. The larval trunk is 0.5mm long, with lateral and median ampullae alternating with the shallow, stalked, median adhesive organs. Ectodermal vesicles continue anteriorly in a row along each side of the median line from postero-ventral and antero-dorsal clumps. There is an otolith and ocellus. The tail is wound almost three quarters of the way around the trunk. The tips of the ampullae have caps of enlarged ectodermal cells.

REMARKS

The species is distinguished from *P. incrustatum*, which also has sand confined to the outer layer of test, by its wide branchial sac with 18 to 20 stigmata per row (instead of about 13), and its large larvae in a brood pouch rather than free in the atrial cavity. *Polyclinum incrustatum* has small, distinct circular systems with conspicuous projecting cloacal apertures which also distinguish it from the present species.

The sandy *P. solum* from the northeastern coast of Australia and Indonesia lacks branchial papillae; and has a long posterior abdomen with gonads in its posterior half, and a narrow branchial sac with only 8 to 10 stigmata per row.

Polyclinum saturnium, another sandy species is separated from the present one by the absence of a brood pouch, but has many other characters in common including a moderately long posterior abdominal neck and a broad branchial sac with about 20 stigmata per row. Specimens assigned to *P. saturnium* from Korea and Japan (see Tokioka 1962; Rho 1966, 1971, 1975) have the brood pouch characteristic of *P. tsutsuii*.

Polyclinum laxum Van Name, 1945, from the Gulf of California has potato-shaped colonies. Van Name thought this species could be a synonym of *P. saturnium* Savigny, 1816 (from the Gulf of Suez). However, embryos in *P. laxum* are probably in a brood pouch (see Van Name 1945) as they are in the present species but not in *P. saturnium*. The only difference evident between the Western Australian and the eastern Pacific specimens are that the latter have a longer oesophageal neck and the zooids do not seem to be so crowded.

Although Tokioka thought them to be unique, the short longitudinal thoracic muscles do occur in other species of this genus.

? *Polyclinum festum*: Van Name, 1918; p.162.

DISTRIBUTION

NEW RECORDS: Western Australia (Broome, WAM1023.83). New South Wales (Arrawarra, QM GH4986). Queensland (Pt Lookout, QM GH4981 GH4984; Myora, QM GH4985 GH4990 GH5027; Bribie I, QM G10124; Kawana Waters, QM GH4989; Noosa, QM GH1496; Pt Vernon, QM GH4991 GH4993 GH5028; Bargara, QM GH4983; Gladstone, QM GH4988; Capricorn Group, QM GH4992 GH4994–5018 GH5023–33 GH5185 GH5279; Lizard I., QM GH4982 GH5017 GH5025 GH5261–2 GH5268; off Cairns, QM GH4987).

PREVIOUSLY RECORDED: Western Australia (Shark Bay — Michaelsen 1930). Queensland (Capricorn Group — Kott 1963; Sarina, Mackay — Kott 1963; Low Is — Hastings 1931). ? Philippines (Van Name 1918). Indonesia (Pizon 1908). Hawaii (USNM 11755 Tokioka 1967). West Indian Ocean (Michaelsen 1919).

The species apparently is a tropical one.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are naked, fleshy, extensive investing sheets or cushions to about 2cm thick. In life thinner sheets are brown, yellowish brown and beige internally. Thicker specimens are greenish-black, to black, often with some yellow, and 'mummy brown' (Ridgeway 1886) internally. In preservative they are brown, red-brown to pink. The test is firm and gelatinous, and does not have embedded sand.

Zooids are arranged in rows along each side of branching canals that radiate from the cloacal apertures. In relatively thin colonies with thin surface test the cloacal apertures are completely sessile, sometimes opening out along the top of the parts of the cloacal canals adjacent to them. They have denticulate borders which contain the tips of the long atrial lips of the zooids in their vicinity. Zooids further away have their atrial lips stretched out with their tips inserted into the test above the canals. The atrial lips contain brown pigment making them very conspicuous through the surface test, outlining not only the cloacal apertures, but also the branching canals, which, when they are crowded, often appear to form a network.

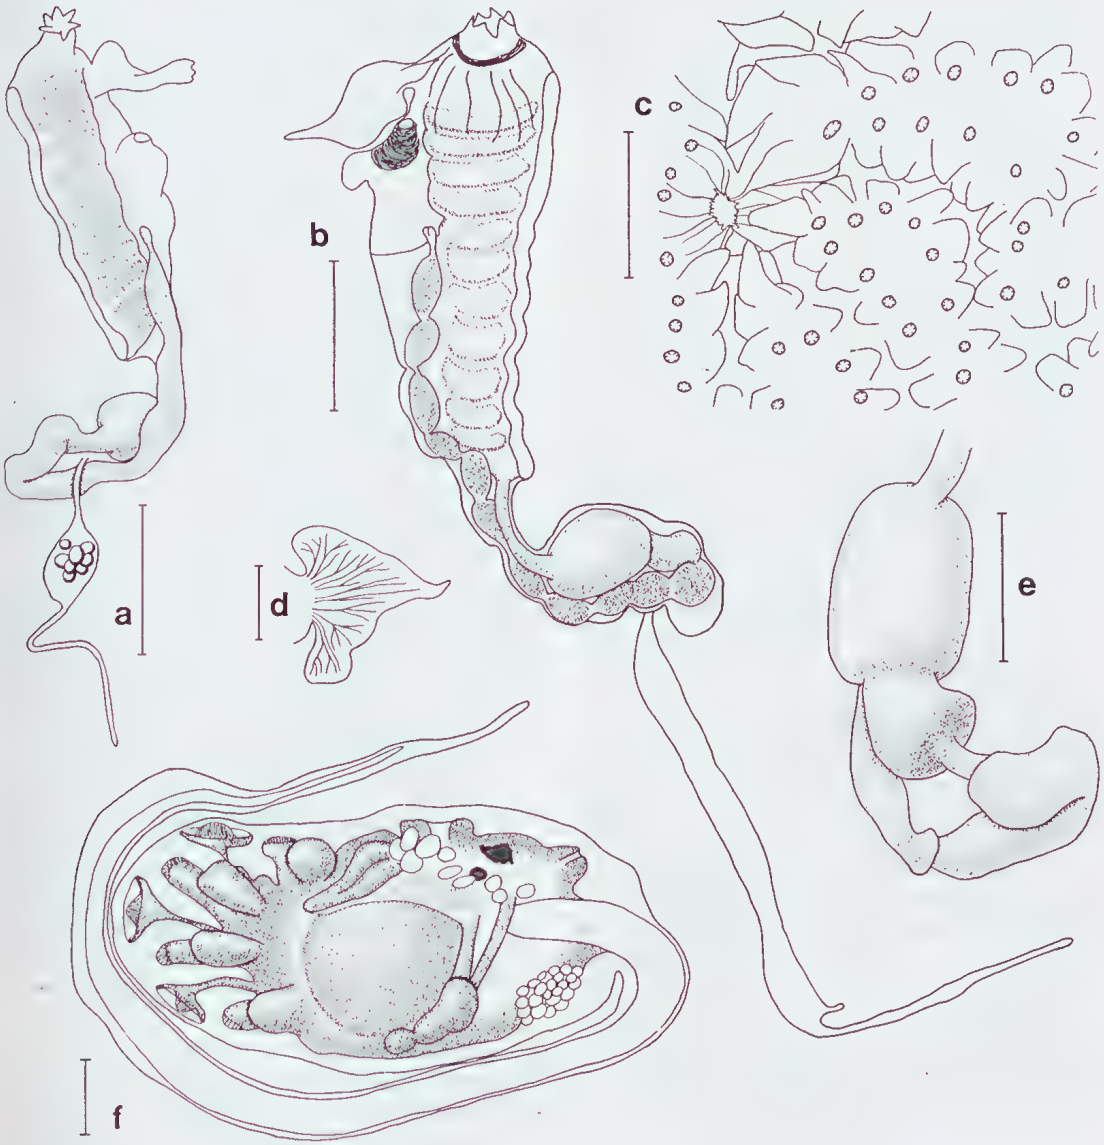

FIG. 35: *Polyclinum vasculosum* — **a**, **b**, zooids (**a**, QM GH1496 with sexual posterior abdomen; **b**, QM GH4984 with vegetative posterior abdomen); **c**, colony showing atrial lips along each side of cloacal canals that converge to common cloacal apertures (QM GH4982); **d**, atrial lip (QM GH4984); **e**, gut loop (QM GH4984); **f**, larva (QM GH4985). Scales: **a**, **b**, 1mm; **c**, 2mm; **d**, **e**, 0.5mm; **f**, 0.1mm.

Thicker colonies, which are recorded from mainland rather than coralline habitats, have less conspicuous systems, and cloacal and zooid apertures. The thick surface test obscures the openings, the denticulations around them, the insertion of the tips of the atrial apertures into the test and the position of the zooids relative to cloacal canals. Sometimes common cloacal apertures are raised on slight conical prominences about 1cm apart and are evenly distributed over the surface. In other specimens each branchial and cloacal aperture is depressed into the surface. In some colonies zooid-free areas of test separate the systems, which have cloacal apertures about 5mm apart. In others, the cloacal systems are contiguous and the only zooid-free parts of the test are those between the rows of zooids.

Vesicles (about 0.04mm in diameter) are evenly scattered in the surface test, about 0.3mm apart, amongst zooid openings, although they often are obscured by zooids and pigment.

INTERNAL STRUCTURE: Zooids in the thinner colonies are more easily removed from the test than those in the thicker ones, which have the atrial lips embedded in thicker, firmer test. The thorax is large and roomy (up to 3mm long). Usually the smaller abdomen (about 2mm long) is bent at right angles to the thorax. The posterior abdomen varies from the short, sac-like sexual organ to the long (up to 3mm) strap-like vegetative one. A delicate, sometimes branched, vascular stolon extends into the test from the end of the posterior abdomen.

The branchial lobes are well-formed and triangular. The atrial lip is long and broad, and usually constricted at the base. Its shape is variable, being tongue-shaped or short and broad with up to 7 denticulations on its outer edge, or leaf-shaped, tapering to a single point. It contains longitudinal muscle bands that extend into it from the dorsal side of the branchial siphon. These divide into separate fibres toward the sides and tip of the lip. The atrial aperture surrounded with circular muscles protrudes forwards on a short siphon, beneath the atrial lip. There is a median dorsal papilla protruding from the body wall posterior to the atrial siphon. About 10 to 15 fine longitudinal thoracic muscles extend from the branchial siphon to about one third of way down the thorax. There are 12 to 14 rows of short oval to rectangular stigmata, the latter being in larger, mature zooids. The dorsal languets are to the left of the mid line, and there are 2 more stigmata on the left than on the right side of the zooid. Stigmata vary from 8 on the right side posteriorly to 16 on the left side anteriorly.

In some colonies (possibly with juvenile zooids) the stigmata are small and oval and rounded papillae are on the transverse vessels (Gladstone QM GH4988). However, this is rare, and papillae were not usually detected.

The oesophagus is relatively long and distally it bends before entering the smooth, oval horizontal stomach, which lies anterior to a horizontal part of the rectum in the ascending limb of the gut loop. The distal end of the loop curves to the left and dorsally and the short neck connecting it to the posterior abdomen is on its dorsal side. The rectum extends anteriorly to halfway up the branchial sac and ends in a 2-lipped anus.

The sexual posterior abdomina are short, teardrop-shaped containing male follicles and ovary. These lengthen to comma shaped organs and subsequently to long and strap-like vegetative posterior abdomina. The latter are found on vegetative zooids around the actively growing borders of the colony. Comma-shaped posterior abdomina with the V-shaped heart posteriorly and a few male follicles and small ovary in the middle or anteriorly, occur as the zooid changes from its sexual to vegetative phase.

Two or 3 embryos are found in the unusually large atrial cavity of zooids collected in May in Moreton Bay, August (but not in March) from the Capricorn Group and in June from Lizard I. The embryos are few and small, especially in relation to the thorax and its roomy peribranchial cavity. It is possible that the species compensates for this by a long reproductive period (producing offspring over much of the year), and by having large long-lived colonies with numerous zooids.

The larval trunks are 0.5 to 0.6mm long. They have 3 shallow, narrow-stalked adhesive organs anteriorly, alternating with median and lateral ampulla, and a postero-ventral and mid-dorsal clump of ectodermal vesicles. The ampullae have conspicuous caps of enlarged epidermal cells, and similar enlarged ectodermal cells are present in the outer walls of the ectodermal vesicles.

REMARKS

Polyclinum vasculosum Pizon, 1908 from Indonesia was described from a small, single system colony. The zooids in branching double rows radiate from the common cloaca. The zooids have 12 rows of stigmata with up to 15 stigmata per row, and no branchial papillae were detected on the transverse vessels. Specimens from Hawaii, the Philippine and Marianas Is., some sandy and

others naked, were assigned to this species (Tokioka 1967), but the naked ones (from the Hawaiian Islands) are the only ones correctly assigned. They have branching double rows of zooids radiating from large cloacal apertures with denticulate borders (like those of *P. constellatum*: see colonies from St. Helena, Michaelsen 1930), dark pigment (yellowish-brown) in the zooids, and colonies that are extensive sheets up to 2.5cm thick. The narrow thoraces, dark pigment, long atrial languets and large cloacal apertures resemble *Polyclinum macrophyllum* which appears to be a synonym of *P. vasculosum*. *Polyclinum festum* Van Name, 1918 from the Philippines, which has large investing colonies, is probably also a synonym of *P. vasculosum*, although the colonies are too mutilated to be sure.

Polyclinum macrophyllum Michaelsen, 1919 from Malagasy, and Western Australia (Michaelsen 1930), with its large muscular atrial lip, narrow thorax, 12 to 14 rows of 10 or 11 stigmata and branchial papillae sometimes on the transverse vessels, cannot be separated from *P. vasculosum*, especially from colonies from the Hawaiian islands (Tokioka 1967). Michaelsen distinguished *Polyclinum macrophyllum phortax* Michaelsen 1930 (from Shark Bay, Western Australia) from the West Indian Ocean *P. macrophyllum typicum* by its almost rough (rather than smooth and slippery) upper surface, the tighter insertion of the atrial tongue into the surface layer of test, and more delicate atrial musculature. However, these distinctions fall within the range of variation of the Australian populations and there well may be a continuous distribution around the Indian Ocean. Thus, assuming the synonymy of *P. macrophyllum* with *P. vasculosum* Pizon, 1908 is valid, *P. vasculosum* has a range from the West Indian Ocean into the Western Pacific to Hawaii (see Tokioka, 1967).

Polyclinum festum Hartmeyer, 1905 from Mauritius has a long, narrow atrial lip and probably does not belong to this species. Although its surface is smooth, sand is present on the base and sides of the colony and sometimes on the surface (see Millar 1975).

The large (6mm) investing colonies, *Polyclinum festum*: Van Name, 1918, from the Philippines, although so mutilated that systems could not be discerned, probably are synonyms of the present species. Van Name (1945) believed that these specimens, as well as *P. festum* from the type locality to be synonyms of *P. constellatum* which also has its type locality in Mauritius. However, all 3 species appear to be distinct. Michaelsen (1930) believed that *P. constellatum* could be distinguished by its branching double row systems while in *P. macrophyllum* (< *P. vasculosum*) branching canals formed a network. However, the complicated branching cloacal canals with a row of zooids along each side, that converge to the cloacal apertures, occur in both species. The primary difference between them appears to be the shape of the colony, viz. a capitate cushion attached by a small area of the base in *P. constellatum*, and in the present species an extensive sheet fixed by the whole of the basal surface. Usually the absence of branchial papillae also is indicative of *P. vasculosum*.

Genus **Aplidiopsis** Lahille, 1890

Type species: *Macroclinum vitreum* Lahille, 1887

Species of this genus resemble those of *Polyclinum*. The zooids differ mainly in the absence of branchial papillae, the relatively large and vertical gut loop, and in some species a ventral band of muscles continuing onto the abdomen and posterior abdomen. As in *Polyclinum* the posterior abdomen is connected to the abdomen by a narrow neck, and the vas deferens takes the characteristic polyclinid course from the left to the right side of the gut loop. As in *Polyclinum*, *Synoicum* and *Sidneioides* the oesophagus curves ventrally to enter the stomach along its dorsal border. A long atrial lip sometimes extends out from the upper rim of the opening as in *Synoicum* spp. and some *Polyclinum* spp. (e.g. *P. orbitum*). In other species the atrial lip arises from the body wall anterior to the opening and closes down over the anteriorly oriented atrial aperture, as in most *Polyclinum* spp. and some *Synoicum* spp. Zooids are arranged in circular or stellate systems.

Generally *Aplidiopsis* zooids are about 1cm long while those of *Polyclinum* are about 5mm or less. Other differences between *Polyclinum* and *Aplidiopsis* are discussed above (see Polyclinidae). The relatively large, vertical gut loop and the larger zooids of *Aplidiopsis* are very often the only reliable characters to distinguish it from *Polyclinum*. Although the posterior abdomen and testis are longer than in *Polyclinum*, the gut loop is vertical rather than horizontal, and the characteristic twist found in *Polyclinum* does not occur in this genus, a relationship to *Polyclinum* is indicated by the ocurse of the vas deferens.

Aplidiopsis is not diverse. In addition to the type species from the Mediterranean, the known

species are *A. pannosa* (Ritter) from Alaska (see Nishikawa 1990) and the related *A. helenae* Redikorzev (see Van Name 1945), *A. atlantica* Monniot, 1974 from the Azores (at 600m), *A. stellata* Monniot and Monniot, 1984 from Guadaloupe, *A. pyriformis* (Herdman, 1886), *A. amoyense* Tokioka, 1967 from China, *A. tokaraensis* Tokioka, 1954a from the Tokhara Is, *A. discoveryi* Millar, 1960 from the North I. (New Zealand), and 3 new Australian species (see below). *Aplidiopsis pannosa*, *A. atlantica*, *A. stellata* and *A. helenae*, *A. confluata* n.sp., and *A. mammillata* n.sp., have delicate muscles confined to the anterior part of the thorax, in contrast to the other known species, which have the thoracic longitudinal muscles converging to a ventral band that extends the length of the zooid. *Aplidiopsis stellata* is known to have a brood pouch at the posterior end of the thorax rather than halfway up as in *Polyclinum*. The 3 species recorded from Australia are from temperate waters.

Key to species of *Aplidiopsis* recorded from Australia

1. Longitudinal muscles extend the length of the zooid; systems circular ..... *A. sabulosa* n.sp.

   Longitudinal muscles do not extend the length of the zooid; systems not circular 2

2. Colony sandy; common cloacal apertures protrude ..... *A. mammillata* n.sp.

   Colony not sandy; common cloacal apertures sessile ..... *A. confluata* n.sp.

Species recorded from waters adjacent to Australia

Aplidiopsis amoyense Tokioka, 1967 from Hsia-men has stellate systems that resemble those of *A. mammillata* n.sp. (see below).

Aplidiopsis discoveryi Millar, 1960 from New Zealand, unlike *A. sabulosa* n.sp., lacks sand altogether. The zooids, arranged in circular systems, can be seen through the transparent test.

Aplidiopsis tokaraensis Tokioka, 1954a from the Tokhara Is have an external layer of sand obscuring the systems. About 10 longitudinal thoracic muscles converge to form a ventral abdominal band. Monniot (1974) believed this species to be a member of the genus *Sidnyum*, with 8 branchial lobes. However, its smooth stomach wall shape of the posterior abdomen preclude that view.

Aplidiopsis confluata n.sp.
(Fig. 36)

DISTRIBUTION

TYPE LOCALITY: Tasmania (Ninepin Point, 5m coll. P. Last 19.7.82, holotype QM GH5514).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colony is a soft, almost spherical, naked head, about 2.5cm in diameter, attached by a short, thick, wrinkled stalk which narrows toward the base, and has some sand adhering to it. Double rows of zooids converge to large, sessile common cloacal apertures which are scattered randomly over the head. The test is soft and translucent internally, though the surface layer is opaque. Zooids are crowded, and cross one another in the centre of the colony and down into the stalk. The test, although it is soft, is tough and the zooids, tightly enclosed in it, are difficult to free from the colony.

INTERNAL STRUCTURE: Zooids are at least 1cm long, of which the thorax is about 2mm the abdomen about 1mm, the posterior abdomen occupying most of the zooid length. The branchial aperture has 6 small, pointed lobes. There is a long, flat, strap-like tongue from the body near the anterior edge of the first row of stigmata. The atrial aperture, with a sphincter muscle, is opposite the second row. About 8 fine longitudinal muscles on each side radiate from the branchial aperture and fade out halfway down the thorax. A median dorsal papilla is posterior to the atrial aperture. There are 16 rows of up to 14 stigmata, the ventral ones progressively reduced in length. The gut loop is vertical, although the oesophagus curves ventrally to enter the smooth-walled stomach. The duodenum expands in diameter to its junction with the short proximal part of the midintestine, and an oval posterior stomach is in the descending limb of the gut loop.

The posterior abdomen is particularly long, extending into the centre of the colony and down into the stalk. It is joined to the left (or ventral) side of the pole of the gut loop by a short narrow neck, but distal to the neck it abruptly increases in diameter and the greater part of the posterior abdomen is of even diameter. Anteriorly gonads are absent from 5mm or more of its length. They occupy about 2mm of the middle part of the posterior abdomen. They consist of a small ovary anteriorly, and a long cluster of almost spherical testis follicles. These are of various sizes, randomly distributed in the cluster, and they are not

in regular longitudinal series. The vas deferens curves around the gut loop onto the other (right or dorsal) side to extend anteriorly to the atrial cavity between the oesophagus and rectum. There are no embryos in this specimen.

REMARKS

The species is unique in its soft sand-free test, crowded zooids and their long posterior abdomina each with a long bunch of testis follicles about half way down. It resembles the other Australian species *Aplidiopsis mammillata* n.sp. in its long longitudinal muscles confined to the anterior part of the long, delicate thorax, and the absence of branchial papillae. The long, strap-like atrial tongue is more conspicuous, there are more stigmata per row but fewer rows, and the posterior abdomen is longer than in either of the other 2 Australian species assigned to this genus. *Aplidiopsis discoveryi* Millar, 1960, from New Zealand has circular systems and a spindle-shaped posterior abdomen distinguishing it from the present species.

Aplidiopsis mammillata n.sp.
(Fig. 37. Plate 7d)

DISTRIBUTION

TYPE LOCALITY: South Australia (Cathedral Rock, near Thistle I., Spencer Gulf, coll. W.H. Sasse 6.4.87, slide 19, holotype QM GH4168).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The holotype is a large cushion 4cm in diameter and 1cm thick. The upper surface is depressed and divided into 3 naked areas by raised sandy elevations continuous with the raised rim around the margin. There are one or 2 systems in each naked area. Each system has sandy strips extending along radii from the peripheral sandy elevated rim to the central protuberant common cloacal aperture. Three or 4 double rows of zooids extend out between the radial strips of sand. Sand is confined to the surface test, however, and never is found internally. Zooids are tightly enclosed in the soft test and are difficult to remove.

INTERNAL STRUCTURE: The zooids are large, 7mm long, the thorax being more than half of the total length. The branchial aperture is small with

FIG. 36: *Aplidiopsis confluata* n.sp. (holotype QM GH5514) — a, colony; b, zooid. Scales: a, 2cm; b, 0.5mm.

6 pointed lobes. The small anteriorly directed atrial aperture is near the anterior end of the zooid.

Fine and inconspicuous longitudinal muscles were detected in the anterior part of each zooid. The atrial lip is long and narrow, arising from the body wall, and is difficult to remove from the test. There are 18 rows of stigmata with about 10 per row. The gut loop is vertical and relatively short. The stomach wall is smooth.

A long, almost cylindrical posterior abdomen, with a narrow neck attaching it to the left side of the gut loop, contains crowded male follicles and a small ovary surrounded by the male follicles.

REMARKS

Aplidiopsis amoyense Tokioka, 1967 from Hsia-men has stellate systems that resemble those of this new South Australian species. Zooids are also similar, with only very delicate muscles, however the Australian species has a larger branchial sac with about 18 rows of stigmata (the Chinese species having 12), and sand adheres to the external test.

Aplidiopsis pannosa is also in this group of species, with delicate muscles, and a smaller gut loop than usual. However, it lacks the characteristic radiating double row systems of *A. amoyense* and the present species.

Aplidiopsis sabulosa n.sp.
(Fig. 38. Plate 7e)

DISTRIBUTION

TYPE LOCALITY: South Australia (Price I., Avoid Bay 15–20m, coll. W.H. Sasse 9.4.87, holotype QM GH4153).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The holotype is a large cushion 10cm in diameter up to 3cm thick and with sand embedded throughout, absent only from the surface around the branchial and common cloacal apertures. The surface is even, without depressions or ridges. The cushion is fixed by a small area of the flat basal surface. Zooids open onto the rounded borders of the colony as well as its upper surface and much of the basal surface as well. Zooids are arranged in circular systems around sessile conspicuously naked common cloacal apertures about 5mm apart.

INTERNAL STRUCTURE: Zooids are about 1.3cm long of which the thorax and abdomen are of equal length and together are about half the total zooid length. Six strong longitudinal muscles from the branchial aperture, with some from the intersiphonal space, extend to the posterior end of the thorax where they join into a single ventral band that extends to the end of the zooid. The atrial lip is a tongue-shaped muscular extension of the upper border of the opening. It is forked at the tip. The atrial opening is anteriorly directed.

There are 20 rows of about 6 stigmata. The gut loop is voluminous. The oesophagus curves into the stomach which has a short dorsal border and a long, curved ventral margin. The duodenum is long and there is an oval posterior stomach at the bottom of the descending limb of the loop. The rectum extends to about halfway up the thorax,

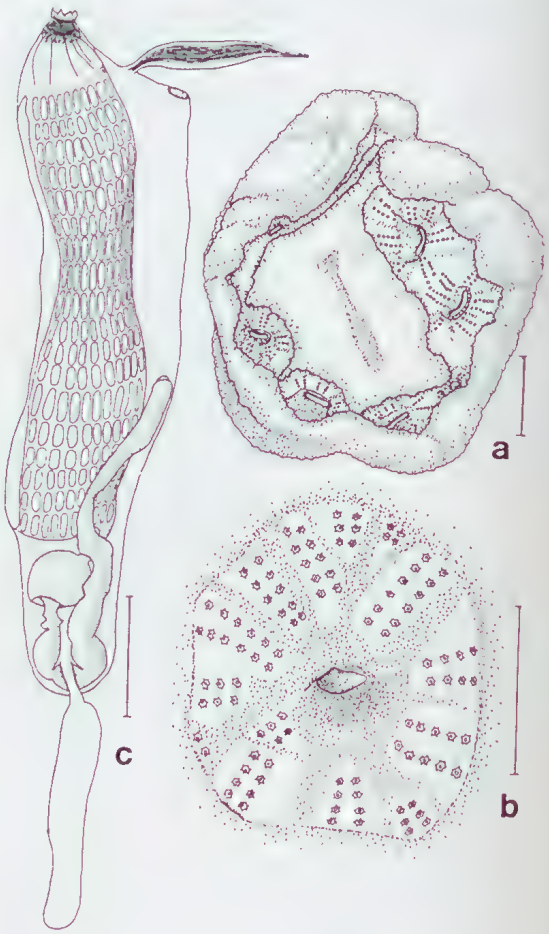

FIG. 37: *Aplidiopsis mammillata* n.sp. (holotype QM GH4168) — **a**, colony from above; **b**, single system with central protuberant cloacal aperture and double rows of zooids converging to it; **c**, zooid. Scales: **a**, 1cm; **b**, 5mm; **c**, 1mm.

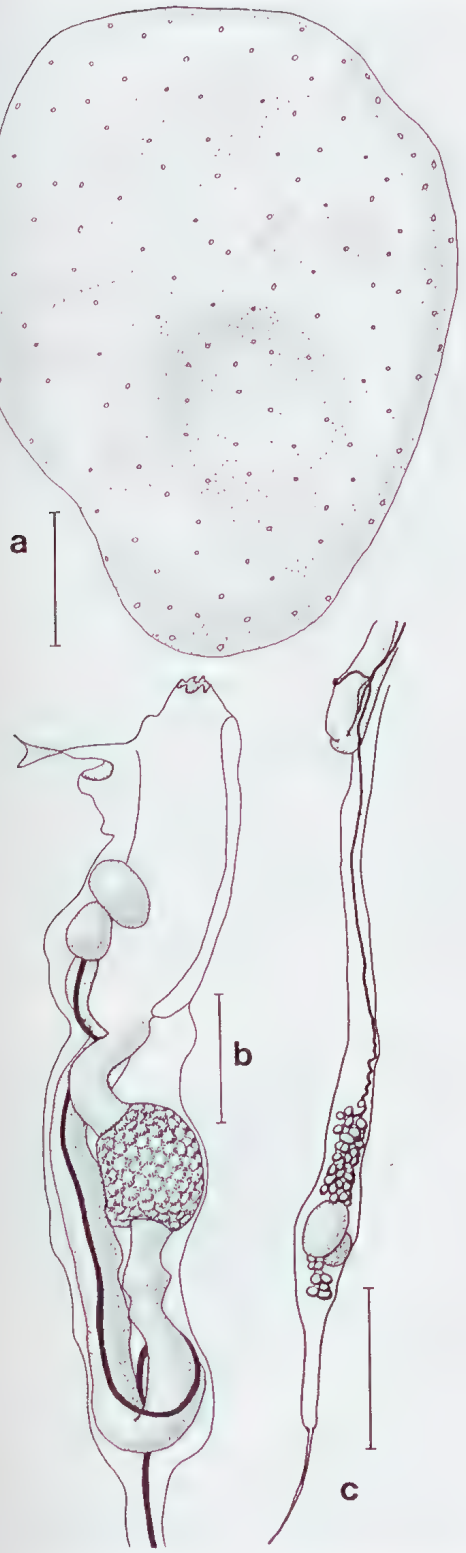

terminating in a bilabiate anus. The stomach wall has internal circular patches of glandular epithelium giving a mulberry-like pattern.

The posterior abdomen is long, with a narrow neck anteriorly joining it to the left side of the pole of the gut loop. This neck portion gradually expands to the posterior gonad-bearing half. Male follicles are small and bunched and the large 2-egg ovary is surrounded by them. At its posterior end, the posterior abdomen tapers to a vascular stolon. The vas deferens curves around the ventral side of the posterior stomach from the left (or ventral) side of the loop and extends along the right side of the curve and inner side of the rectum to open at the level of the anus.

Two or 3 early embryos crowded in a longitudinal series are in the posterior part of the atrial cavity of the holotype (collected in April). Tailed larvae were not present.

REMARKS

Aplidiopsis mammillata has about the same number of rows of stigmata as the present species, but slightly more per row. It is also distinguished by its delicate musculature, smaller gut loop, smooth stomach wall, short and cylindrical posterior abdomen and its radial double-row systems.

Aplidiopsis sabulosa has circular systems like *A. discoveryi*, and *A. confluata*, and is distinguished by its embedded sand, and small number of stigmata in each row.

Aplidiopsis tokaraensis has sand on the outer surface, but not embedded in the test. The zooids have 18-20 stigmata and 12 rows, clearly distinguishing them from zooids of the present species.

Genus **Sidneioides** Kesteven, 1909

Type species: *Sidneioides tamaramae* Kesteven, 1909.

The genus resembles *Polyclinum* in its short longitudinal muscles, large muscular atrial lip that arises from the body wall anterior to the opening and its smooth-walled and bilaterally symmetrical stomach. It differs in having a relatively large ovary. The position of the ovary at mid-thoracic level, and a relatively large vertical gut loop. A median dorsal papilla projects from

FIG. 38: *Aplidiopsis sabulosa* n.sp. (holotype QM GH4153) — **a**, colony from above; **b**, thorax and abdomen with 2 embryos in atrial cavity; **c**, posterior abdomen. Scales: **a**, 2cm; **b**, 1mm; **c**, 2mm.

the body wall behind the atrial aperture as in many species of *Polyclinum* and *Synoicum*. The vas deferens passes around the ventral side of the descending gut loop to lie on the right side of the rectum as in *Polyclinum*. The voluminous vertical gut loop, absence of branchial papillae, and long posterior abdomen are more like *Aplidiopsis* than *Polyclinum*.

The larvae are small, sometimes smaller than those of *Polyclinum*. Although they have similar lateral ampullae and ectodermal vesicles, median ampullae are not present.

Three species of this genus are known. One is indigenous, with a wide range (from Westernport to Gladstone) on the eastern coast of Australia. The other known species are recorded from Japan (see Tokioka 1953):

Sidneioides japonense Redikorzev, 1913, recorded from Japan and Indonesia (Tokioka 1953, Millar 1975, Nishikawa 1990) forms a flat cushion with irregular furrows and protruding cloacal apertures on the upper surface. As in *S. tamaramae* a layer of sand adheres to the surface test, but sand is not present internally. The species are distinguished by their colony shape, and by the longer rows of stigmata and longer larval trunk of *S. japonense* (see Tokioka 1953).

Sidneioides snamoti (Oka, 1927) is distinguished by its systems which resemble those of *Polyclinum vasculosum*, with branching cloacal canals converging to protuberant cloacal apertures. The zooids differ from those of other species in having more rows of stigmata (17 to 19), as well as a large number of perforations in each row (see also Tokioka 1953, Nishikawa 1990).

Sidneioides tamaramae Kesteven, 1909
(Fig. 39. Plate 7f)

Sidneioides tamaramae Kesteven, 1909, p.277, Kott, 1957, p.104; 1976, p.63.

DISTRIBUTION

NEW RECORDS: New South Wales (Ulladulla, QM G11859; Twofold Bay, AM Y2151; Merewether, MV). Queensland (Gladstone Harbour, QM G9808).

PREVIOUSLY RECORDED: Victoria (Western Port — Kott 1976). New South Wales (Tamaramae Bay — Kesteven 1909; Merewether — AM Y1318–9 U3831 Kott 1957).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies consist of upright mushroom-shaped lobes widest across their free ends where often they are subdivided into separate shallow lobes, each with a central protruding cloacal aperture. Branchial openings are inside a ridge around the outer margin of each subdivision. The colony lobes narrow toward the base where they are continuous with the basal common test. The small colonies from Gladstone are separate lobes, without the basal common test (QM G9808). The diameter across the free end of each terminal branch is about 1cm, and the rounded subdivisions each containing a single circular system, are about 0.3mm in diameter. The free terminal part of each lobe is nearly 1cm long, and the overall height of the colony is up to 3cm. The whole outer surface is covered with a thick layer of sand. Sand is not present internally. Although the test is rather tough, the whole colony is soft, flaccid, and colourless in preservative. The outer free ends of all the lobes are level with one another and crowded together, and the upper surface has a cauliflower-like appearance. The large, muscular atrial lip of each zooid is extended into the central of the colony lobe and is inserted into the test around the cloacal aperture.

INTERNAL STRUCTURE: The zooids are about 6mm long including the posterior abdomen, which is attached to the abdomen by a long, narrow neck. The thorax is about two-thirds of the length of the abdomen. Six to 10 fine longitudinal muscle bands are on the anterior half of the thorax. The atrial aperture is projected forwards, and the anterior atrial lip, containing longitudinal and fine transverse muscles arises from the body wall anterior to the aperture. Twelve to 14 rows of stigmata, each with about 12 stigmata, are separated from one another by plain-edged transverse vessels each containing a narrow band of muscles.

The voluminous gut loop is vertical and the stomach smooth-walled. The posterior abdomen, joined to the abdomen by a narrow neck, is short, tear-drop-shaped to long and almost cylindrical or elliptical and is packed with male follicles. The relatively large ovary, with up to 18 eggs of various sizes, is in the thorax just on the right side of the anal opening, half way up the thorax. The colony from Gladstone collected in April has up to 8 embryos in the anterior half of the right peribranchial cavity.

The larval trunk is 0.4mm long (one of the smaller viviparous larvae known in the Ascidiacea). The tail is wound almost the whole way around it. Four lateral ampullae are present each side of the adhesive organs, and there are clumps of postero-ventral ectodermal vesicles each side of the base of the tail, and a row of about 6

ectodermal vesicles along each side of the mid-dorsal line.

REMARKS

The colony closely resembles that of *Polyclinum orbitum*. The shape and consistency of the colonial lobes are the same, and both zooids and larvae are very similar in size in these two species. The larvae of the present species, also resemble those of *P. orbitum* in the absence of median ampullae. *Sidneioides tamaramae* can be distinguished by the absence of branchial papillae, the position of the ovary, and the atrial lip, which in *P. orbitum* extends out from the upper rim of the aperture (as it does in *Aplidiopsis*, but seldom in other species of *Polyclinum*). The present species also has fewer rows of stigmata, fewer stigmata per row, and a larger and more vertical gut loop than *P. orbitum*.

The thickness of the basal common test varies, the type specimens having a basal plate (Kesteven 1909) rather than the upright stalk of the newly recorded colonies from Ulladulla (QM G11859).

Genus **Synoicum** Phipps, 1774

Type species: *Synoicum turgens* Phipps, 1774.

Zooids are small, and form circular or double-row systems. Colonies are sessile cushions, or investing sheets, or stalked heads. Despite the small size of the zooids there are 4 to 20 rows of

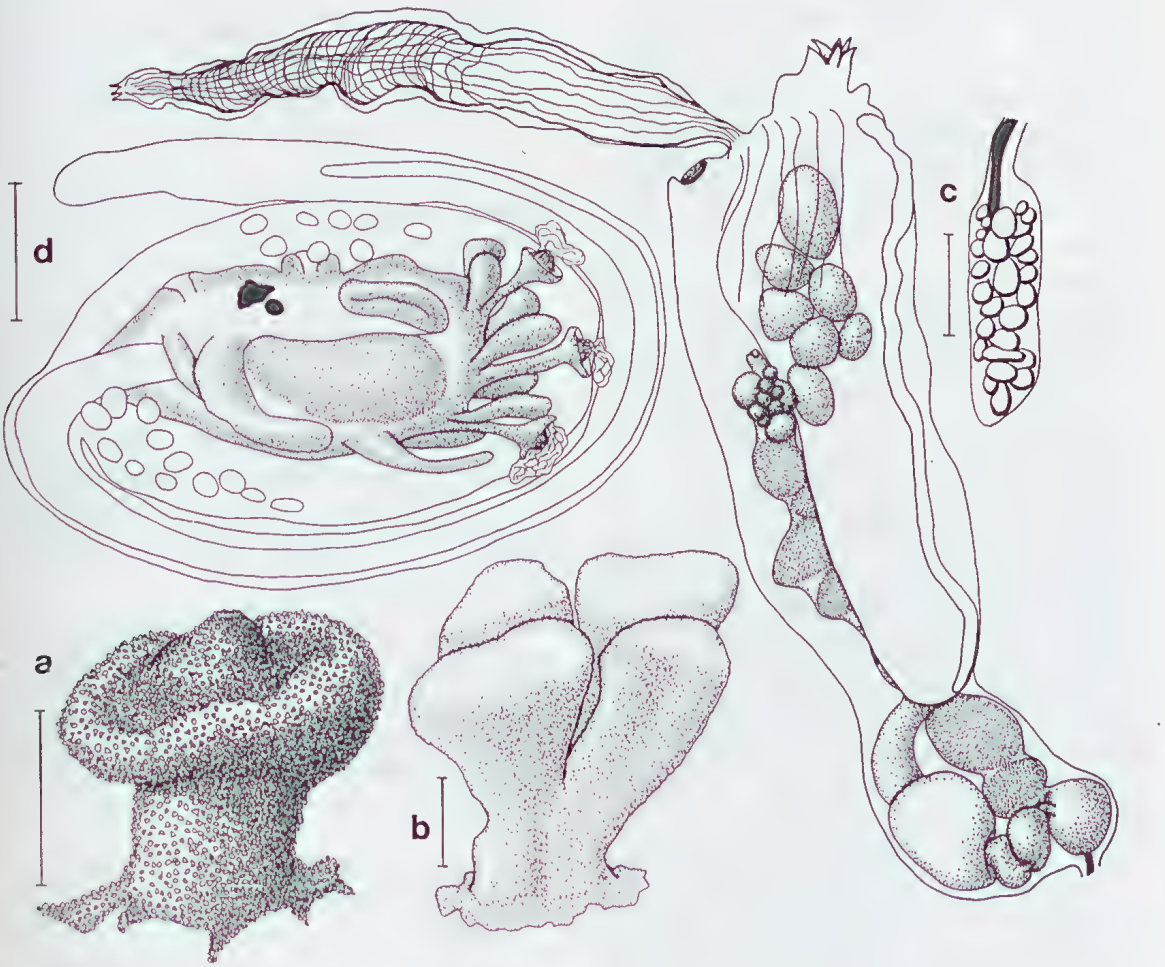

FIG. 39: *Sidneioides tamaramae* — **a**, lobe of a colony (QM G9808); **b**, portion of a colony (QM G11859); **c**, zooid with ovary to right of the distal part of the rectum and embryos in atrial cavity (QM G9808); **d**, larva (AM Y1318). Scales: **a**, **b**, 5mm; **c**, 0.5mm; **d**, 0.1mm.

stigmata and up to 20 stigmata per row. Longitudinal muscles form a wide band along each side of the abdomen and posterior abdomen. Gonads are in the long, narrow posterior abdomen which is continuous with, and not constricted off from, the abdomen. The oesophagus is curved to enter the bilaterally symmetrical stomach a short way along its dorsal border. The stomach wall is smooth or it has circular mulberry-like swellings. Sometimes it is quadrate in section but it never has true longitudinal folds. The gut loop is narrow and vertical, not being twisted or horizontal as in *Polyclinum*. The male follicles are in longitudinal series (rather than being bunched) with the ovary anterior to them.

The atrial aperture is large, and often produced dorsally on a roomy siphon. The rim of the opening often has minute pointed teeth except anteriorly where it is produced into a lip. *Synoicum macroglossum* is the only species with the lip separated from the aperture. The dorso-median papilla on the body wall just behind the atrial aperture, often actually on the atrial siphon itself, occurs in most species, as it does also in *Aplidiopsis*, *Sydneioides* and in many *Polyclinum* spp. It is not a species character as Michaelsen (1930) thought it was.

Embryos usually are incubated in the postero-dorsal half of the atrial cavity, sometimes (when large) occupying the whole of the cavity. In a few species (e.g. *S. sacculum* n.sp.) the embryos are incubated in a brood pouch constricted off from the postero-dorsal corner of the thorax (rather than half-way up as in *Polyclinum*).

Larvae have median and lateral ectodermal ampullae, each with columnar ectodermal cells forming a cap over the terminal end like those of *Polyclinum*. Dorsal and ventral vesicles resemble those of *Polyclinum*, branching off epidermal strands that trail posteriorly on each side of the mid-dorsal and mid-ventral lines. In other species the vesicles are median rather than lateral and the median stems from which they branch are shorter than the lateral ones of *Polyclinum* — dorsal as well as ventral vesicles being anterior, just behind the ampullae.

In many species the branchial lobes are relatively shallow and inconspicuous (e.g. *S. bowerbanki*). In *Synoicum papilliferum* and *S. macroglossum* the atrial lips are produced from the body wall anterior to the aperture (as in the majority of *Polyclinum*). However, in other species of the genus the atrial opening is relatively primitive, with the atrial lip represented by a simple expansion of the the upper rim of the opening (as in *Polyclinum orbitum* and *Aplidiopsis*). Two or 3 lobes are on the tip of the atrial lip and other small lobes are present on the posterior rim of the opening. The condition is reminiscent of the *angolanum* group of species in *Eudistoma* (see Kott 1990) in which rudimentary cloacal systems consist of zooids arranged around shallow rudimentary cloacal cavities that are little more than depressions in the surface test (see Kott 1990). Thus the atrial aperture generally present in *Synoicum* may be a relict of an early stage in the evolution of cloacal cavities.

The presence or absence of mulberry-like swellings of the stomach wall are reliable species characters. Although these swellings are sometimes inconspicuous in small zooids, Berrill's (1950) view that the stomach is smooth in small zooids but mulberry-like in large ones is not confirmed in the present study. In certain species the stomach is large, falling into horizontal folds. Such a stomach, known from *Synoicum concavitum* n.sp. and *S. atopogaster*, resembles the stomach of *Morchellium pannosum* n.sp. and *M. albidum* n.sp. It was formerly the characteristic of the genus *Atopogaster* by which it was separated from *Synoicum*.

The curved oesophagus of *Synoicum* which usually (but not always) enters the stomach along its dorsal border, resembles that of *Polyclinum* and the Holozoinae rather than the barrel shaped, vertical and more or less radially symmetrical stomach of Diazonidae, Polycitoridae, *Ritterella* and *Aplidium*.

Synoicum rubrum (Abbott and Trason, 1968), initially assigned to *Ritterella*, apparently has closer affinities with the present genus as, despite its lack of zooid systems, it has a characteristic mulberry-like stomach with the oesophagus entering its dorsal surface.

Synoicum is cosmopolitan, known from both northern and southern hemispheres, especially in polar waters. It is well represented in Australia by indigenous species, of which the majority are temperate, although some are tropical (Table 6). It is most diverse in New Zealand waters (see Millar 1982).

Key to species of *Synoicum* recorded from Australia

1. Stigmata in 4 rows ..... *S. bowerbanki*
   Stigmata in more than 4 rows 2

2. Colony long, narrow, cylindrical stalks with zooids opening onto terminal head 3

Colony not long, narrow, cylindrical stalks with zooids opening onto terminal head 5

3. Stigmata in 9 rows; more than one system per lobe; tropical ..... *S. buccinum* n. sp.
Stigmata in more than 9 rows; one system per lobe; temperate 4

4. Stomach wall mulberry like; system stellate ..... *S. angustum* n.sp.
Stomach wall not mulberry-like; system circular ..... *S. arenaceum*

5. Stomach wall mulberry-like 6
Stomach wall not mulberry-like 8

6. Colony separate flat-topped lobes on sandy base ..... *S. sacculum* n. sp.
Colony not separate flat-topped lobes on sandy base 7

7. Colony a flat irregular sheet; surface raised into dome-like swellings over each system ..... *S. intercedens*
Colony not a flat irregular sheet; surface not raised into dome-like swellings over each system ..... *S. erectum* n. sp.

8. Atrial lip separate from aperture 9
Atrial lip not separate from aperture 10

9. Sand in layer externally; temperate ..... *S. papilliferum*
Sand not in layer externally, tropical ..... *S. macroglossum*

10. Parastigmatic vessels present .. *S. atopogaster*
Parastigmatic vessels not present 11

11. Zooids arranged in conspicuous longitudinal double row systems ..... *S. longistriatum* n.sp.
Zooids not arranged in conspicuous longitudinal double row systems 12

13. Cloacal cavities beneath deep depressions in surface 13
Cloacal cavities not beneath deep depressions in surface 16

13. Cloacal canals surround elevated zooid-free areas ..... *S. chrysanthemum* n.sp.
Cloacal canals do not surround elevated zooid-free areas 14

14. Conspicuous elevated ridges around depressions in surface ..... *S. castellatum* n.sp.
Conspicuous elevated ridges not present around depressions in surface 15

15. Stigmata up to 18 per row ..... *S. concavitum* n.sp.
Stigmata up to 12 per row ..... *S. tropicum*

16. Colony of numerous lobes on sandy base 17
Colony not numerous lobes on sandy base ..19

17. Colony lobes sandy 18
Colony lobes naked ..... *S. suarenum* n.sp.

18. Systems more than one per lobe ..... *S. durum* n.sp.
Systems one per lobe ..... *S. obscurum* n.sp.

19. Colony, flat-topped ..... *S. galei* n.sp.
Colony not flat-topped 20

20. Thorax long and narrow, about 16 rows of stigmata ..... *S. prunum*
Thorax not long and narrow, about 8 rows of stigmata ..... *S. citrum* n.sp.

Species recorded from waters adjacent to Australia

Synoicum apectetum Millar, 1982, from the northern tip of the North I. of New Zealand, has colonies resembling those of *S. buccinum* n. sp. However the New Zealand species has only one or 2 systems per colony lobe, and its atrial lip is separate from the aperture, as in *S. papilliferum.*

Synoicum haurakiensis Brewin, 1951 from the Hauraki Gulf, has a mulberry-like stomach, and the atrial lip apparently from the upper rim of the aperture. The colony is stalked and the systems are circular. The species is distinguished from *S. sacculum* n. sp. by its stalked colony.

Synoicum herdmani Brewin, 1956 from Chatham I., New Zealand has stalked lobes with circular systems. Zooids have a smooth stomach. The atrial lip appears to be independent of the aperture. The flat-topped colony may be distinctive (see below, *S. arenaceum*).

Synoicum hypurgon Michaelsen, 1924 from Hauraki Gulf, New Zealand, is not conspecific with the specimens from Fremantle which Michaelsen (1930) assigned to *S. hypurgon* as forma galei. The New Zealand colonies are club- or pear-shaped, with obscure systems, faecal pellets in the test, naked upper surface and sandy base, smooth stomach wall, atrial lip from the upper rim of the opening and a brood pouch constricted off from the body wall like *S. sacculum* n. sp. It resembles the tropical Australian *S. suarenum* n. sp., although the latter lacks a brood pouch, and has a dorsal papilla.

Synoicum kuranui Brewin, 1950b, from Great Barrier I., New Zealand, has flat-topped, sandy lobes up to 1.5cm high, reducing in diameter toward the base. The zooids, in round or oval systems, have mulberry-like stomachs. It is distinguished from *S. sacculum* n. sp. by the shape of the colonies, with their narrow sandy basal stalks. Kott (1963) assigned specimens

TABLE 6. Summary of characters of species of *Synocium* recorded from Australia

from Heron I. to this species, but re-examination has shown them not to be conspecific (see *Synoicum durum* n. sp.). Other colonies assigned to this species from Fiji (Kott 1981) and Indonesia (*S.? clavatum*: Millar, 1975) appear to be colonies of *S. suarenum* n. sp.

Other species from the South I. of New Zealand (see Millar 1982) not likely to occur in Australia, are *S. stewartense* (Michaelsen, 1924), *S. pererratum* (Sluiter, 1912), *S. otagoensis* Millar, 1982 and *S. occidentalis* Millar, 1982.

Synoicum angustum n.sp.
(Fig. 40a,b)

DISTRIBUTION

TYPE LOCALITY: Tasmania (45 nautical mls NNE of East Sister Is, 39°00'S 148°25'E, 92m sandy bottom, epibenthic sled CSIRO *Soela* Statn 22, coll. W. Zeidler 14.10.84, holotype SAM E2570, paratypes SAM E2572 E2573.

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are almost spherical heads (about 1cm diameter) on the terminal free ends of narrow branching sandy stalks about 6cm long and 0.5cm diameter. Zooids are in double rows along the sides of the head converging to a terminal, sessile common cloacal aperture. Sand adheres to the head to form a light covering but a thick coat of sand is crowded on the stalk. Sand is not embedded internally.

In preservative the zooids are reddish, and these, showing through the translucent test and the light covering of sand, make the head appear as brownish-red. The colour of the living colony is not known.

INTERNAL STRUCTURE: Zooids are robust when contracted, but only about 4mm long, the thorax and abdomen of equal length and together about half the length of the zooid. When extended it is probable that they are thread-like and extend down into the stalk. The rim of the branchial aperture is divided into 6 rounded lobes, and the atrial aperture has a moderately long, pointed, fleshy lip from the upper border of the opening. A median dorsal papilla behind the lower rim of the atrial aperture is a flat tongue-like projection or flap bent anteriorly or posteriorly against the zooid. Ten longitudinal muscles are on the thorax and extend down the rest of the zooids as a ventral band. About 14 rows of stigmata have 20 or more stigmata per row. These could not be counted accurately owing to the contracted thorax. The oesophagus and post-pyloric part of the gut loop are long. The stomach has rounded swellings in its wall to give a mulberry-like appearance.

The posterior abdomen has a moderately long sometimes branched terminal vascular appendix. Neither mature gonads nor embryos are present in this type material.

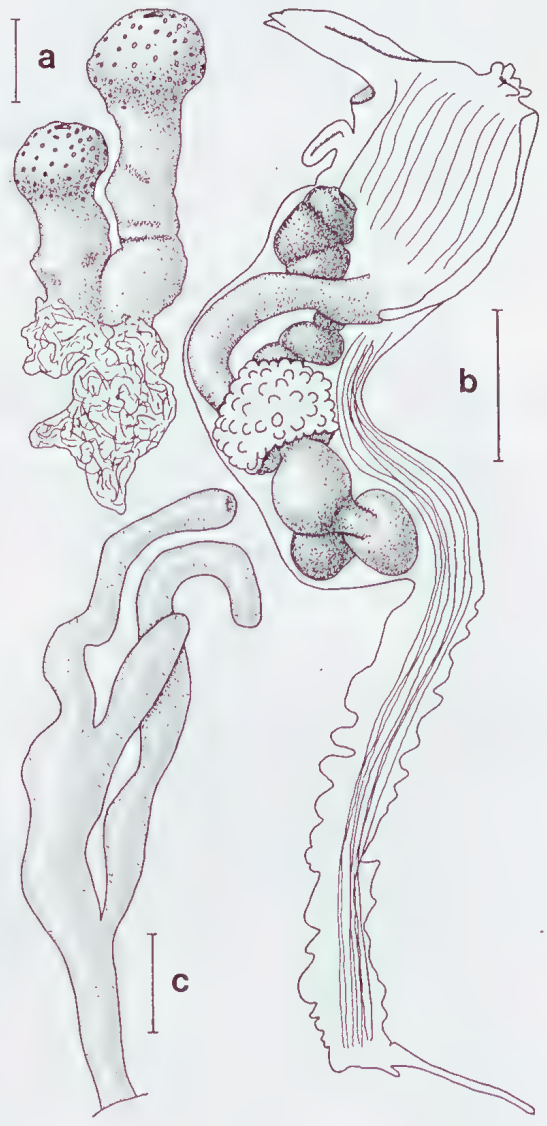

FIG. 40: *Synoicum angustum* n.sp. — **a**, colony (paratype SAM E2572); **b**, zooid (holotype SAM E2570). *Synoicum arenaceum* — **c**, colony (MV F58686). Scales: **a**, 5mm; **b**, 1mm; **c**, 1cm.

REMARKS

This species has the same mulberry-like stomach and the same temperate ranges as *S. sacculum* n.sp., from which it is distinguished by the long, narrow branching stalks of its small but distinctive colonies and its long posterior abdomen. The colonies of other stalked species of this genus, viz. the tropical *S. buccinum* n.sp., and the temperate *S. arenaceum* are distinguished by their circular (rather than radiating double-row) systems and smooth stomach walls. *Synoicum erectum* n.sp. also has a mulberry-like stomach and naked heads on a sandy base. However a number of circular systems opening on the upper surface of *S. erectum* and narrower thoraces with only about 8 stigmata per row distinguishes it from the present species. The flap-like dorsal papilla is also unique, distinguishing *S. angustum* from all others is this genus.

Synoicum arenaceum (Michaelsen, 1924)
(Fig. 40c)

Macroclinum arenaceum Michaelsen, 1924, p.406,
Synoicum arenaceum: Millar, 1960, p. 361; 1982, p.21.

DISTRIBUTION

NEW RECORD: Victoria (off Cape Howe, MV F58686).
PREVIOUSLY RECORDED: ? Victoria (Port Phillip Bay — Millar 1960). New Zealand, Stewart I. (Michaelsen 1924). The new record is from 274m.

DESCRIPTION

EXTERNAL APPEARANCE: The newly recorded specimen is a narrow, cylindrical branching stalk, branching twice, and about 6cm long overall. The terminal branches are about 4mm diameter. Each branch occupies about one third of the total length. The tip of each terminal branch is naked, about the same diameter as the rest of the stalk, with a central sessile cloacal aperture around which the zooids appear to be arranged. The remainder of the colony is covered with sand, and also sand is embedded internally.

INTERNAL STRUCTURE: The zooids in this specimen are muscular and very contracted and few details of their morphology can be determined. The atrial lip is produced from the rim of the atrial aperture. There are at least 13 rows of stigmata. The large smooth-walled stomach is halfway down the abdomen. Gonads are not mature.

REMARKS

The identification of this specimen is based on the form of the colony. However the free end of the head is expanded and flat in the type specimen, but not in the present specimen. Millar (1966) did not describe the specimen he recorded from Port Phillip Bay. Kott (1969) thought this species to be synonymous with the sub-antarctic *A. recumbens*; and Millar (1982) referred to proposals that *S. arenaceum, S. herdmani* and *S. kuranui* are conspecific. Generally the relationships of these species are unresolved, although *S. kuranui* unlike the others has a mulberry-like stomach, and appears to be different. Further, colonies of the present species have long cylindrical branching stalks different from the tapering ones of *S. kuranui*. At this stage the New Zealand populations require review, and more Australian material is needed to establish the status of this species and its populations on both sides of the Tasman Sea.

Synoicum atopogaster Kott, 1963
(Fig. 41)

Synoicum atopogaster Kott, 1963, p.89.

DISTRIBUTION

NEW RECORDS: None.
PREVIOUSLY RECORDED: Western Australia (W of the Abrolhos — AM U3927 holotype Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: The colony is a thick, cylindrical upright lobe, 5cm high and 2.5cm in diameter. A few smaller lobes are present around the base. The test of the lower half of the colony is firm, while that of the upper half is soft. A crowded layer of sand adheres to the surface test of the lower half, and some is on the upper surface between bare patches.

Zooids extend out to occupy the whole length of the colony, but when contracted they are found either near the top, or withdrawn down into the base. They are arranged in 4 or 5 systems opening around the upper surface. Each common cloacal aperture appears to be surrounded by a circle of zooids, with their branchial apertures protected by a ridge of surface test.

The holotype colony is wrinkled transversely and its head is displaced laterally.

INTERNAL STRUCTURE: The zooids are large, the thorax and abdomen of contracted zooids being at least 4mm long. They have about 30 longitudinal muscle bands on the thorax and these continue as a wide band along the ventral surface of the abdomen and posterior abdomen. When

contracted, this muscle band draws up the posterior abdomen alongside the abdomen. The branchial aperture is on a short, narrow siphon with the rim divided into 6 lobes. The 2 ventral lobes are slightly enlarged and dorsally-directed. The atrial aperture has a fleshy lip from the anterior rim and a few irregular lobes on the posterior rim.

Each of the 17 rows of up to 10 stigmata is crossed by a parastigmatic vessel, and both primary transverse and parastigmatic vessels have a dorsal languet. Transverse vessels contain muscle fibres. The oesophagus is long, the stomach voluminous, collapsed into transverse folds. The duodenum and mid-intestine are relatively long and narrow and the oval posterior stomach large.

The gonads consist of a clump of male follicles about halfway down the posterior abdomen, with a small ovary anterior to them. The vasa efferentia join to form the vas deferens about halfway up the side of the male follicles, rather than each follicle separately joining the vas deferens as it passes up the length of the posterior abdomen.

A single embryo is present in the atrial cavity of zooids of the holotype colony. The larval trunk is 1.3mm long. A median ampulla with 2 or 3 branches is in each interspace between the median adhesive organs. Minute epidermal vesicles branch off the epidermis and lie in the thin layer of test that surrounds the large trunk. The yolk mass is large, the developing adult organs are crowded into the posterior end of the trunk.

REMARKS

The zooids of this species are, in some respects,

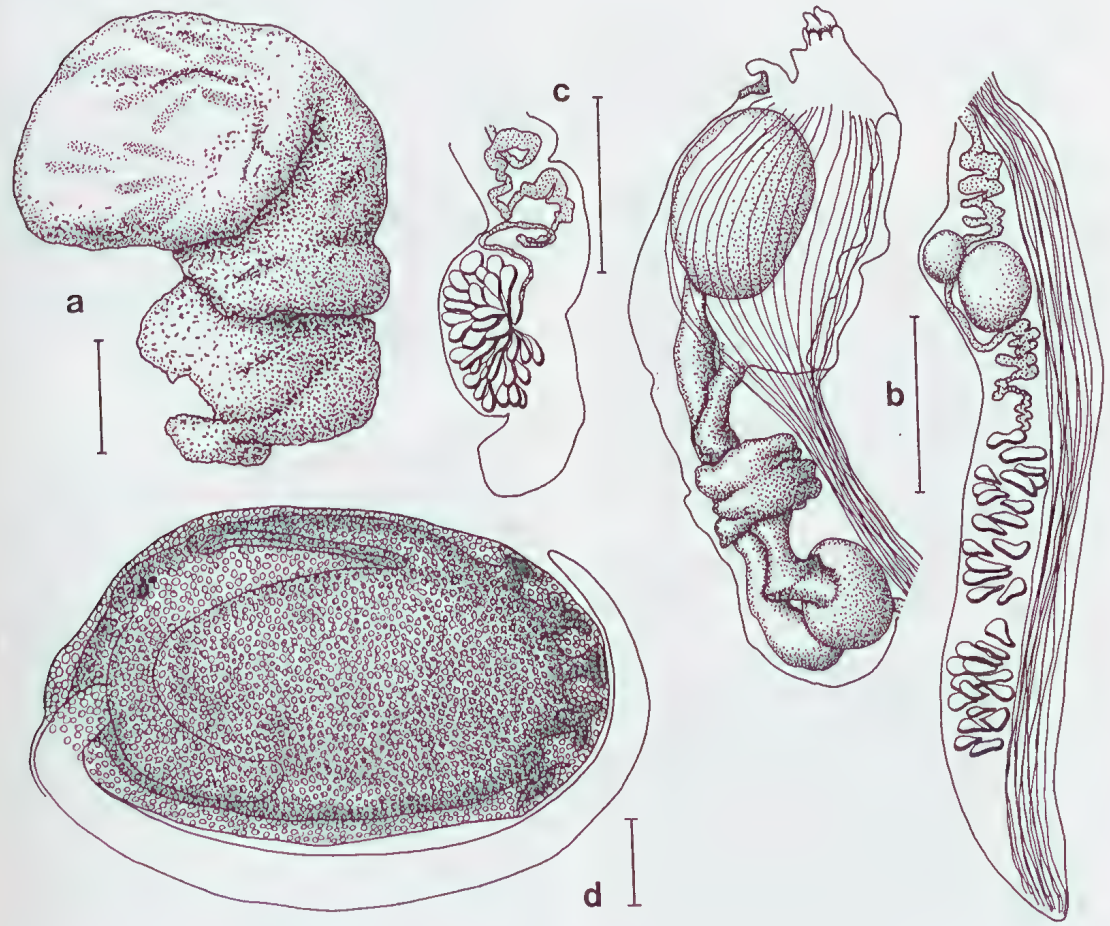

FIG. 41: *Synoicum atopogaster* (holotype AM U3927) — **a**, colony; **b**, zooid; **c**, contracted posterior abdomen; **d**, larva. The epidermal vesicles in the test around the sides of the larval trunk are not shown. Scales: **a**, 1cm; **b**, **c**, 1mm; **d**, 0.2mm.

like those of *S. concavitum* n.sp., having a similar large stomach, a strong ventral muscle, and conspicuous transverse muscles in the branchial sac. However, *S. concavitum* n.sp., has a flat rather than upright colony with more numerous, but smaller systems in firm, naked, gelatinous test.

The relationship of the species to *Morchellium pannosum* n.sp. is discussed below. The course of the vas deferens resembles that of *Pseudodistoma candens* n.sp., but a phylogenetic relationship between these taxa is not implied.

Synoicum bowerbanki Millar, 1963
(Fig. 42. Plate 8a)

Synoicum bowerbanki Millar, 1963, p.697.

DISTRIBUTION
NEW RECORDS: Victoria (Portland, QM GH38, SAM E2551, MV F59372).
PREVIOUSLY RECORDED: Western Australia (Fremantle — Millar 1963). Millar (1963) records a further specimen from an unknown Australian locality.

DESCRIPTION
EXTERNAL APPEARANCE: Colonies are upright and club-shaped (to 6cm high) to almost spherical (to 5cm in diameter). A short stalk from the under surface reduces in diameter toward the substrate, although in some specimens it is divided into branched roots. Several of the newly recorded specimens (SAM E2551, QM GH38) have a single layer of sand grains attached to the surface test, interrupted over the zooid openings. Several upright, club-shaped colonies (MV F59372), however, are naked with basal sandy roots. Sand is not present internally.

Zooids are arranged in evenly spaced circular cloacal systems of about 6 zooids around a central cloacal aperture. Each system is about 5mm in diameter.

The red test of living colonies becomes transparent and pink in preservative, although this is obscured by the surface layer of dark grey sand grains. The naked colonies are opaque purple on the surface, but transparent internally. The test is gelatinous and firm, but soft.

INTERNAL STRUCTURE: Zooids are long (to 1cm) and thread-like. When contracted, the thorax and abdomen together are about one third of the total length. The terminal branchial aperture is almost smooth-rimmed, the 6 branchial lobes being almost completely suppressed. The atrial aperture is on a relatively long siphon, with its anterior border produced into a lip with its tip divided into 3 rounded lobes which are inserted into the rim of the cloacal aperture. Apart from the sphincter muscles around the apertures, thoracic musculature is limited to about 14 fine longitudinal and oblique muscles. These extend in a band along each side of the abdomen and posterior abdomen. There are 4 rows of stigmata with up to 15 per row. The oesophagus is curved, the stomach wall is smooth. The duodenal part of the gut is long and the mid-intestine is expanded before opening into an oval posterior stomach in the bend of the gut loop. The anal opening is about one-third of the way up the thorax.

A group of 3 or 4 oocytes are posterior to a gonad-free part of the posterior abdomen behind the gut loop. Behind the ovary are testis follicles in a single longitudinal series sometimes occupying most of the length of the posterior abdomen. The testis follicles are spent in the colonies with embryos being incubated. The species may be protandrous.

Zooids of colonies collected in July (QM GH38) have up to 5 embryos at a time in the atrial cavity. They are at different stages of development, and perhaps were fertilised in the oviduct. Larvae have a trunk 0.7mm long. Small adhesive organs on slender stalks alternate with conical median ampullae. There also are 4 rounded lateral ampullae on each side. Ampullary vesicles develop on a posteriorly projecting median stalk both ventrally and dorsally. The larval tail reaches to the anterior end of the trunk.

REMARKS
The holotype of this species from Fremantle (Millar 1963) and the specimens Millar described at the same time, from an unknown locality, are fleshy naked masses, up to 9cm in maximum extent, and 3cm thick. Most of the newly recorded specimens have a single layer of sand adhering to the surface test, although some club-shaped ones from Portland (MV F59372) are naked, but with sandy basal root-like projections of the test. However, all known specimens have an almost smooth branchial aperture, a conspicuous atrial siphon with a tridentate tip on the anterior lip, smooth stomach wall, a single row of male follicles, 4 rows of up to 15 stigmata, and a similar larva. Although the cloacal systems of the type specimens are not described, the unusual almost smooth branchial apertures together with the reduced branchial sac support the view that the newly recorded material from south-eastern Australia (in which there is some variability in shape and in the presence of a surface layer of sand) is

conspecific with the type specimens (Millar 1963).

The oesophagus of *Synoicum* spp. is characteristically longer than in most other genera of the Polyclinidae, and its curve is also characteristic of the genus. However, the oesophagus of the type specimen of *S. bowerbanki* figured by Millar (1963, p.697) is unusually long in relation to the total length of the gut loop, the stomach being in the posterior third of the abdomen rather than half way down it as is more usual.

Synoicum buccinum n. sp.
(Fig. 43. Plate 8b)

DISTRIBUTION

TYPE LOCALITY: Coral Sea (Marion Reef, cave, 8m, coll. N. Coleman 24.8.77 AMPI 209, holotype QM GH5045). Queensland (Heron I., rubble zone, sandy substrate, coll. P. Kott 26.2.84, paratypes QM GH5046; W. reef crest, W. Wistari Reef, coll. P. Kott 12.9.84, paratypes QM GH5047; NW corner Wistari Reef, coll. P. Kott 3.11.86, paratypes QM GH5048).

FURTHER RECORDS: Queensland (Capricorn Group, QM GH5049–52 GH5585).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are slender, sandy, cylindrical, irregularly bent, branching stalks. The terminal branches are about 1cm long and 3mm in diameter expanding toward the free end into a rounded to flat-topped or flattened mushroom-like naked head up to 1.5cm in diameter onto which the zooids open. Each terminal

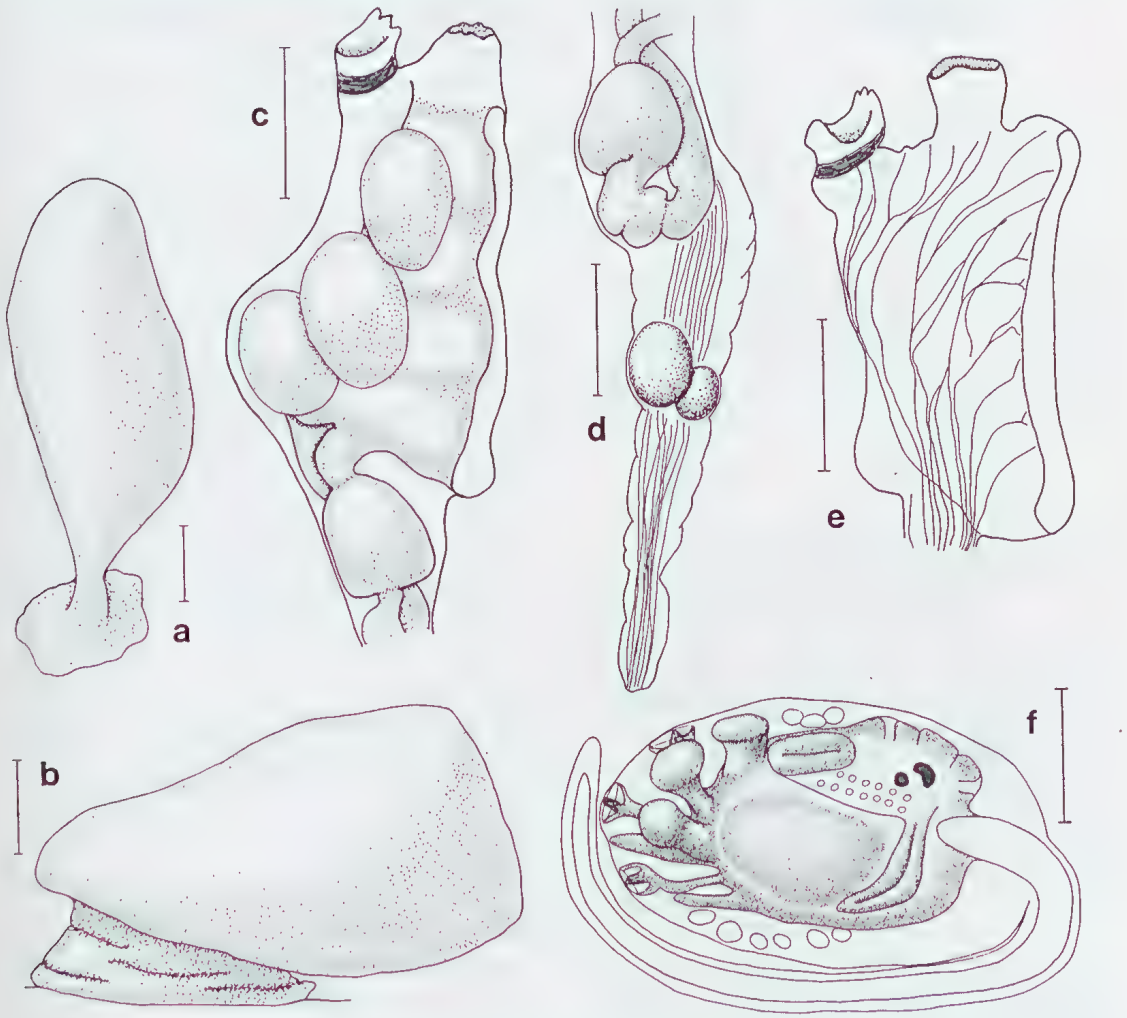

FIG. 42: *Synoicum bowerbanki* — **a**, **b**, outline of colonies (MV F59372, QM GH38); **c–e**, parts of zooids (QM GH38); **f**, larva (QM GH38). Scales: **a**, **b**, 1cm; **c–e**, 0.5mm; **f**, 0.2mm.

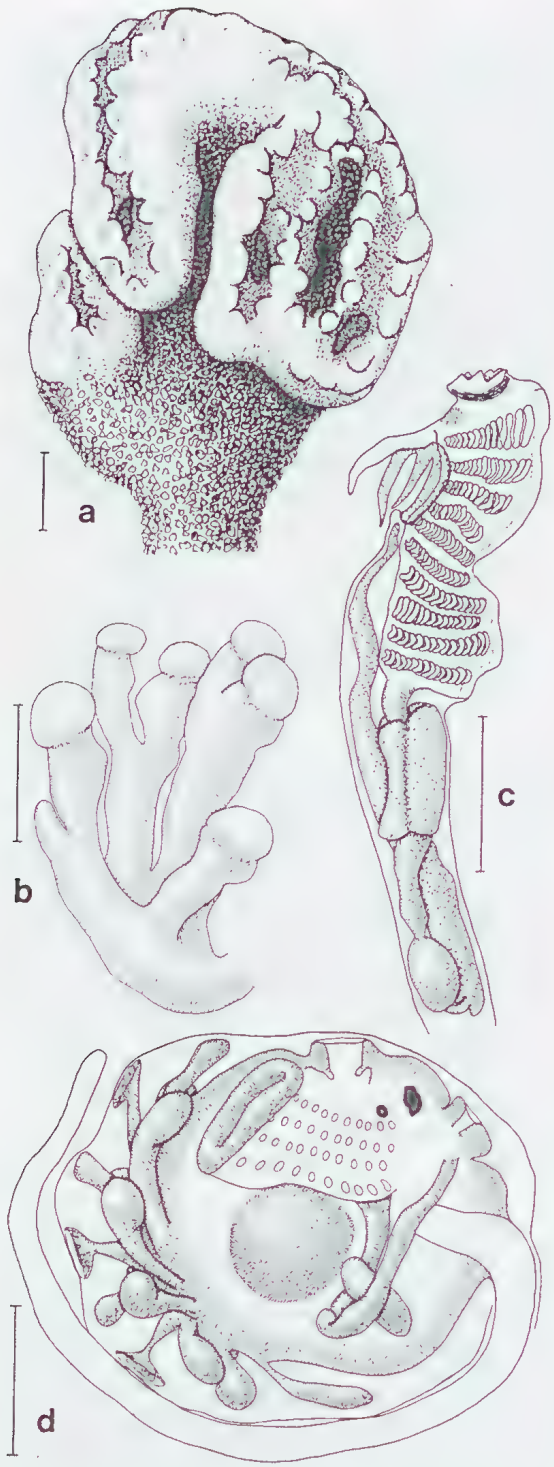

FIG. 43: *Synoicum buccinum* n.sp. — **a**, **b**, colonies (**a**, detail of systems, paratype QM GH5048; **b**, outline of holotype QM GH5045); **c**, thorax and abdomen (QM GH5299); **d**, larva (paratype QM GH5047). Scales: **a**, 2mm; **b**, 1cm; **c**, 0.5mm; **d**, 0.2mm.

stalk contains from one to 5 or 6 circular to long systems of 6 or more zooids around large, sessile common cloacal apertures. The systems often are separated from one another by deep furrows in the surface test.

Sand is on the external surface of, and embedded through, the stalk, making it hard, but not brittle. The sand sometimes projects up into the centre of the head and forms partitions around the systems. It is always absent from around the zooids in the soft, upper layer of translucent test, through which the zooids can be seen perpendicular to the terminal surface. Sometimes green algal cells are embedded in the surface test together with a scattering of sand particles.

In life the head is 'orange buff' or 'orange rufus' with zooids 'orange chrome' (Ridgeway 1886), but the sandy stalk has no colour and usually is embedded in the substrate.

INTERNAL STRUCTURE: Zooids are moderately small, the thorax and abdomen together being about 2mm long. The posterior abdomen is very long, projecting down into the stalk. One or 2 stolonic vessels are at the posterior end of the posterior abdomen. About 6 fine longitudinal muscle bands extend the whole length of the zooid. The atrial apertures are wide and sessile, with a frilled margin. Muscles are present around the sides and posterior rim of the aperture, and the outside ones loop back across the postero-dorsal surface of the body. The atrial aperture can probably be closed by contraction of the muscles around it, but in most of the zooids examined the dorsal border of the zooid is contracted and concave, partially occluding the aperture. The anterior rim of the atrial aperture is produced into one to 3 long, pointed lips. Nine rows of stigmata are in the pharynx, with 16 per row posteriorly, and 20 per row anteriorly. The gut loop is vertical, and the oesophagus relatively straight. The smooth-walled stomach is quadrate in section and sometimes appears to have 4 folds. These are not true folds. The duodenal area is moderately long, and a posterior stomach is in the bend of the gut loop.

Two rows of male follicles are in the posterior half of the posterior abdomen of the holotype and a small ovary is anterior to the male follicles. A single embryo is in the atrial cavity of this specimen lot (collected in August). Two embryos, one an advanced tailed larva, are present in specimens collected in September. Larvae have an almost spherical trunk about 0.65mm long with the tail wound about three quarters of the way around it. There are median and lateral ampullae, but epi-

dermal vesicles were not detected in the larval test. Both otolith and ocellus are present.

REMARKS

The straight oesophagus and more or less barrel-shaped stomach of this species approach the condition found in *Aplidium* spp. However, stomach folds, when they occasionally are found, do not appear to be structural and the stomach generally is smooth, justifying its position as a species of *Synoicum*.

The colonies resemble those of *S. arenaceum* Michaelsen, 1924 and *S. apectetum* Millar, 1982, from temperate New Zealand waters. The species is distinguished from both by the numerous systems in each head, and further distinguished from Millar's species by the origin of the atrial lip from the rim of the aperture (rather than separately from the body wall anterior to the opening), and by the length of the larval trunk (only 0.5mm in Millar's species). *Synoicum arenaceum* is also distinguished by its more numerous rows of stigmata.

Synoicum castellatum n.sp.
(Fig. 44. Plate 8c–e)

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I, North Point, 5m, coll. D. Parry 4.11.86, holotype QM GH5160; coll. R. Day 4.7.73, paratypes QM GH5163).

FURTHER RECORDS: Western Australia (Exmouth Gulf, QM GH5401). Queensland (Capricorn Group, QM GH5161–2 GH5164–5 GH5512 GH5587 GH5590; Swain Reefs, AM Roche ZQ 326; Broadhurst Reef, QM GH5351 GH5503; Whitsunday Is, QM GH5508; Hook and Hardy Reefs Channel QM GH5376 GH5509; Lizard I., QM GH5332; Raine I., QM GH5627). Northern Territory (Gulf of Carpentaria, AMY1062).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are robust, usually massive cushions to 10cm diameter and about 2cm high. The upper surface has raised rounded ridges that surround more or less circular to irregularly shaped, or stellate depressions. A conical cloacal aperture protrudes from the centre of each depression rising above the level of the rounded ridges. The branchial apertures are around each depression at the base of the raised ridges. A shallow but extensive cloacal cavity surrounded by the zooids is beneath each depressed area. The test is translucent, firm and gelatinous. In life colonies are 'fleshy' coloured, with 'isabella' colour (Ridgeway 1886) in the centre of the ridges. In preservative the flesh colour becomes beige, some darker grey along the ridges and in the margins of the colony, and minute dark pigment cells in the test.

The zooids are in rigid compartments in the firm test. They are large and not crowded. Neither embedded nor adherent sand is present.

INTERNAL STRUCTURE: Zooids are large and robust, the thorax and abdomen together about 1cm, even in contracted zooids. The posterior abdomen is at least twice that length. Each branchial aperture has 6 large triangular lobes and a strong sphincter muscle behind the branchial lobes. The atrial tongue is fleshy, sometimes long and pointed, sometimes contracted and blunt and occasionally divided into 2 lobes. Five small pointed papillae are evenly spaced around the rim of the atrial aperture posterior to the atrial tongue, which extends out from the anterior rim of the opening. About 30 longitudinal muscles are in the parietal wall of the thorax, and these continue along the length of the zooid. Transverse muscles are in the transverse vessels of the branchial sac. Short stumpy connecting branches from the muscles in each transverse vessel cross the atrial cavity in connecting vessels about one third of the distance from the dorsal mid-line. These muscles break into terminal branches which join with the eighth to tenth longitudinal muscles on each side of the pharynx. The connecting vessels with their contained muscles effectively divide the atrial cavity into a dorsal chamber (containing faeces and embryos) and a ventral chamber on each side of the pharynx.

The branchial sac is long and wide with 18 to 22 rows of stigmata. In the centre of the sac about 30 stigmata are in each row but the rows dramatically reduce in length posteriorly.

The stomach is large, and its shape sometimes is obscured by horizontal folds when contracted. The stomach wall is smooth externally in the relaxed zooid, but with some variability in its internal lining. Occasionally vertical divisions separate the glandular lining into 4 to 8 ribbon-like bands. In other specimens these bands become irregular patches of glandular epithelium interrupted by branching internal ridges which may be parallel to one another toward the posterior end of the stomach. The remainder of the descending limb of the gut loop has the usual duodenum, proximal part of the mid-intestine, small posterior stomach, and the distal part of the mid-intestine which opens into the rectum at the base of the ascending limb of the gut loop. The

anus is trumpet-shaped and circular. It is not divided into 2 lips. A few relatively large oocytes are anterior to 2 irregular, crowded series of more or less club-shaped testis follicles, in the posterior half of the long, cylindrical posterior abdomen.

One to 3 large embryos are being incubated in the dorsal peribranchial cavity of zooids collected at Heron I. in June and July, but not in August, September or November. Larvae have a trunk 1.0mm long, with the tail wound three-quarters of the distance around it. Median ampullae alternate with the 3 narrow-stalked, shallow adhesive organs. Bands of crowded epidermal vesicles are crowded across the dorsal and ventral mid-lines behind the adhesive organs and extend anteriorly along each side of the mid-line.

Remarks

These large, robust, naked colonies with their zooid systems opening into large depressed areas separated by high rounded ridges of naked test, superficially resemble both *Lissoclinum patella* (Didemnidae: see Kott 1980) and *Aplidium crateriferum* (see below). The large, protuberant

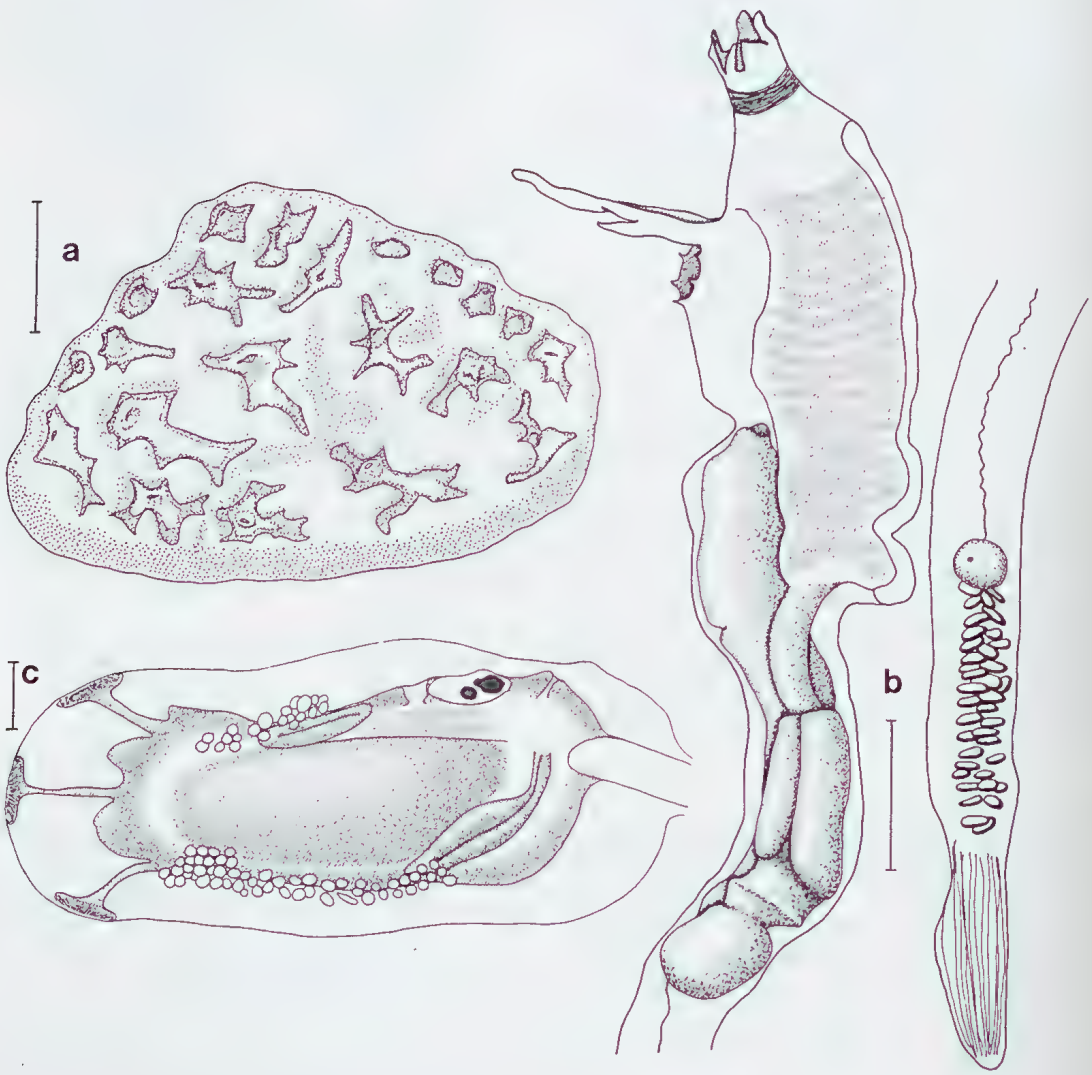

FIG. 44: *Synoicum castellatum* n.sp. — **a**, colony (holoytpe QM GH5160); **b**, zooid (QM GH5164); **c**, larva (QM GH5163). Scales: **a**, 2cm; **b**, 1mm; **c**, 0.1mm.

common cloacal apertures of the latter also resemble those of the present species. In addition to the differences in its stomach wall, *A. crateriferum* systems open into depressions that are long, slightly curved with excentric cloacal apertures rather than the more circular to stellate depressions with central common cloacal that occur in the present species. *Aplidium crateriferum* also has a differently shaped zooid from that of the present species, with the atrial lip separated from the aperture and a narrow thorax with only 8 (rather than the present 30 stigmata).

Aplidium clivosum n.sp. has a similar robust colony, but the zooids are in double rows along cloacal canals that converge to the common cloacal apertures.

Synoicum chrysanthemum n. sp.
(Fig. 45)

DISTRIBUTION

TYPE LOCALITY: Western Australia (NW Bluff Point 27°40'S 113°03'E, 130m, CSIRO 22.8.63, holotype WAM 1031.83; paratype 21.8.63 WAM 1032.83; 80km W of Dongara 64m, MV Sprightly 19.2.76, paratype WAM 850.83 *QM GH2115*).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are mushroom-like consisting of a spherical to conical head to 5cm in diameter, on a thick, cylindrical stalk 3 to 4cm long and 1cm in diameter. Basally the stalk divides into 2 or 3 short thick roots.

The preserved colonies are opaque and white. Sand is crowded in the surface layer of test, but becomes less so internally. The surface of the head is covered with circular zooid-free areas (about 5mm in diameter) which swell out from the surface a little. These are surrounded by cloacal canals which lie beneath depressions or creases in the surface test. The layer of test over the cloacal canals is thin but opaque with sand embedded. Common cloacal cavities are where several of the circular canals meet beneath a large common cloacal aperture. Cloacal canals are rigid with sand and in the examined colonies the branchial sacs are exposed directly to them through the large atrial apertures.

INTERNAL STRUCTURE: The thorax and abdomen together are about 3mm long, with the thorax longer than the abdomen. The posterior abdomen

FIG. 45: *Synoicum chrysanthemum* n.sp. (paratype QM GH2115) — a, colony; b, relaxed zooid with wide open atrial aperture. Scales: a, 2cm; b, 0.5mm.

is particularly long, extending into the centre of the head and down into the stalk.

One to 3 shallow to pointed, fleshy atrial lips are produced from the body wall just anterior to the atrial sphincters. The atrial aperture is open for about the middle two-thirds of the length of the thorax. No dorsal papilla was seen, although its presence could have been obscured by the wide open atrial aperture. About 10 rows of 10 long narrow stigmata are in the branchial sac. The stomach is smooth, and quadrate in section. Gonads were not observed in the examined material.

REMARKS

The organisation of the cloacal systems, with zooids in double rows, one row along each side of the narrow canals that surround the raised circular areas on the surface, resembles some *Aplidium* species (e.g. *A. tabascum* n.sp., *A. cellis* Monniot, 1987) from the tropical western Pacific. The present species is stalked, unlike the sessile sheets of these *Aplidium* spp. It is further distinguished by the sand which is crowded throughout the test.

Synoicum citrum n. sp.
(Fig. 46. Plate 8f)

DISTRIBUTION

TYPE LOCALITY: Victoria (Wilson's Promontory, Waterloo Bay, 25m vertical face, coll. J.E. Watson 26.1.78, holotype QM GH 5104). Tasmania (Satellite I. off Bruny I., d'Entrecasteaux Channel, 6m vertical face, coll. J.E. Watson 18.2.72, paratype MV F59369).
FURTHER RECORDS: South Australia (Port MacDonnell, QM5104 GH2294). Tasmania (Satellite I. off Bruny I., MV F59366).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are rounded, cushion-shaped, sessile and fixed by a small part of the basal surface. The test is gelatinous and translucent. The zooids open onto the upper surface. The known colonies are squashed, often mutilated. Zooids are crowded. They may be arranged in circular systems but these are obscure. The colonies are up to 2cm high and up to 3cm in maximum dimension. Zooids are said to have been bright yellow in a yellow matrix when alive.

INTERNAL STRUCTURE: Contracted zooids are nearly 5mm long, the fleshy thorax and abdomen together being about half of the total length. The thorax is especially large, with 12 to 20 longitudinal muscle bands that extend the length of the zooids. Conspicuous sphincters are present around the base of the branchial siphon. The branchial lobes are relatively low and rounded. The atrial lip, continuous with the anterior rim of the aperture, is fleshy and usually bilabiate, with each lobe long and pointed.

Seven or 8 rows of about 20 stigmata are in the branchial sac. The stomach is large almost spherical and smooth walled. Long double rows of male follicles are in the relatively short posterior abdomen.

REMARKS

The species is distinguished by its fleshy, ses-

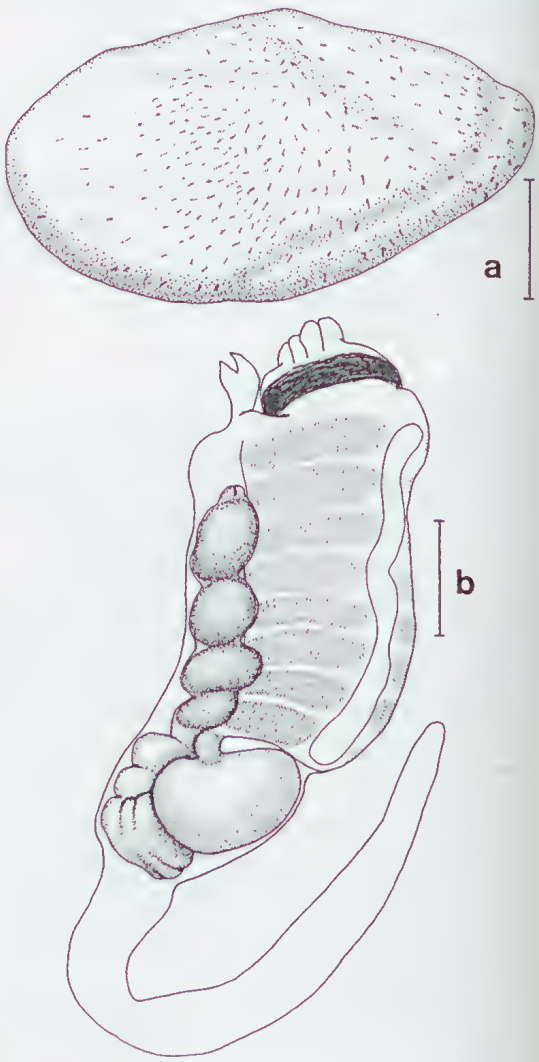

FIG. 46: *Synoicum citrum* n.sp. (holotype QM GH5014) — a, colony; b, zooid. Scales: a, 1cm; b, 0.5mm.

sile, cushion-shaped, translucent, greenish-yellow colony, which lacks sand either on the outside or embedded in the test. Zooids are relatively large for this genus, but they have fewer rows of stigmata than most other species. *Synoicum prunum*, which has a range on the mid- to north-eastern Australian coast, also has firm gelatinous colonies but the known ones are larger than the present species, and the zooids are smaller, with narrow thoraces.

Many species of this genus known *in situ* have red colonies, often with red zooids, rather than the yellowish colour of the present one.

Synoicum concavitum n.sp.
(Fig. 47. Plate 8g)

DISTRIBUTION

TYPE LOCALITY: Western Australia (Eclipse I. SW entrance to King George Sound, rocky granitic reef, large boulders, coll. AIMS Bioactivity Group 26.3.89, holotype QM GH5465).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colony is an irregular cushion about 6cm in maximum dimension and up to 3cm thick. The test is firm, gelatinous, and slightly translucent. It is orange in life, but brown in preservative. Sand is on the under surface and sides of the colony, but the upper surface is naked and even. Sand is absent from the upper (thoracic) layer of test but is sparsely but evenly scattered through the lower part of the colony. The upper surface of the colony is depressed over the circular cloacal cavities. Branchial apertures of the zooids (about 12) in each system open around the perimeter of each depression. The ventral lobes of each branchial aperture extend horizontally directing the openings toward the large, protuberant cloacal aperture that rises from the centre of each depression.

INTERNAL STRUCTURE: Zooids are brown in preservative. They are large, the thorax and abdomen of about equal length, and together about 3mm long even when contracted. The branchial siphon is moderately long, with 6 pointed lobes, the ventral ones usually longer than the dorsal ones (see above). The atrial siphon, also protruding, has 3 small pointed lobes around its posterior rim, and a long strap-like tongue from the upper rim of the opening. This tongue has a straight tip with small denticulations on it.

A large number of fine longitudinal muscle bands are on the thorax, making an almost con-

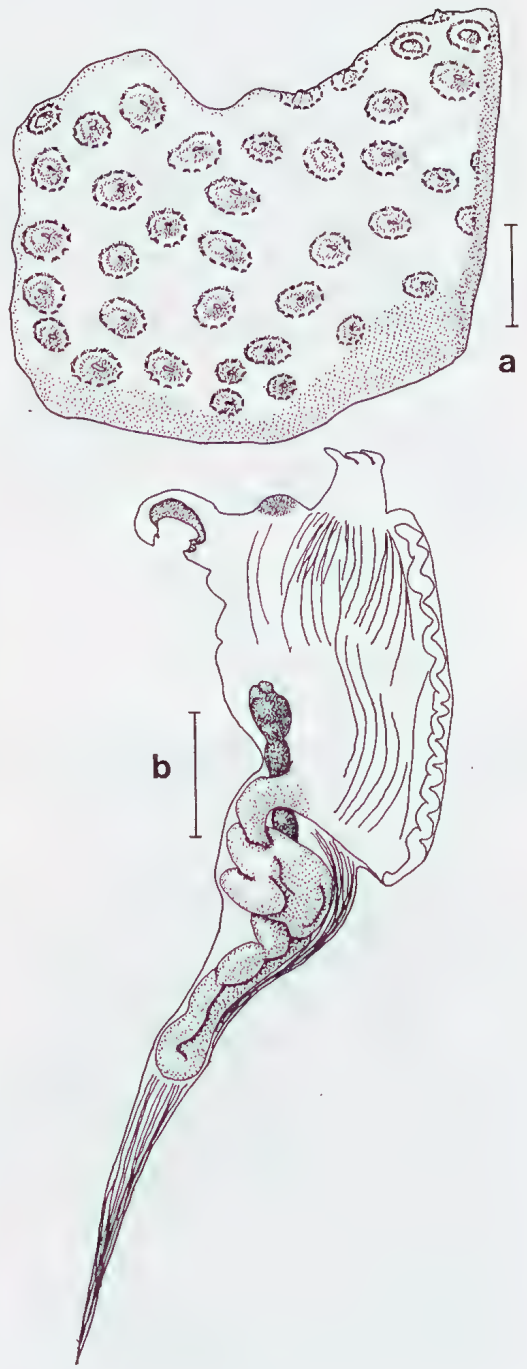

FIG. 47: *Synoicum concavitum* n.sp. (holotype QM GH5465) — a, part of colony from above; b, zooid. Scales: a, 1cm; b, 0.5mm.

tinuous coat. These extend in a band along the ventrum of the abdomen and along both sides of the posterior abdomen. Transverse muscles are in the transverse vessels. The pharynx is wide, with 15 rows of stigmata with up to 18 per row. The gut loop is moderately long, with the large, voluminous stomach about halfway down the abdomen. The stomach wall is smooth, although in these specimens it often is collapsed into irregular or horizontal folds. The duodenum and proximal part of the mid-intestine are long, and almost continuous. There is an oval posterior stomach at the base descending limb of the gut loop. The posterior abdomen is relatively short and tapering in these zooids. Gonads are not developed.

REMARKS

The species resembles *Synoicum tropicum* in the form of its systems. It is distinguished principally by the larger branchial sac of the present species.

Synoicum durum n.sp.
(Fig. 48)

Synoicum kuranui: Kott, 1963, p.88.

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I., low tide, coll. R. Carson June 1961, holotype AM U3990).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: Small wedge-shaped to inverted conical lobes, reducing in diameter toward the base, to 1cm high and 0.8cm diameter across the flat upper surface. Sand is in a surface layer around the sides of the lobes, and on the upper surface and internal test between the systems. Two to 4 circular systems, each of up to 10 zooids, open on the flat top of each of the lobes, and sand is absent from the surface above these systems. Each system has a central sessile common cloaca. At first the test is yellowish in preservative and zooids are red, but subsequently all colour is lost.

INTERNAL STRUCTURE: The zooids are small, up to 2mm long, of which the thorax and abdomen is about half. Ten longitudinal muscles are on each side of the thorax, and these extend in a wide band along each side of the abdomen and posterior abdomen. The branchial siphon is short and

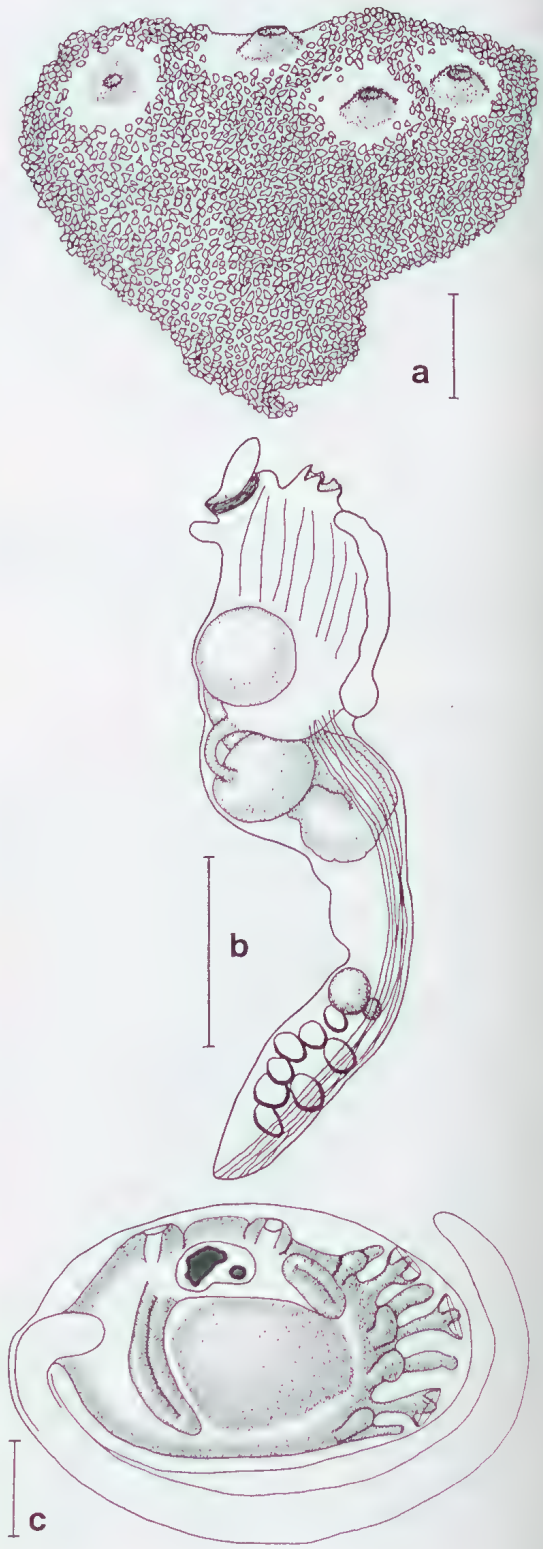

FIG. 48: *Synoicum durum* n.sp. (holotype QM U3990) — **a**, colony; **b**, zooid; **c**, larva. Scales: **a**, 2mm; **b**, 0.5mm; **c**, 0.1mm.

there are 6 distinct lobes. The rounded atrial lip is produced from the upper rim of the atrial siphon. A distinct median dorsal papilla is behind the atrial siphon. There are about 10 rows of 15 stigmata. The oesophagus curves ventrally to enter the large, smooth walled stomach. A gonad-free part of the posterior abdomen is behind the abdomen, but the posterior two-thirds of the abdomen is occupied by the irregular double row of large male follicles with the small ovary anterior to them.

Up to 2 embryos are in the posterior half of the atrial cavity. Tailed larvae are amongst the smaller viviparous larvae known, having a trunk only about 0.4mm long. They have median and lateral ampullae, and an otolith and ocellus. The tail is wound about three quarters of the way around the trunk.

REMARKS

These colonies do slightly resemble those of the New Zealand *S. kuranui* Brewin, 1950 which, however, has shallow circular swellings on the stomach wall, giving it a slightly mulberry-like appearance. The species also resembles *S. suarenum* n. sp., having an atrial lip from the upper border of the opening, a smooth stomach, a dorsal papilla, embryos being incubated in the posterior half of the atrial cavity, and circular systems opening on the flat upper surface of the colony lobes. There is, however, a difference in the relative size of the zooids and larvae in these two species, viz. 2mm and 0.4mm respectively in *S. durum*, and up to 1cm and 0.6mm in *S. suarenum* n. sp.

Synoicum erectum n. sp.
(Fig. 49)

DISTRIBUTION

TYPE LOCALITY: Victoria (south of Warnambool, 250 – 350m, from shark lines, coll. V. Johnstone 14.5.69, holotype MV F59367). South Australia (SSW Eucla 33°17'S 128°12'E, 18m, CSIRO RV *Soela* 13.1.89, paratype SAM E2554).

FURTHER RECORD: Victoria (27mls east of Gabo I., SAM E2555).

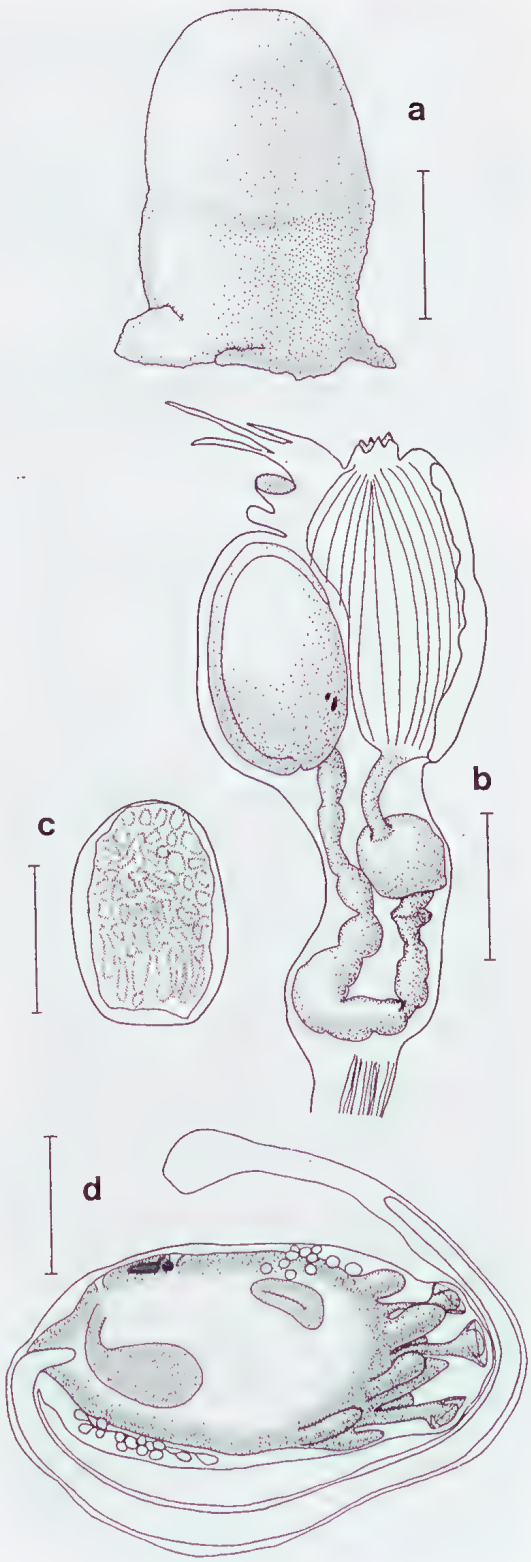

FIG. 49: *Synoicum erectum* n.sp. — **a**, colony outline (paratype SAM E2554); **b**, thorax and abdomen with embryo in atrial cavity (holotype MV F59367); **c**, internal wall of stomach (paratype SAM E2555); **d**, larva (holotype MV F59367). Scales: **a**, 1cm; **b**, **c**, 0.5mm; **d**, 0.2mm.

DESCRIPTION

EXTERNAL APPEARANCE: The holotype colony has been mutilated, but it appears to have been an upright cone, 3cm high and about 3cm in diameter across the flat base. The colony is covered with a thin layer of sand. Some root-like processes spread out around the base. Internally the test is very soft with only sparse embedded sand grains. Zooids, opening to the surface around the upper part of the cone, are crowded, possibly in circular systems. There is no trace of pigmentation in these zooids.

The Gabo I. and the paratype colonies are very similar to one another, smaller (to 2.5cm high) than the holotype, and retaining red colour in the zooids which are seen through the relatively light encrustation of sand on the upper half of the colony. The lower half of each of these colonies is slightly reduced in diameter and is more thickly encrusted with sand, forming a short, thick stalk. The base of the stalk is packed with embedded sand, but there is very little sand embedded in the rest of the soft internal test. Crowded circular systems of 8 to 9 zooids can be seen around the top half of each colony.

INTERNAL STRUCTURE: Zooids are robust, but when contracted the thorax and abdomen are less than 1mm long. The posterior abdomen is long. Branchial lobes are well defined, but relatively shallow. The atrial lip extends out from the anterior border of the aperture, long and fleshy, sometimes bifid at the tip, sometimes undivided and pointed, or with a fringe of up to 10 points on the straight edged tip. There is a small median dorsal papilla behind the atrial aperture. Longitudinal muscles (about 12) from the thorax extend back along each side of the zooid to its posterior extremity.

The pharynx has about 12 rows of about 8 stigmata, but these were difficult to count, as all the colonies have contracted zooids. The gut loop is almost the same length as the thorax in most of the examined zooids, but, as the thoraces are invariably more contracted than the abdomen, this ratio probably varies with the condition of the zooids.

The oesophagus is long, narrow and curves to enter the stomach. The stomach wall usually has glandular thickenings of the inner wall. However sometimes (SAM E2555) there are mulberry-like external swellings on some parts of the stomach. The distal part of the descending limb of the gut loop has the usual long duodenum, expanded mid-intestine, posterior stomach, and narrow intestine opening into the rectum at the proximal end of the ascending limb of the loop. The posterior abdomen is long and cylindrical. Only the ovary could be clearly identified, halfway down the posterior abdomen of the Gabo I. specimen (MV F2555).

Up to 2 embryos are incubated in the atrial cavity of specimens collected in May (MV F59637) and October (SAM E2555). They were not present in the paratype colony collected in January (SAM E5554). The larval trunk is about 0.7mm long, and the tail is wound about three quarters of the way around it. There are median and lateral ampullae, and patches of postero-ventral and antero-dorsal epidermal vesicles.

REMARKS

The zooids are small (though not as small as those of *S. prunum*), but the larval trunk is longer than usual for *Synoicum* spp. *Synoicum sacculum* n. sp. has a similar temperate range to the present species; and it also has the atrial lip from the upper rim of the aperture, a mulberry-like stomach, narrow thoraces, and red zooids and colonies. However, *S. sacculum* n. sp. has a short posterior abdomen with bunched male follicles, a brood pouch constricted off from the thorax, and larvae with a shorter trunk than those of the present species. Also, *S. sacculum* has a multilobed colony with a naked surface that is produced into rounded protrusions over each system of zooids (unlike the present species which has a fine encrustation of sand and a smooth external surface).

The sandy lobes of this species resemble those of *S. partitionis* Monniot, 1987, from New Caledonia. The latter species is distinguished by its wide pharynx with 18 rows of stigmata as well as by its tropical occurrence.

Synoicum galei n. sp.

Macroclinum hypurgon: Michaelsen, 1930, p.535 f. galei.

Not *Synoicum hypurgon*: Kott, 1963, p.86 (> *Aplidium* spp.); 1976, p.62 (< *Polyclinum fungosum*).

DISTRIBUTION

TYPE LOCALITY: Western Australia (Fremantle — Michaelsen 1930).

FUTHER RECORDS: None.

DESCRIPTION (after Michaelsen 1930)

EXTERNAL APPEARANCE: The colonies are irregular, flat topped cushions or sheets, with broad ridges and furrows on the surface, up to 5cm in maximum dimension and 1.8cm high. The test is

soft, but with a tough, thin outer cuticle. Zooids (from 4 to 11) are arranged in circular to oval systems. The cloacal apertures are sessile, and depressed into a groove. Sparse sand is present on the margin, but the upper surface of the colony is naked.

INTERNAL STRUCTURE: The zooids are about 1cm long, of which about 8mm is posterior abdomen. The thorax is longer than the abdomen. The branchial lobes are inconspicuous. The atrial siphon has the tongue extending from the upper rim of the aperture. Two loose bands of muscle extend along each side of the zooid to its posterior end. The stomach is smooth-walled. A brood pouch is constricted off from the postero-dorsal corner of the thorax. It always contains 2 embryos.

REMARKS

Despite the difference in colonies and the absence of the faecal pellets that occur in the type specimen from New Zealand, Michaelsen (1930) assigned the Western Australian specimen to *S. hypurgon* on the basis of the similarities in the zooids. However there are differences between the New Zealand and Fremantle colonies, and they are not conspecific. A new species is erected to accommodate the Fremantle specimens referred to *S. hypurgon* f. galei: Michaelsen, 1930. The species is distinguished from others which have the atrial lip associated directly with the rim of the aperture by the smooth stomach wall, absence of a dorsal papilla, and the flat-topped irregular colony with surface ridges and furrows.

Kott (1963), interpreting the dark oval bodies embedded in the test as faecal pellets, assigned colonies — one each from Heron I. and Rottnest I. — to the present species. Re-examination of these specimens (AM Y1382 U3991) has shown them to be *Aplidium lobatum*.

Embryos are incubated in a brood pouch (as they do in the present species) in *S. sacculum* n. sp., which has lobed colonies, a dorsal papilla and a mulberry-like stomach wall distinguishing it.

The broad ridges and furrows on the surface are reminiscent of those in *Aplidium crateriferum* and *A. lobatum* n. sp. However the latter species has a distinctive zooids which more closely resemble those of *S. papilliferum* (see below) than of the present species.

Synoicum intercedens (Sluiter, 1909) (Fig. 50)

Morchellium intercedens Sluiter, 1909, p.108.

Synoicum intercedens: Monniot and Monniot, 1987, p.81.

?*Synoicum suesanum* Michaelsen, 1919, p.27.

DISTRIBUTION

NEW RECORDS: Queensland (Capricorn Group, QM GH5084–5101 GH5105–7 GH5180 GH5182 GH5193 GH5253 GH5256 GH5282 GH5499 GH5566 GH5571–2 GH5591–2 GH5608 GH5672).

PREVIOUSLY RECORDED: Indonesia (Sluiter 1909). Moorea, Tahiti (Monniot and Monniot 1987).

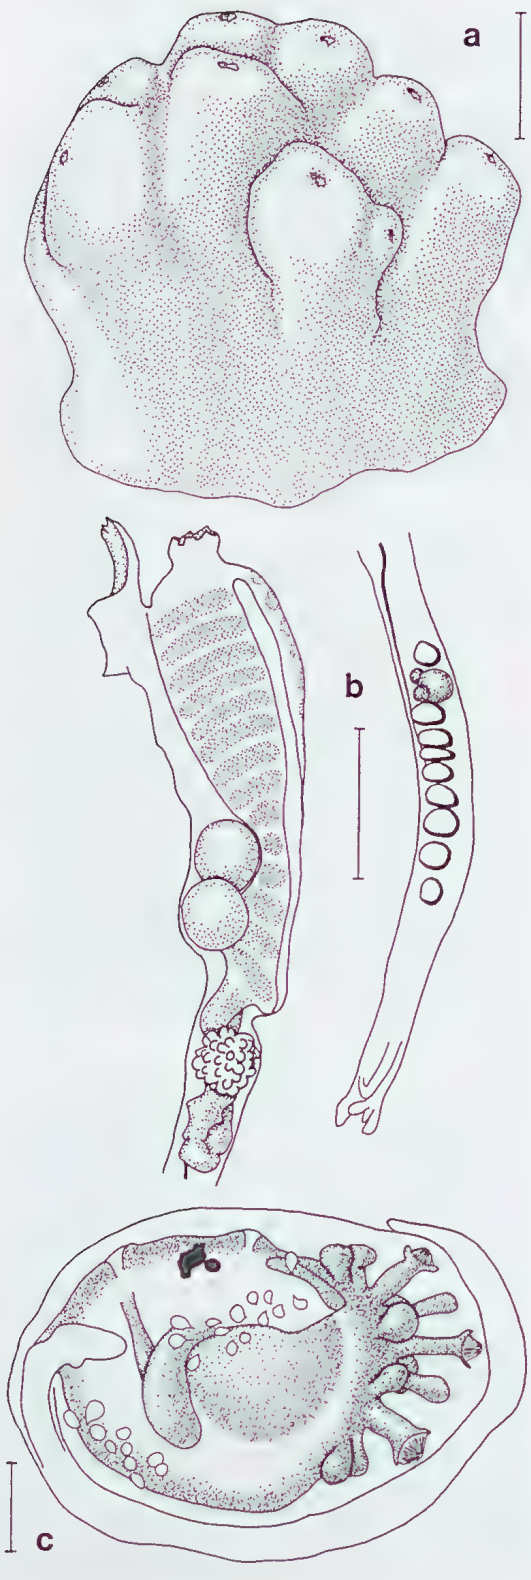
Although at present there are no records from Australian locations, other than those from the southern end of the Great Barrier Reef, it is probable that the species will be found generally around the northern part of the continent and in the western Pacific.

DESCRIPTION

EXTERNAL APPEARANCE: The colonies form cushions up to 3cm long with the upper surface divided into low, rounded swellings to domes from 3 to 10mm in diameter, projecting up to 5mm from the solid sandy basal common test and outer margin of the colony. Each of these protuberances has a large central sessile common cloacal aperture. One specimen has a few randomly distributed test swellings each containing a single system of juvenile zooids on the surface of a mass of firm gelatinous basal test (QM GH5090) and probably is a regenerating colony. Sometimes only a shallow crease is in the surface test delineating the circular area that is homologous with a rounded projection in other specimens. Sand sometimes lies in the crease between the surface swellings, and is present in the basal test. Up to 10 zooids are in each system.

The test is particularly opaque and firm in consistency in larger colonies, but is transparent and soft but firm in small ones. The living colonies are a chestnut or claret colour, or 'claret brown', or 'chocolate brown', or 'aster purple' (Ridgeway 1886), with 'madder brown' cells throughout the test. Some small colonies, when living, are described as 'red cherries projecting from sandy base and margin'. Zooids are 'burnt carmine' or 'aster purple' (Ridgeway 1886), or brownish-black. Basally colonies are yellowish, probably owing to the embedded sand showing through the brown test. In preservative the colonies are light yellowish, cloudy and translucent and the zooids are reddish-brown.

INTERNAL STRUCTURE: Zooids are up to 1cm long. Six rounded lobes surround the branchial aperture. The atrial siphon is relatively large, its



upper border is produced into a long lip with 3 small lobes on its tip. Sometimes the atrial lip curves around to form a tube with its lumen continuous with that of the siphon itself. A small papilla projects from the dorso-median line near the base of the posterior border of the atrial siphon. Eight fine longitudinal and oblique muscles are on the thorax and these extend along each side of the abdomen and posterior abdomen in a narrow band. There are 14 to 17 rows of 12 to 14 stigmata. The oesophagus is curved, entering the relatively short dorsal border of the stomach. The stomach wall is covered with rounded prominences (mulberry-like). The duodenal area is wide, the mid-intestine inflated and an oval posterior stomach is in the bend of the gut loop. The anal opening is about one-third of the distance up the thorax.

Gonads are in the middle third of the posterior abdomen, the small ovary behind the most anterior of the testis follicles, which extend back in a single series, or are bunched together when muscles contact.

Two embryos (but not tailed larvae) are in the posterior part of the atrial cavity of specimens collected in November (QM GH5087). Specimens collected in April and May have 3 embryos including a tailed larvae lined up in the atrial cavity (QM GH5088 GH5091). The larval trunk is about 0.50mm long. It has median and lateral ampullae alternating with the adhesive organs. Epidermal vesicles branch off strands that extend along each side of the mid-dorsal line as in *Polyclinum*, but ventral vesicles appear to be median. The lateral ampullae sometimes appear to have lost their connection with the epidermis.

REMARKS

The species is distinguished from others by its surface swellings each containing a circular system, and its mulberry-like stomach. The surface swellings are very variable and they are not always conspicuous. Thus the fact that Sluiter (1909) did not observe them may not be significant. Other characters of the newly recorded material conform with the type specimen, and the Australian and Indonesian specimens appear to be conspecific. *Synoicum intercedens*: Monniot and Monniot, 1987, has fewer rows of stigmata than either the type or the present Australian specimens, and the number of stigmata per row

FIG. 50: *Synoicum intercedens* — **a**, colony (QM GH5087); **b**, zooid (QM GH5087); **c**, larva (QM GH5107). Scales: **a**, 5mm; **b**, 1mm; **c**, 0.1mm.

has not been reported. Otherwise these French Polynesian specimens appear to conform with the type material. *Synoicum suesanum* Michaelsen, 1919 has similar colonies with circular systems, and 13 to 15 rows of stigmata with 10 to 12 per row. Michaelsen (1919) distinguished the species by the depression separating the systems. However that depression sometimes occurs in *S. intercedens*. There is no known character separating *S. suesanum* from the present one.

The new Australian temperate species *Synoicum sacculum* n. sp. has a mulberry-like stomach, but its systems are not separated from one another by grooves or depressions, and a single embryo is incubated in a stalked brood pouch. The tropical *Synoicum suarenum* n. sp. which is sympatric with *S. intercedens* and is the same dark colour has, like *S. sacculum* n.sp., many circular systems in each of its wedge-shaped lobes, and lacks grooves or subdivisions which, in the present species, tend to isolate the systems from one another. *Synoicium suarenum* n.sp. is further distinguished by its smooth-walled stomach and larger larval trunk.

Synoicum macroglossum (Hartmeyer, 1919) and *S. tropicum* (Sluiter, 1909) are also distinguished from the present species by their smooth-walled stomachs.

Synoicum longistriatum n.sp.
(Fig. 51)

DISTRIBUTION

TYPE LOCALITY: Western Australia (off Cockburn Sound, 32°S 155°08'E CSIRO Cruise 144/DM4/63, 110m, coll. L. Thomas 28.8.63, holotype QM GH5583.

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colony is an upright, almost cylindrical lobe, slightly expanded terminally. It is 7cm high and about 3cm in diameter. Basally there are sandy root-like projections of the test. The lower third of the lobe, comprising the lower part of the stalk, is transversely wrinkled, and covered with a layer of sand. The middle third has a layer of finer sand and is not wrinkled. The naked upper third has openings of the crowded zooids. These, seen through the transparent test, appear to be arranged in crowded longitudinal rows converging to cloacal apertures on the terminal free end. The crowded zooids are perpendicular at the surface, but posteriorly they curve down into the stalk of the colony.

INTERNAL STRUCTURE: In this colony a large quantity of sand fills the pharynx of most of the zooids, obscuring its structure. The branchial apertures have 6 lobes, and atrial apertures are large openings with the upper rim extended out to form a tongue. About 12 fine longitudinal muscles are in the thoracic body wall. These extend along the length of the abdomen and posterior abdomen. Stigmata are in 16 rows of about 16. The stomach is large and voluminous, without longitudinal folds, but sometimes collapsing into irregular or horizontal ones. Double rows of male follicles are in part of the long posterior abdomen of some of the zooids, although the ovary was not detected.

FIG. 51: *Synoicum longistriatum* n.sp. (holotype QM GH5583) — colony. Scale: 1cm.

REMARKS

The colony is distinctive and unique in this genus, superficially resembling that of *Distaplia australiensis* (see Kott 1990). However, the zooids are characteristic of the Polyclinidae. The *Aplidium* species with longitudinal double-row systems converging to the top of the head, viz. *A. australiense*, *A. geminatum* n.sp., *A. inflorescens* n.sp. and *A. paralineatum* n.sp. are distinguished by their numerous stomach folds. The shape of the colony and its sandy surface resembles *S. atopogaster*, but the form of the systems differ.

It is unfortunate that this unique specimen is not well preserved. Nevertheless as it is a unique colony form and unlikely to be confused with other species in this genus, it is considered appropriate for it to be designated holotype. It is probable that damage was caused to the specimen by the way it was collected (beam trawl), rather than its treatment after collection.

Synoicum macroglossum (Hartmeyer, 1919)
(Fig. 52. Plate 9a)

Macroclinum macroglossum Hartmeyer, 1919, p.126.

DISTRIBUTION

NEW RECORDS: Queensland (Heron I., QM GH5055; Mackay, QM GH5421).

PREVIOUSLY RECORDED: Western Australia (Cape Jaubert — Hartmeyer 1919).

DESCRIPTION

EXTERNAL APPEARANCE: One colony (QM GH5055) is a large flat-topped cushion 6cm in diameter, 2cm high, with rounded margins and a vertical border. Sand is present on the base and around the border, but not on the upper surface. Sparse sand is present internally in the lower half of the colony, but it becomes even more sparse toward the centre, as if it was gradually moving in from the sandy outer border. The colony from

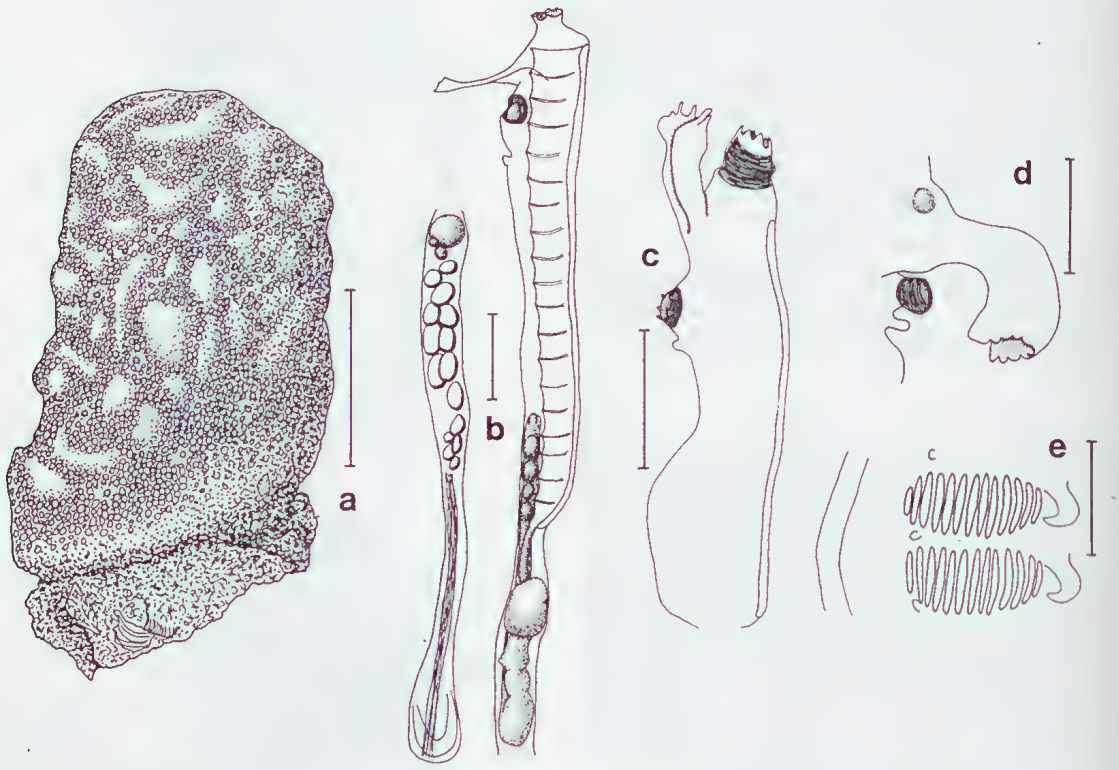


FIG. 52: *Synoicum macroglossum* — **a**, colony (QM GH5421); **b**, whole zooid severed between thorax and posterior abdomen (QM GH5055); **c**, **d**, thorax and atrial aperture, with atrial lip shown in different positions (QM GH5421 GH5055); **e**, portion of right branchial wall (QM GH5055). Scales: **a**, 2cm; **b**, **c**, 1mm; **d**, **e**, 0.5mm.

Mackay is an upright cone, 6cm high, with sand around the base and sparsely embedded through the test.

The test is translucent and gelatinous but firm and rigid in both specimens. Circular to long, low swellings, with shallow depressions between them are on the upper surface. The small and inconspicuous branchial openings can be seen around the periphery of the swellings, and in the depressions between them. Large cloacal apertures occur in the depressions, especially where 2 or more converge. These apertures either are sessile, or they protrude on surface swellings created by thickened test over the circular cloacal cavities that are formed at the junctions of the cloacal canals.

Internally the posterior ends of the zooids crisscross one another. The test is pale yellowish-brown to greenish-yellow in preservative, and the preservative itself is stained yellow-orange. One living specimen (QM GH5055) was, 'mummy brown' internally and 'seal brown' (Ridgeway 1886) on the surface. The other (from Mackay) is said to have been black when living.

INTERNAL STRUCTURE: Zooids are long (to 1.5cm) and narrow. The thorax is about one-third of the length of the zooid, and the abdomen and about half of the gonad bearing part of the posterior abdomen together comprise another third. Eight longitudinal muscles extend the length of the thorax, and are reduced to 2 or 3 each side of the abdomen and posterior abdomen. The branchial aperture is on a trumpet-shaped siphon that appears to be fixed in the firm surface layer of test. A sphincter is around the base of the siphon. The long, muscular atrial lip has a dentate tip, and is difficult to remove from the test where it lies over the top of the cloacal cavity. It arises from the body wall opposite the first row of stigmata, anterior to the muscular atrial aperture which lies opposite the third row of stigmata. A sphincter is also present around the atrial aperture. When contracted, the atrial lip curves over the aperture. A papilla projects from the body wall just behind the atrial siphon opposite the fifth row of stigmata. Nineteen rows of 12 to 14 fairly long stigmata are in the branchial sac, although the number reduces posteriorly. A wide strip of unperforated test is each side of the endostyle. There is a minute papilla on each transverse vessel at about the level of the third ventral stigma on each side of the body. A row of robust dorsal languets are to the left of the dorsal mid-line.

The gut loop is vertical and narrow — the oesophagus curves ventrally to enter the bilaterally symmetrical, smooth-walled stomach. The duodenum is large, the mid-intestine inflated and a large oval posterior stomach is in the bend of the gut loop. The bilabiate anus opens at the level of the fourth row of stigmata from the posterior end of the thorax.

A very short gonad-free part of the posterior abdomen is behind the gut loop. A small ovary is anterior to the oval testis follicles which are in 2 longitudinal series, alternating with one another. Sometimes (but not always) an extent of the posterior end of the posterior abdomen is free of gonads. A V-shaped heart is in the posterior extremity of the posterior abdomen. The newly recorded specimens collected in November, have well-developed ovaries, but no embryos were found.

REMARKS

The species is distinguished by its protruding atrial siphon, separate atrial lip, narrow zooid and robust cushion-shaped colony. The type specimen differs from the present one in the presence of a layer of sand on the upper surfaces as well as around the margin; and in the presence of up to 14 rows of stigmata rather than the 18 of the present eastern Australian colonies. Hartmeyer (1919) did not observe the small branchial papilla toward the ventral end of each transverse vessel, but these are inconspicuous and obscured unless the thorax is completely relaxed.

The dorsal papilla and separate atrial lip are like *S. papilliferum* (Michaelsen, 1930) and the zooids also have similar numbers of stigmata. However, although Michaelsen believed the dorsal papilla was unique to his species (see below), it occurs in both *Polyclinum* and *Synoicum*. Although the conspicuous cloacal apertures and long curving double row systems of the present tropical species may be different from *S. papilliferum* (in which Michaelsen did not find any cloacal apertures and could not determine the form of the systems), at present the only character definitely known to separate the species is the presence of sand adhering to the external test of the temperate *S. papilliferum*. Species of *Aplidium* with similar zooids (e.g. *A. lobatum*, *A. cratiferum*) lack a median dorsal papilla, and have different systems from those of the present species. *Synoicum chrysanthemum* has similar systems, but the colonies are different.

Synoicum obscurum n.sp.
(Fig. 53)

DISTRIBUTION

TYPE LOCALITY: Victoria (Bass Strait, reef off Ninety-mile Beach, 90km SW of Lakes Entrance, coll. J. Watson R3E/36 1977, holotype QM G12726, paratype QM G12727).

FURTHER RECORD: NSW (Arrawarra, QM GH5589).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are thick mats with sand crowded throughout making them hard and brittle. The mats are made up of sandy cone-shaped, upright lobes which adhere closely to one another. The terminal free ends of these lobes project from the upper surface of the colony as rounded swellings, each of which accommodates a circular system of up to 12 zooids. Zooids are tightly enclosed in the sand and hard to remove from it although the thin channels that accommodate the zooids are rigid. The zooids surround a shallow common cloacal cavity (in the terminal end of each lobe) which opens through a common cloacal aperture in the centre. Branchial apertures are inside, and protected by, the rounded margin of the terminal end of each lobe. The cloacal cavities beneath the upper surface of colony confer a loose appearance to the surface layer of brittle sand-filled test.

INTERNAL STRUCTURE: The zooids are relatively muscular, with about 20 longitudinal bands on the thorax. These muscles extend posteriorly to form a band along each side of the mid-ventral line. Zooids are relatively long, even when contracted the thorax, abdomen and gonad-bearing anterior part of the posterior abdomen are about 6mm long, while the long posterior part of the posterior abdomen, without gonads in it, extends into the sandy base of the colony.

The 6 branchial lobes are rounded. An atrial siphon protrudes from the dorsal surface, and a flat atrial tongue with a tridentate tip is produced out from the upper rim of the opening. The lower rim of the atrial opening is divided into 3 small lobes. A pointed median dorsal papilla is at the base of the atrial siphon. About 20 rows of up to 20 stigmata appear to be present, although the pharynx is too contracted for accurate counts. Irregular internal glandular areolations of the stomach wall are present, especially on the mesial side of the stomach (against the intestine). A few

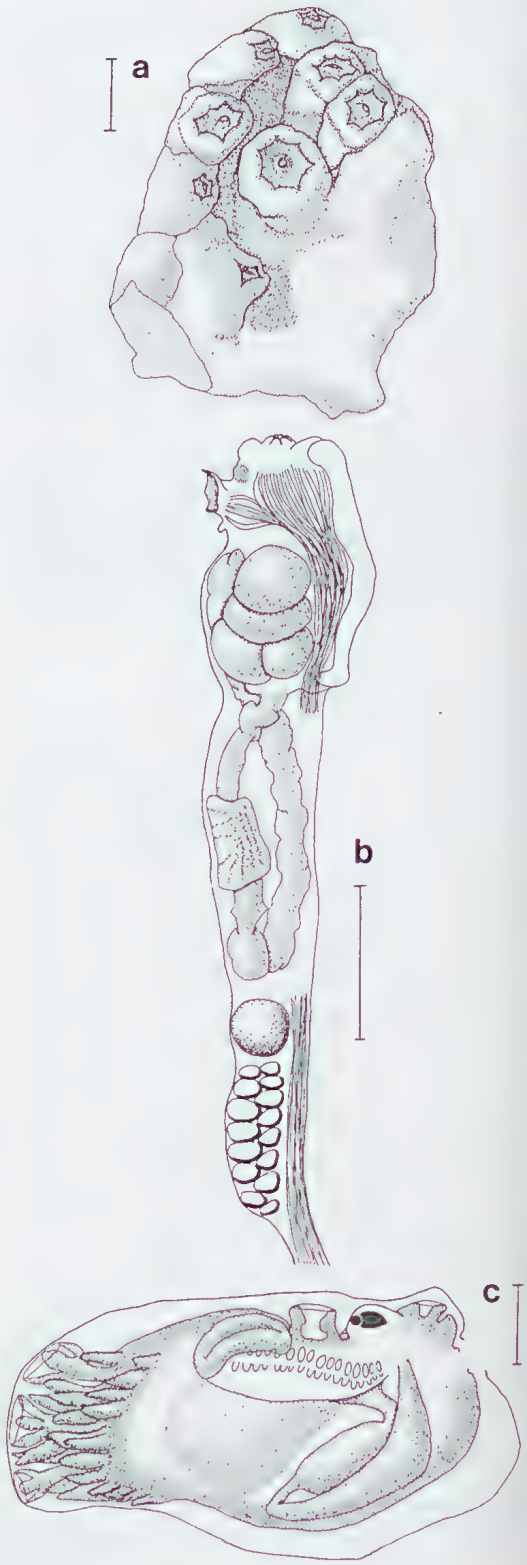

FIG. 53: *Synoicum obscurum* n.sp. (holotype QM G12726) — **a**, colony; **b**, zooid; **c**, larva, tail removed. Scales: **a**, 5mm; **b**, 1mm; **c**, 0.1mm.

of these shallow glandular areas sometimes form irregular longitudinal ridges which resemble the longitudinal folds of *Aplidium*. The duodenal, mid-intestinal and posterior stomach regions are characteristic for the genus.

In the type material, a large ovum is present behind the gut loop, anterior to a short double longitudinal series (about 8 per series) of testis follicles. The posterior abdomen continues posterior to the testis follicles, which protrude dorsally from it as a result of the contraction of the ventral muscles. Four or 5 embryos are crowded in the atrial cavity.

The larval trunk is 0.6mm long. The anterior end is obscured by numerous narrow ectodermal ampullae. There are 3 median adhesive organs, and an ocellus and otolith are in the cerebral vesicle.

REMARKS

A similar colony form is found in many species of *Aplidium* (e.g. *A. bacculum* n.sp., *A. filiforme* n.sp.). However, despite the presence of some longitudinal glandular ridges in the stomach wall, the present species is distinguished from the genus *Aplidium* by the shape of its zooids with a relatively primitive lobed atrial opening and the median dorsal papilla.

Synoicum durum has colonies consisting of sandy lobes, but the test above each system is naked, and each lobe has 2 or 3 systems.

Synoicum papilliferum (Michaelsen, 1930)

Macroclinum papilliferum Michaelsen, 1930, p.530.
Synoicum papilliferum: Millar, 1966, p.360. **Not** Kott, 1963, p.87 (< *Polyclinum tenuatum* n. sp.); 1972a, p.16; 1972b, p.177 (< *S. sacculum* n. sp.).

DISTRIBUTION

NEW RECORDS: None.

PREVIOUSLY RECORDED: Western Australia (Bunbury — Michaelsen 1930). Victoria (Nepean Peninsula — Millar 1966).

DESCRIPTION (after Michaelsen 1930)

EXTERNAL APPEARANCE: Colonies are cushion shaped or irregular sheets, up to 3cm diameter and 2.4cm high. Sometimes they are fixed by a narrowed base. The preserved colonies are transparent and yellowish, with an external layer of sand. Some sand is present internally but it is not as crowded as it is externally. The outer layer of test is tough. Cloacal cavities are present at the level of the atrial apertures, but cloacal apertures were not seen.

INTERNAL STRUCTURE: The zooids are vertically arranged in the test, with their posterior abdomina criss-crossing. The body wall is delicate with about 10 longitudinal muscle bands. The branchial siphon is conspicuous with a well developed sphincter at its base. The short atrial siphon, surrounded by a sphincter muscle, projects laterally from the body wall a short distance behind the atrial lip, which is narrow, but not long, and its tip is produced into 2 or 3 small papillae. A conspicuous median papilla projects from the body wall just behind the atrial siphon. Sixteen or 17 rows of 9 or 10 stigmata are in the long, narrow thorax. The oesophagus curves to enter the smooth stomach which is about halfway down the abdomen. A short gonad-free area is behind the abdomen, in front of the single row of male follicles that occupies the rest of the narrow posterior abdomen. When the posterior abdomen contracts, the male follicles are drawn up into a double row. Two short vascular stolons project from the end of the zooid.

REMARKS

Although Michaelsen thought the papilla was unique, it does occur in species of *Polyclinum* as well as in other *Synoicum* species. Nevertheless Kott (1963; 1972a,b) followed Michaelsen and assigned specimens of *S. sacculum* n. sp. and *Polyclinum tenuatum* to this species because, like *S. intercedens* and *S. suarenum* n.sp., they had a dorsal papilla. However, all these species are readily distinguished from the present one by having the atrial lip extending from the anterior rim of the aperture. *Synoicum macroglossum* has both a separate atrial lip and a dorsal papilla, but is distinguished from the present species by its conspicuous cloacal systems with raised cloacal apertures and the absence of an external layer of sand.

Although they differ in having a dorsal papilla, zooids of the present species, with their long, narrow thorax, long muscular branchial siphon, and atrial siphon separate from the atrial lip, resemble those of certain *Aplidium* spp. (e.g. *A. cratiferum*, *A. lobatum*, see below). The stomach folds of some of these *Aplidium* spp. are few and indistinct, but they all have distinct cloacal systems that distinguish them from the present species.

Millar (1966) records that his specimens of *S. papilliferum* had all the features of the type specimens, except the dorsal papilla. However, as there

is no other known temperate species of *Synoicum* with similar characters, it is possible that the papilla was obscured in the material he examined.

Synoicum prunum (Herdman, 1899)
(Fig. 54. Plate 9b)

Psammaplidium prunum Herdman, 1899, p.84.
Synoicum prunum: Kott, 1963, p.87.

DISTRIBUTION
NEW RECORDS: New South Wales (Arrawarra, QM GH5394). Queensland (Bribie I., QM G2102; off Cape Tribulation, QM GH799).
PREVIOUSLY RECORDED: New South Wales (Port Jackson — AM G2101 Herdman 1899).

DESCRIPTION
EXTERNAL APPEARANCE: Like the holotype, the colony from Cape Tribulation is upright, oval, converging to a narrow sandy base produced into sandy roots. It is about 7cm high and 4cm in diameter. The specimen from Bribie I. is massive (14cm long and 9cm maximum diameter), lumpy, oval and football-shaped overall, but with deep creases dividing it into lobes. It has no obvious point of fixation.

The internal test always is firm and gelatinous with long tough fibres in it. It is almost opaque in preservative, while the outside layer is tough and hard with occasional patches of sand embedded. The long thread-like zooids are found withdrawn from the surface and criss-cross one another through the internal test. Their arrangement is obscure and the form of the systems was not determined.

INTERNAL STRUCTURE: Both newly recorded colonies are in a vegetative stage, many developing buds being present. Adult zooids are thin and thread-like. The very long, thin posterior abdomen is up to 2cm, being many times the length of the rest of the zooid (only about 2mm long when contracted). The contracted thoraces (QM GH799) are slightly longer than the abdomen, and when extended (QM G2102) they are at least twice the length of the abdomen. About 12 fine longitudinal muscles are on the thorax and these extend the length of the zooid in a band on each side. A single fleshy atrial lip continuous with the anterior rim of the atrial aperture has a straight tip with a single, small, pointed, median tooth. The branchial lobes are only shallow. A small dorsal papilla arising from the body wall behind the atrial aperture can be seen in the contracted zooids, but was not detected in the extended ones.

Fourteen dorsal languets were counted in the specimen from Cape Tribulation, indicating that there are 15 rows of stigmata, the same number as in the Bribie I. zooids. The thoraces are characteristically narrow and up to 8 stigmata per row were counted. The abdomen is small. The narrow and characteristically long oesophagus curves to enter the smooth-walled, small stomach which is halfway down the abdomen. The relatively long duodenum, inflated mid-intestine and posterior

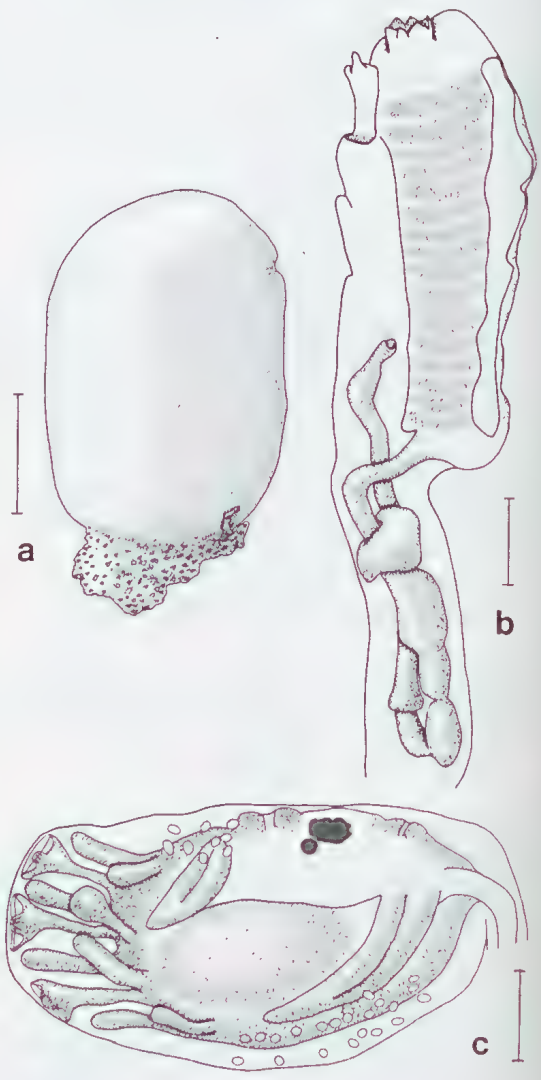

FIG. 54: *Synoicum prunum* — a, colony outline (QM GH799); b, thorax and abdomen (QM GH799); c, larva (holotype AM G2101). Scales: a, 2cm; b, 0.2mm; c, 0.1mm.

stomach are distal to the stomach in the descending limb of the gut loop. Gonads are not developed in the newly recorded specimens. They are present in the long posterior abdomen of the type specimen, which also has 2 embryos in the atrial cavity.

The larval trunk is 0.55 to 0.65mm long. It has median and lateral ectodermal ampullae alternating with the 3 median adhesive organs, and patches of ectodermal vesicles antero-dorsally and postero-ventrally.

REMARKS

The large, almost naked colonies of this species are unique in the Australian fauna. There are some dark, greenish-black colonies of *Polyclinum vasculosum* recorded from Moreton Bay that reach the same size as the present species and superficially can be confused with it. *Synoicum citrum* has naked but sessile colonies, smaller than those of *S. prunum*, with larger zooids, fewer rows of stigmata and more stigmata per row.

Synoicum sacculum n. sp.
(Fig. 55. Plate 9c–e)

Synoicum papilliferum: Kott 1972a, p.16; 1972b, p.177; 1976, p.62.

DISTRIBUTION

TYPE LOCALITY: South Australia (Waldegrave I. in caves, 2m strong waves, coll. S. Shepherd 25.11.73, holotype SAM E2556, paratypes QM GH5044). Victoria (Flinders, jetty piles, 5m, coll. N. Coleman 18.6.77 AMPI 201, paratype QM G10163).

FURTHER RECORDS: South Australia (St. Vincent Gulf, West I. — Kott 1972a; Thorny Passage, SAM E2491). Tasmania (W. Granville Harbour, SAM E2552).

The Tasmanian specimen was taken from a depth of 425m.

DESCRIPTION

EXTERNAL APPEARANCE: The colony consists of crowded sessile, flat-topped to rounded lobes about 1cm in diameter rising from a sandy basal membrane or test mass. Sometimes the lower half of the lobe is constricted to form a thick stalk with some sand embedded. Sand is sparse internally in the upper part of each lobe. Sand is sometimes present on the upper surface, although the test above the zooid systems is usually left naked. The test is very soft internally. Zooids form circular systems of 2 to 3mm diameter with up to 10 zooids around a central cloacal aperture. The cloacal apertures are about 2cm apart, and are evenly spaced on the top of each lobe. In one small (1.7cm high) flat-topped colony (SAM E2491) the branchial openings are around the outer margins of surface depressions, and sessile cloacal apertures are in the centre. The test is raised in firm rounded ridges between the depressions.

In life the lobes are bright red, with bright red zooids. In preservative the test is yellowish and translucent, and the preservative is stained a yellowish-red.

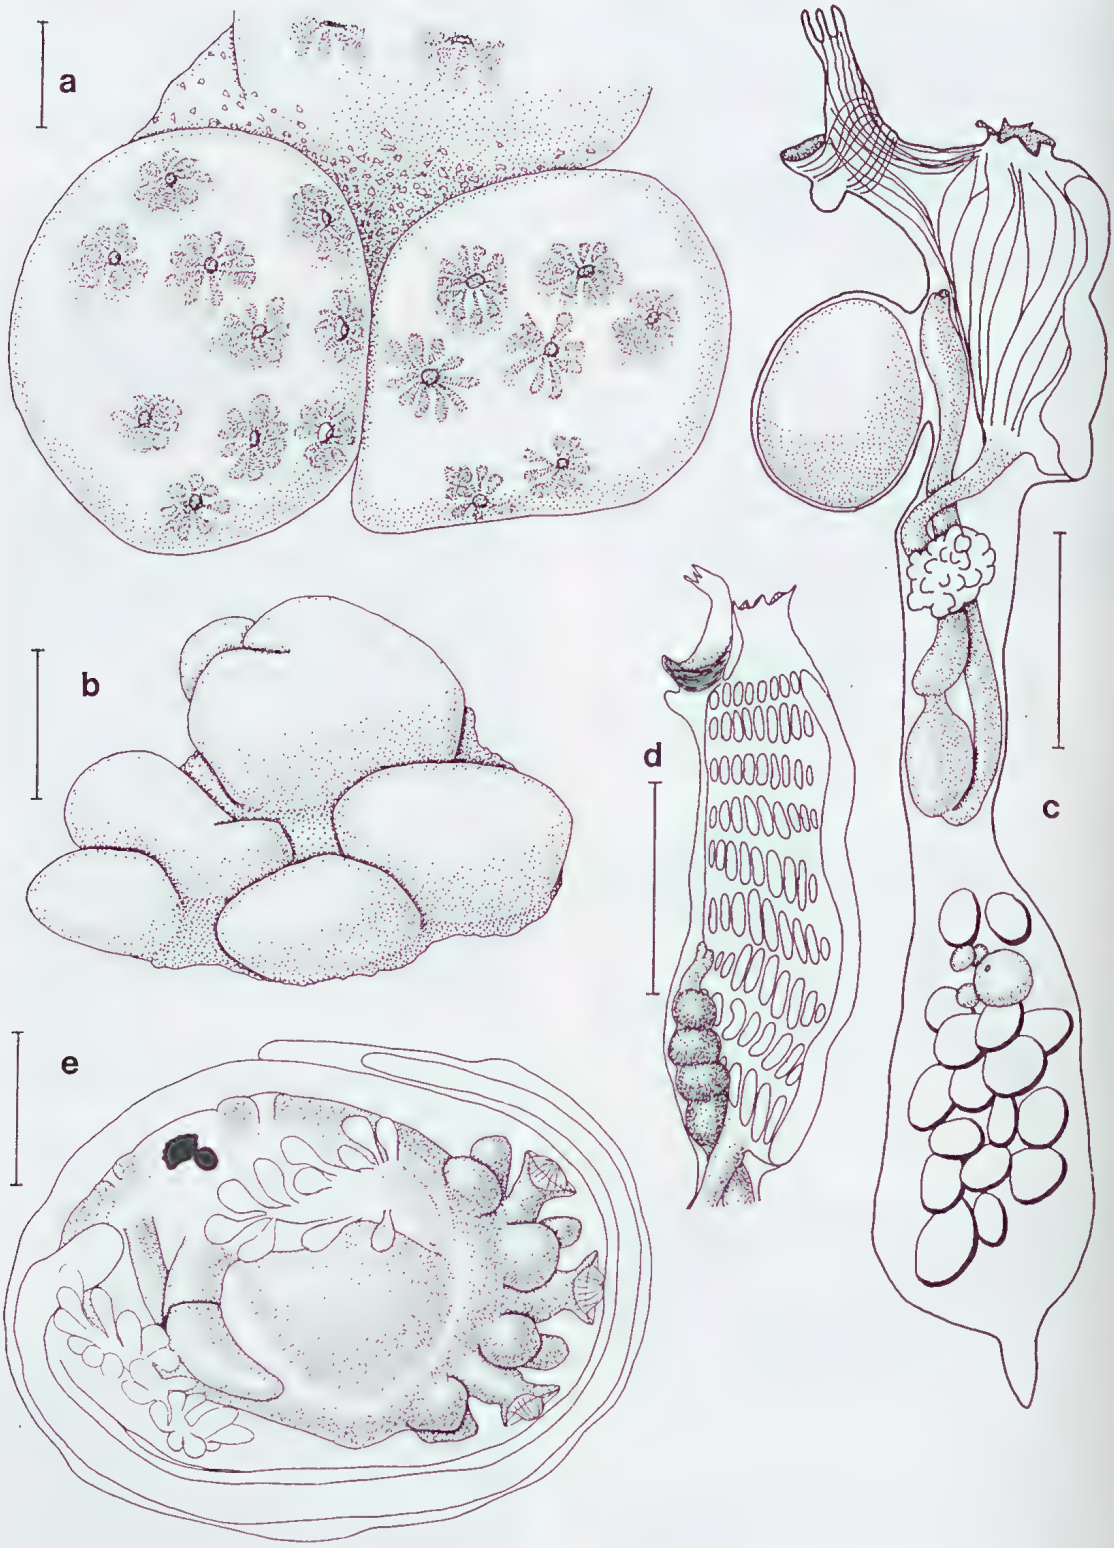
INTERNAL STRUCTURE: The zooids are 2 to 3mm long, with a short posterior abdomen. The thorax, abdomen and posterior abdomen are each about one third of the total length. There is a fine, short posterior vascular stolon. About 6 fine longitudinal and oblique muscles are on the thorax and these continue along the length of the zooid. Strong muscles extend from the branchial siphon along the atrial siphon (which often is long) onto the atrial lip which continues out from the anterior rim of the opening. The straight tip of the atrial lip has 3 narrow finger-like papillae evenly spaced along it. A papilla is in the mid-dorsal line behind the atrial aperture, sometimes carried out along the siphon when that is produced dorsally.

About 8 short stigmata are in 9 or 10 rows. The oesophagus is long and curved, and the stomach, about halfway down the abdomen has mulberry-like swellings in its wall. The duodenal area is long, the mid-intestine inflated, and an oval stomach is in the bend of the gut loop. The anal opening is opposite the third last row of stigmata. Colonies with large mature male follicles in the short posterior abdomen have about 20 bunched around the ovary (SAM E2491, QM GH5044). These colonies also have one to 3 embryos, up to the tailed larval stage, present in a brood pouch constricted off from the postero-dorsal corner of the thorax.

The larval trunk is almost spherical, 0.4mm in diameter, with otolith and ocellus, postero-ventral vesicles, and median and lateral ampullae anteriorly. The tail is wound about three quarters of the way around it.

REMARKS

The form and colour of the colonies is distinctive, as are the atrial lip from the anterior rim of the opening with finger-like papillae on its tip, the mulberry-like stomach, and the short posterior abdomen with bunched male follicles. The spherical larval trunk also is unusual. The brood pouch constricted off from the body wall is reminiscent of the one described for *Macroclinum*



a
b
c
d
e

hypurgon f. galei: Michaelsen, 1930 although the latter contains 2 embryos, its stomach is smooth, and its colonies are not lobed.

A dorsal papilla similar to the one in the present species, a short posterior abdomen and a similar atrial aperture occurs in the tropical species *S. suarenum* n. sp. However in the latter species the stomach is smooth, the larvae are not spherical and a brood pouch is not constricted off from the body wall.

Synoicum erectum, a species that overlaps the South Australian range of the present one, has sandy colonies consisting of single lobes rather than the many lobes of the present species. The zooids can be distinguished by their longer posterior abdomen, longer larval trunk and absence of a brood pouch.

Synoicum suarenum n. sp.
(Fig. 56. Plate 9f,g)

Synoicum kuranui: Kott, 1981, p.159.

DISTRIBUTION

TYPE LOCALITY: Queensland (Capricorn Group, Wilson Reef, rubble zone, low tide, coll. P. Kott Jan 1977, holotype QM GH5080; Heron I., rubble zone, low tide, coll. P. Kott 4.11.86, paratype QM GH5070).

FURTHER RECORDS: Queensland (Capricorn Group, QM GH5066–9 GH5071–9 GH5081–3 GH5176 GH5178; Hardy Reef, QM GH5377; Lizard I., QM GH5277 GH5586); Fiji (Kott 1981). Indonesia (Millar 1975).

DESCRIPTION

EXTERNAL APPEARANCE: Flat-topped wedge- to top-shaped lobes, crowded together and narrowing to the base where they are joined by common basal test or by connecting strands to adjacent lobes. Sometimes the basal stalk portion of the lobe is branched and there are 2 heads from a basal common stalk. Colonies from Hardy Reef have long stalks (longer than those from Heron I.); narrowing toward the base. When alive and inflated the separate lobes that make up the colony appear confluent. The separate lobes are more apparent when it is removed from the substrate. The flat-topped lobes are up to 2.5cm high and up to 3.0cm in diameter at the top. In life colonies have a characteristic appearance resembling a pig's kidney both in colour and form. They are always opaque, shiny cherry coloured, crimson, and a dark maroon, plum colour, or 'pansy-' 'pomegranate-', 'Indian-' to 'aster-purple' (Ridgeway 1886). In preservative colonies become brownish-black, but the colour eventually is lost altogether. At first the preservative is stained orange-yellow, and clouds of brownish-black pigment cells are in the test. Circular cloacal systems of 4 to 8 zooids are evenly spaced over the surface. The central common cloacal apertures are in slight surface depressions about 2.5mm apart, and each system is about 2.5mm in diameter. The rim of each common cloacal aperture has small denticulations, into which the denticulations on the tip of the atrial lips of each zooid fit. The cloacal chambers are shallow and circular, being almost completely open to the exterior through the large cloacal aperture. The test is firm and gelatinous. Sand is absent from the surface, and from the internal test. Up to 15 systems occur in one lobe of the colony.

INTERNAL STRUCTURE: The zooids are less than 1cm in length, even when distended, and the thorax is half the total length of the zooid. The posterior abdomen is generally relatively short for a species of this genus. One or 2 short vascular appendages are at the posterior end of the posterior abdomen. The 6 branchial lobes are small and pointed. The atrial siphon is short but wide, with its upper border produced into a short, broad tongue with 3 to 5 short pointed teeth on its broad, straight outer edge. There is a median pointed papilla projecting out from the dorsal line behind the atrial aperture. About 12 fine longitudinal and oblique thoracic muscles in bands of moderate width extend along each side of the thorax and abdomen and are inserted into a projecting horn on each side of the posterior abdomen. Sixteen rows of 10 short, oval stigmata are in the branchial sac, each row reducing in length dorsally and ventrally. The oesophagus is curved and the dorsal border of the stomach between the oesophageal and duodenal openings is relatively short. The stomach wall is smooth externally, but internally it has some glandular areolations. The duodenal area is long, the mid-intestine inflated and an oval posterior stomach is in the bend of the gut loop. The bilabiate anus is about one-third of the distance up the thorax. The posterior abdomen is continuous with the abdomen and the gonads are in its posterior half, there being a narrow gonad-free neck of variable length behind the gut

FIG. 55: *Synoicum sacculum* n.sp. — **a**, **b**, colonies (paratype QM G10163, **a**, showing circular systems; **b**, colony outline); **c**, zooid with embryo in brood pouch (SAM E2491); **d**, thorax (paratype QM G10163); **e**, larva (paratype SAM E5044). loop. The ovary is mixed in with the anterior testis follicles, which are either in one or 2 irregular longitudinal series or, when muscles are contracted, bunched in the posterior end of the posterior abdomen, giving it a sac-like appearance. There are about 20 testis follicles.

Embryos (up to 3) are in the posterior end of the atrial cavity of zooids collected in January, April and May. Tailed larvae have a trunk about 0.6mm long. Median and lateral ampullae are present. A postero-ventral cluster of epidermal vesicles is in the larval test each side of the mid-line, near the

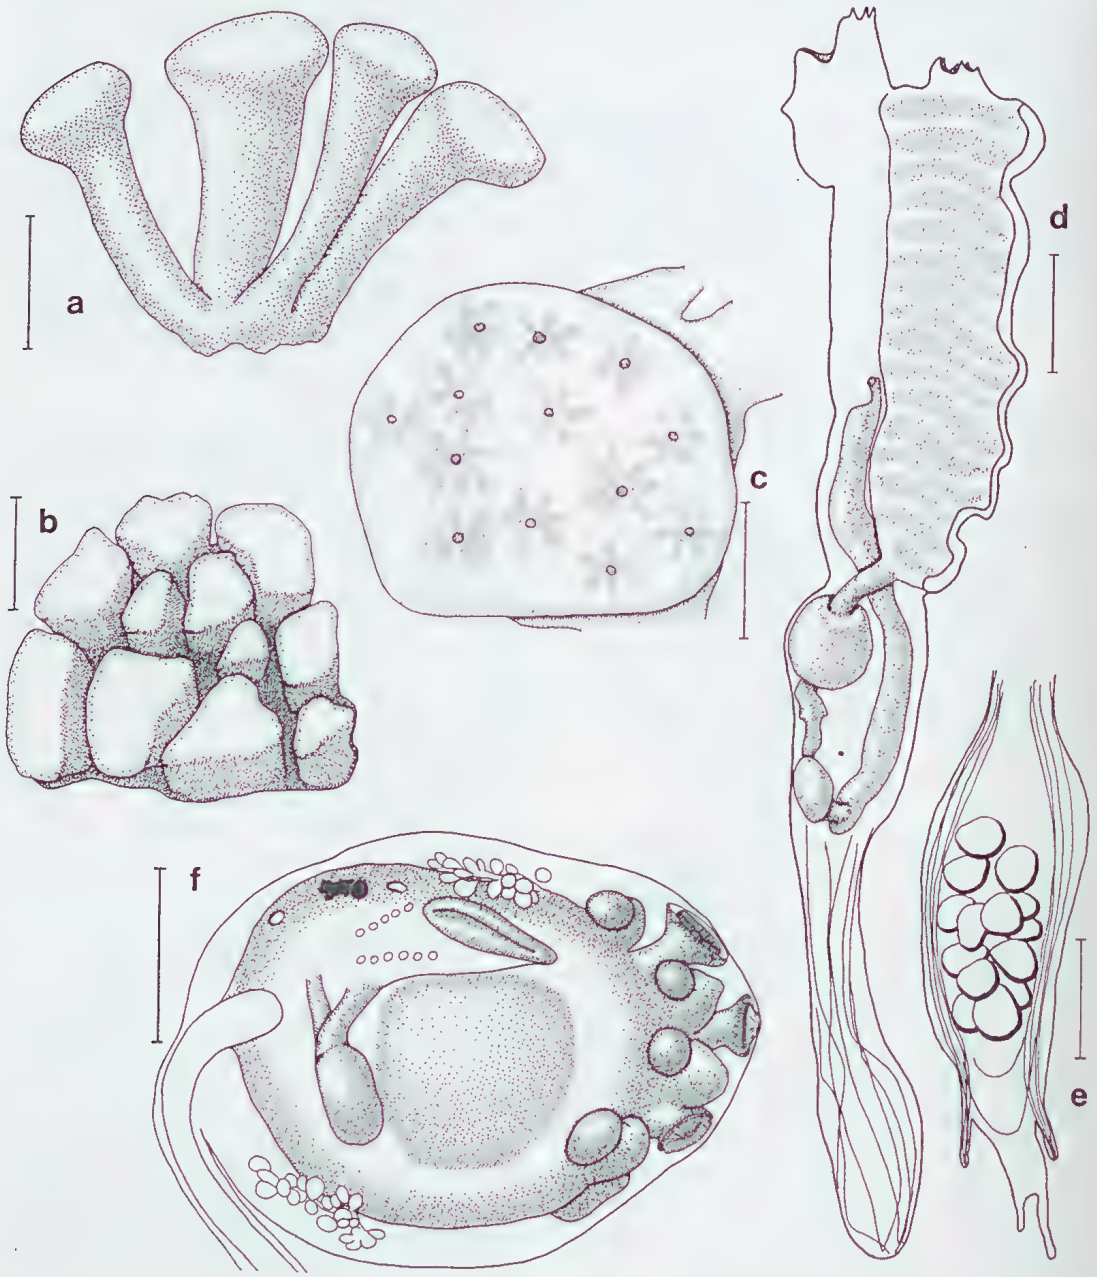

FIG. 56: *Synoicum suarenum* n.sp. — **a**, colony with longer lobes (QM GH5377); **b**, colony with short lobes (holotype QM GH5080); **c**, colony from above showing systems (QM GH5067); **d**, zooid (QM GH5067); **e**, posterior abdomen showing gonads bunched in posterior end (paratype QM GH5070); **f**, larva (QM GH5073). Scales: **a**, 1cm; **b**, 2cm; **c**, 5mm; **d**, **e**, 0.5mm; **f**, 0.2mm.

base of the tail. These separate from an epidermal strand that trails posteriorly through the test, from each side of the mid-line ventral to the adhesive organs. A similar strand of epidermis from which epidermal vesicles separate off into the dorsal test above the endostyle is on each side of the mid-dorsal line behind the adhesive organs. The tail winds about two-thirds of the distance around the trunk. The lateral ampullae separate from the rest of the larval ectoderm and become large and spherical.

REMARKS

In those colonies with male follicles clumped in the posterior end of the zooid, the anterior part of the posterior abdomen is relatively narrow, resembling the neck of a polyclinid posterior abdomen. However, the species has characters of *Synoicum* rather than *Polyclinum*, viz. the mid-intestine is large and inflated, the gut loop straight and relatively long, and the cloacal systems small.

Synoicum clavatum (Oka, 1927) from Japan resembles the present species in some characters, but it differs in having larger round-topped rather than flat-topped lobes with longer, narrow stalks. There is some confusion regarding the characters of the Japanese species, however, for Nishikawa (1990) records 20 to 24 longitudinal muscles and 10 to 12 stigmata, but Tokioka (1954b) reported only 12 muscles and 20 stigmata (see Tokioka 1954b, Pl. IVF). The colours of living colonies of the Japanese populations, which could provide more evidence of their relationships with one another and with the present species, have not been recorded.

Synoicum clavatum: Millar, 1975 from the Philippines has flat-topped lobes containing circular cloacal systems similar to those of the newly recorded Australian material; and the zooids have 8 to 9 longitudinal muscles similar to those from Heron I. However, although they are in 15 rows like the Australian material, Millar reports about 20 stigmata per row in his specimens. The flat-topped Philippine colonies, therefore, are only questionably conspecific with the Australian colonies. The dorsal papilla has not been recorded for Philippine or Japanese specimens. *Synoicum kuranui* Brewin, 1950b from Great Barrier I. (New Zealand) are sandy capitate lobes with crimson zooids and areolated stomach walls and are readily distinguished from the present species. *Synoicum kuranui*: Kott, 1963 from Heron I. is not conspecific with either the present one or with the New Zealand species (see *S. durum*, above). The sympatric *S. intercedens* has sessile cushion-like colonies with sandy margins. Their upper surface with swellings corresponding to the systems, larger systems, longer atrial tongues, a mulberry-like stomach and a smaller larva.

Synoicum suarenum is a tropical species and it differs from the temperate *S. sacculum* by the shape of the colony lobes (sessile in *S. sacculum*), the smooth stomach wall (mulberry-like in *S. sacculum*), and the small, almost rudimentary cloacal systems with the wide cloacal aperture exposing the cloacal cavity to the exterior, as in some *Eudistoma* spp. (*angolanum* group: Kott 1990).

Synoicum tropicum (Sluiter, 1909)
(Fig. 57)

Atopogaster tropicum Sluiter, 1909, p.107.

DISTRIBUTION

NEW RECORD: Western Australia (NW Shelf, QM GH5056).

PREVIOUSLY RECORDED: Indonesia (Sluiter 1909).

The species is known only from the type and from the newly recorded portion of a colony.

DESCRIPTION

EXTERNAL APPEARANCE: The specimen is a wedge-shaped slice of what appears to have been a large, upright lobe, about 12cm high. The test is firm and the surface naked.

Zooids are arranged in circular systems of 8 to 20. The branchial apertures are around the margin of a circular depression about 5mm diameter in the surface test. A conspicuous common cloacal aperture protrudes on a conical prominence in the centre of each circle of zooids. The test is white and opaque, with a patch of dark pigment where each zooid opens to the surface. Common cloacal apertures are about 7mm apart, an area of test without zooid openings separating the circles of branchial apertures from one another.

INTERNAL STRUCTURE: The zooids in the present piece of a colony have not been adequately fixed and cannot be dissected or manipulated without disintegrating. They are, as in the type specimen, perpendicular to the surface. The zooids of the type colony (Sluiter 1909) have 12 rows of 8 to 10 stigmata. The gut forms a simple loop, the stomach wall is smooth, and there is a long posterior abdomen.

REMARKS

The present specimen agrees with the type in having circular depressions on the surface with

branchial apertures around the margin of each depression, protruding cloacal apertures, and no sand either embedded or adhering to the surface. The circular surface depression is characteristic. Although circular systems with a large circular cloacal cavities surrounded by zooids occur in other species of *Synoicum*, the well-spaced and depressed circles of the present species are unusual.

The horizontal stomach folds that characterised the genus *Atopogaster* (to which Sluiter assigned this species), are artefacts that occur in species with large, smooth stomachs and *Atopogaster* is here proposed as a junior synonym of *Synoicum*.

Genus **Morchellium** Giard, 1872

Type species: *Amaroucium argus* Milne Edwards, 1842.

The known species have a relatively long oesophagus. A vertical, barrel-shaped stomach halfway down the abdomen is smooth or has mulberry-like swellings in the stomach wall. Gonads are in the posterior abdomen with the ovary anterior to the serially arranged testis follicles. Rows of stigmata are numerous. The atrial aperture is wide and open, often forming a protuberant siphon with an enlarged uppper rim. Neither the atrial lip nor the sphincter muscle are as well developed as they are in *Aplidium* and *Polyclinum*. The posterior abdomen is narrow and continuous with the abdomen, there being no constriction between them.

The number of rows of stigmata are in the range known for other genera of the Polyclinidae. However the number per row (20 to 30) generally exceeds that of all other genera of this family, being almost as numerous as in Polycitoridae and *Sigillina* spp. The number of stigmata per row in Protopolyclinidae, and in some *Ritterella* spp., are of this order. In Euherdmaniidae and Placentelidae they are more, and in Pseudodistomidae less numerous.

Although they are not present in the type species, the Australian species of this genus have parastigmatic vessels in the branchial sac. A few species of *Aplidium* — e.g. *A. caeruleum* (Sluiter, 1906) — and *Synoicum atopogaster* also have parastigmatic vessels (see Kott 1969) and so do certain Protopolyclinidae (*Monniotus* spp., *Condominium*) and certain *Ritterella* spp. (see above)

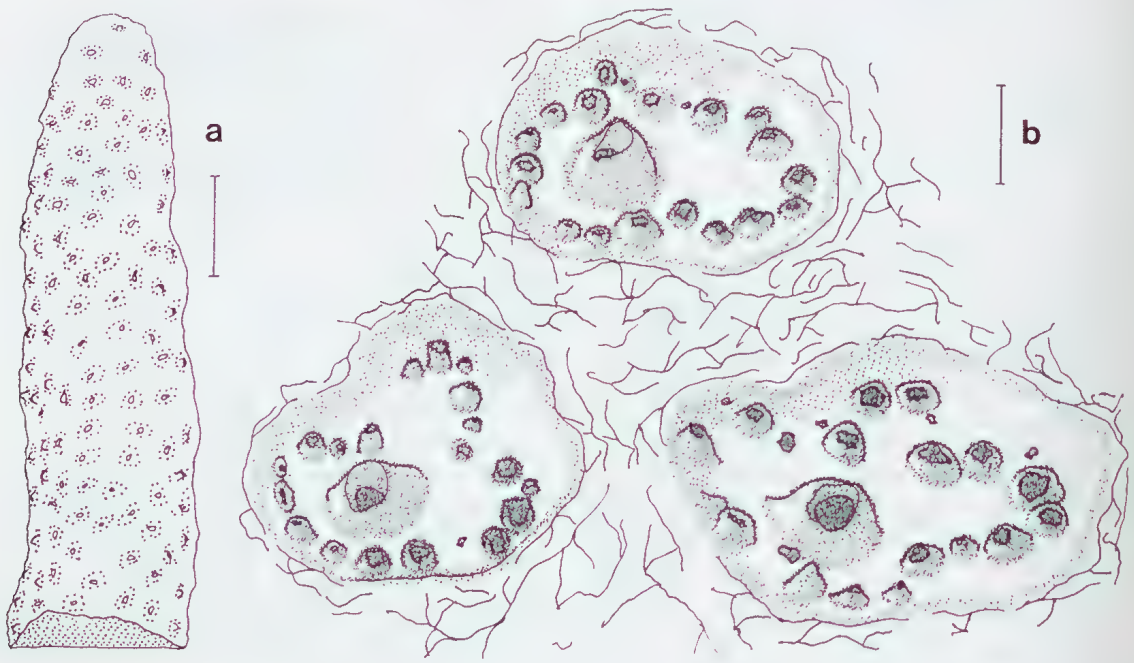

FIG. 57: *Synoicum tropicum* (QM GH5056) — **a**, part of colony; **b**, circular systems with protuberant branchial apertures surrounding a larger, central common cloacal aperture, each depressed into the surface. Scales: **a**, 2cm; **b**, 2mm.

as well as holozoid genera *Distaplia*, *Sycozoa* and *Hypsistozoa*. Thus no profound phylogenetic significance can be attached to the presence of these vessels in *Morchellium* species. Parastigmatic vessels hold in place the long, parallel interstigmatic bars that occur in most species with particularly long, narrow stigmata. These generally occur when there are few rows of stigmata relative to the size of the branchial sac. Probably the presence of parastigmatic vessels, preventing distortion of the stigmata, maintaining the dimensions of their apertures and the effective operation of the cilia lining them, is a convergent character in the taxa referred to above.

The transverse thoracic muscles of the Australian species *M. pannosum* n.sp. are unique in the Polyclinidae, although they are known in *Sigillina* (Holozoidae), Polycitoridae (see Kott 1990) and some Ritterellidae (see above). The pigment spots in each of the branchial lobes (as in the Diazonidae and *Euherdmania* spp.) are also unsual. Neither of these characters occurs in *M. albidum* n.sp. Thus, they do not seem to be generic characters as the genus is currently defined. Nor do they occur in *Synoicum*.

Morchellium argus (type species) has 4 symmetrically arranged unusual pigment spots around the apertures (Berrill 1950), but these are not homologous with the diazonid-like pigment spots of *M. pannosum* n.sp.

The large atrial aperture, and barrel-shaped stomach without longitudinal folds found in both Australian species are similar in certain *Synoicum* spp. from which *Morchellium* is distinguished only by its 8 branchial lobes.

The type species is from the English Channel and the west coast of Britain, Ireland and France.

The species discussed below are the only 2 of this genus described from Australia. They differ from one another principally in their colonies, *M. pannosum* n.sp. having sandy lobes, each with a single system, and *M. albidum* n.sp. having numerous circular systems in each cushion-like colony.

Morchellium partitionis (Monniot, 1987) from New Caledonia, the only species of thus genus previously recorded from the tropical western Pacific, is divided into sandy claviform lobes and is 2cm high. The external test is thickly encrusted with sand. Its colony form is similar to that of *M. pannosum* n.sp., and it has a similar number of rows of stigmata (13 to 14) and a similar number of stigmata per row (18). However its lack of parastigmatic vessels and its mulberry-like stomach distinguish it.

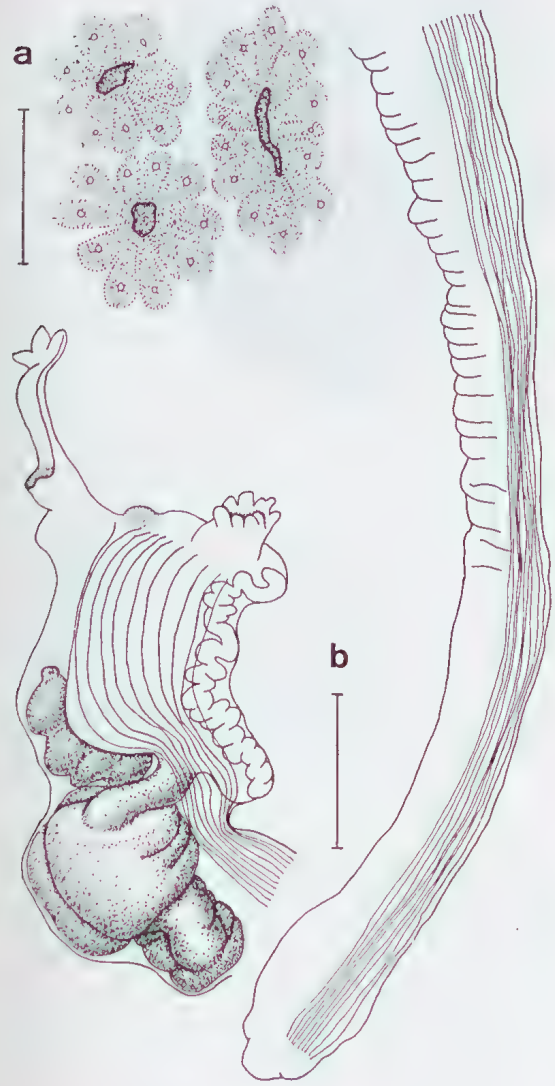

FIG. 58: *Morchellium albidum* n.sp. (holotype QM GH5582) — **a**, part of upper surface showing zooid systems; **b**, zooid, with detached posterior abdomen showing ventral muscle band. Scales: **a**, 4mm; **b**, 0.5mm.

Morchellium albidum n.sp.
(Fig. 58)

DISTRIBUTION

TYPE LOCALITY: South Australia (West Bay, Wedge I., southern Spencer Gulf, Earthwatch site 2, coll. A. Butler 16.2.88 QM GH5582).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colony is a large, oval bolster 4cm long and 3cm wide. Zooids are arranged in crowded, circular systems of up to 12, with large sessile common cloacal apertures in the centre of each. The test is firm and transparent and the zooids, seen clearly from the surface, are translucent-white in preservative. An opaque white deposit is in the surface test between the systems.

INTERNAL STRUCTURE: Zooids are large and robust. However, the thorax and abdomen together are as little as 1.4mm long when contracted. The posterior abdomen is longer. The rim of the branchial aperture has 8 conspicuous rounded lobes. The atrial aperture protrudes from the dorsal surface, and its anterior rim is sometimes produced into a strap-like tongue, with 3 pointed terminal lobes. In other specimens the atrial lip is shorter and broader, the 3 terminal lobes being more conspicuous than the tongue itself. A median dorsal papilla is present behind the aperture. The thorax has about 12 longitudinal muscles which form a wide band along the ventral border of the abdomen and posterior abdomen. When contracted this ventral band draws the posterior abdomen up alongside the abdomen.

Stigmata are in about 12 rows of probably up to 12, but the thorax is too contracted to allow accurate counts to be made. Each row of stigmata is crossed by a parastigmatic vessel.

The stomach is voluminous, and collapsed into irregular, more or less horizontal folds. The posterior abdomen is about the same length as the rest of the zooid. It contains a double series of male follicles and an ovary anterior to these.

REMARKS

The zooids of this species resemble those of *Morchellium pannosum* n.sp., as well as *Synoicum atopogaster* and *S. concavitum*. The naked bolster-like colonies differ from all these except the last, which, however, has firmer test, less crowded systems, and lacks parastigmatic vessels. The present species also has fewer rows of stigmata, and fewer per row than *Synoicum atopogaster* or *Morchellium pannosum* n.sp.

Morchellium pannosum n.sp.
(Fig. 59)

DISTRIBUTION

TYPE LOCALITY: Victoria (Port Phillip Heads, 18m, fast current, coll. J. Watson 10.9.77, holotype QM G12722).

The species is said to be common off Port Phillip Heads.

DESCRIPTION

EXTERNAL APPEARANCE: The newly recorded specimen is an irregular mass of sandy test, up to 3cm high, with the upper half of the colony divided into flattened to cylindrical lobes about 1cm in diameter.

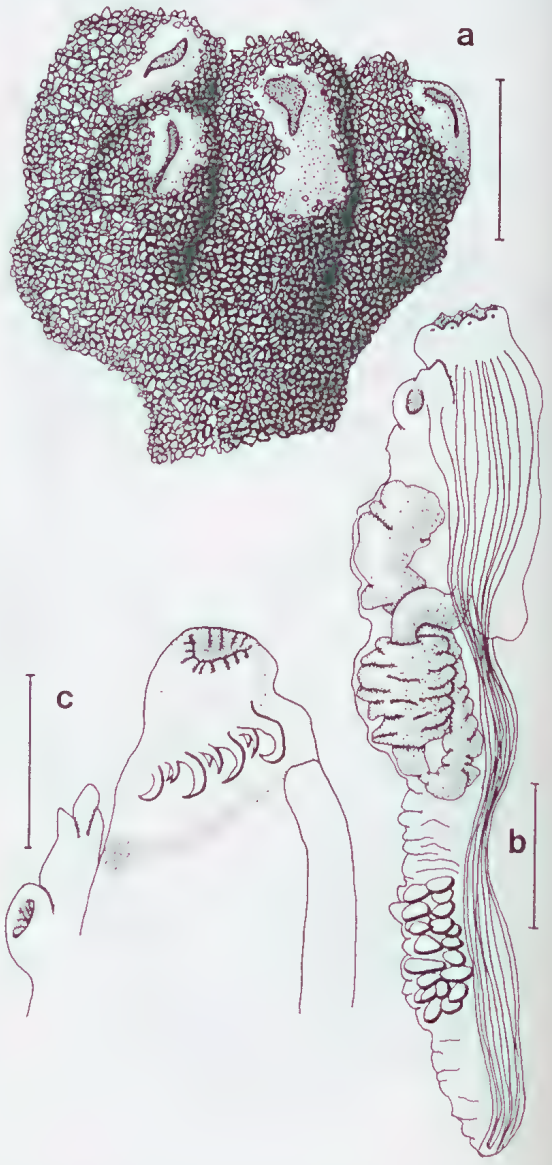

FIG. 59. *Morchellium pannosum* n.sp. (holotype QM G12722) — **a**, part of colony; **b**, whole zooid; **c**, anterior part of zooid showing atrial lip, atrial aperture, branchial aperture and tentacles, and position of neural complex. Scales: **a**, 5mm; **b**, 1mm; **c**, 0.5mm.

A bare area with a large usually long, narrow opening in the centre is on the upper surface of each of the lobes, which contain single, or occasionally 2 cloacal systems. The cloacal cavities are relatively shallow.

The test is very soft, jelly-like, flaccid and translucent. Internally, sand is present in the base of the colony, but not elsewhere. The living zooids are reported to have been mauve.

INTERNAL STRUCTURE: The zooids are robust. About 20 strong longitudinal muscle bands on the thorax extend along on each side of the ventral line of the abdomen and posterior abdomen in 2 wide bands. On the thorax there also appears to be a layer of transverse muscle fibres over the longitudinal thoracic bands. In these contracted zooids (about 6mm long), the abdomen is shorter than the thorax, which is about the same length as the posterior abdomen. The latter curves ventrally as a result of the strong ventral longitudinal bands.

The rim of the branchial aperture appears to have 8 very shallow lobes in which there are faded pigment spots, although in some contracted specimens the rim looks puckered and gathered rather than lobed. A fleshy tridentate lip extends out from the upper rim of the atrial aperture. There are about 16 branchial tentacles of about 3 size groups, each group in a circle at slightly different levels in the base of the branchial siphon. About 15 rows each of about 20 long stigmata are folded along a parastigmatic vessel. The stomach is large, smooth-walled, and has irregular transverse folds that probably result from its collapse. The duodenum is moderately long, and a posterior stomach is in the bend of the gut loop. The voluminous rectum extends halfway up the thorax. A double row of male follicles are in the middle of the posterior abdomen.

REMARKS

In addition to the number of branchial lobes, the species distinctive characters are its fleshy body wall, strong (including transverse) muscles, roomy, transversely folded stomach, parastigmatic vessels, and distinctive lobed colony with flaccid test and large naked cloacal apertures.

The transversely folded stomach is similar to that of *Synoicum atopogaster* and *S. tropicum* (Sluiter, 1909). It was previously thought to be characteristic of the genus *Atopogaster* (< *Synoicum*).

Zooids resemble those of *Synoicum atopogaster* Kott, 1963 which has a similar number of stigmata, parastigmatic vessels and longitudinal muscles that draw the posterior abdomen up alongside the abdomen. The present species is distinguished by its 8 branchial lobes and their associated pigment spots, transverse thoracic muscles and single cloacal system per lobe.

Genus **Aplidium** Savigny, 1816

Type species: *Aplidium lobatum* Savigny, 1816.

Zooids usually are small and thread-like with a relatively, narrow thorax and gonads in a posterior abdomen that is continuous with (rather than constricted off from) the abdomen. There are 6 or sometimes 8 branchial lobes. The atrial tongue is relatively small and rises from the anterior rim of the opening or from the body wall anterior to it. The atrial cavity also is relatively small. Longitudinal muscles extend the length of the thorax and continue onto the abdomen and posterior abdomen. Transverse muscles are in the transverse branchial vessels, joining with the longitudinal muscles in the parietal body wall through atrial connectives. The gut loop is vertical with a vertical rather than curved oesophagus and a vertical barrel-shaped stomach with parallel longitudinal folds in its wall. In *Aplidium*, like *Synoicum*, but unlike *Polyclinum*, *Aplidiopsis*, and other families of Aplousobranchia with a short abdomen, the post-duodenal or proximal part of the mid-intestine — between the duodenum and posterior stomach — has more or less the same diameter as the duodenum rather than being narrower. A short distal section of mid-intestine lies between the oval posterior stomach (which usually is in the bend of the gut-loop) and the rectum. Often there are small pockets (caeca) each side of the proximal end of the rectum, and these form a rectal valve. The anus opens one third to halfway up the atrial cavity.

Larvae are small, the trunk usually less than 1mm and most often less than 0.8mm. Three small, shallow adhesive organs on long slender stalks are present in the anterior mid-line. Median and lateral ectodermal ampullae sometimes are present anteriorly, and usually there are ectodermal vesicles at the anterior end of the trunk. These are 2, 3 or more deep in a wide band, or in a single series, forming an arc along each side of the median adhesive organs. Sometimes they also occur in the median line between the adhesive organs (Fig. 60). The vesicles separate from, or sometimes remain directly attached to the ectoderm by, fine, sometimes branched, stalks. This

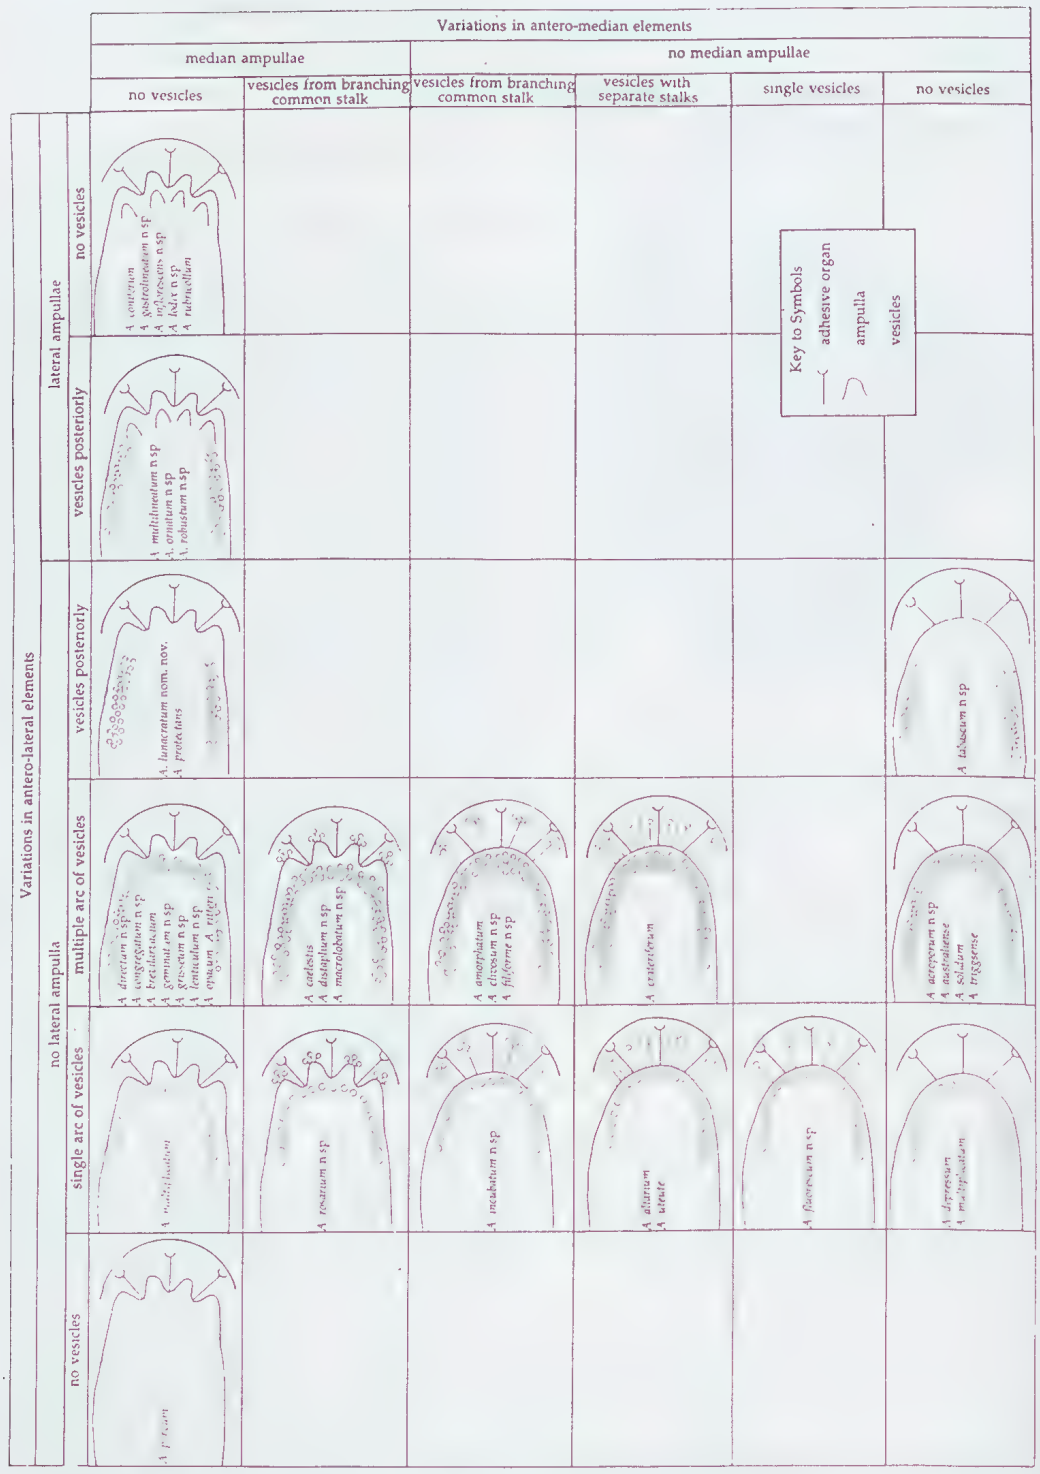

FIG. 60. Epidermal elements of the anterior end of the larval trunk in *Aplidium* spp. (showing their relative position, but not their precise number for any one species; diagrammatic).

constitutes a distinction from *Polyclinum* in which the only vesicles are those that branch off long strands of ectoderm which trail back through the larval test, one on each side of the mid-dorsal and mid-ventral lines and form postero-ventral and antero-dorsal patches of vesicles. These patches of vesicles occasionally also occur in *Aplidium*, but are seldom the only ones present. As in *Polyclinum*, the larval ocellus and otolith in *Aplidium* are well developed.

Colonies often are large, but appear to be well integrated, with zooids organised into cloacal systems and with an external morphology of the colony that enhances its interactions with the external environment. Thus, branchial openings may be protected in depressed parts of the surface test, at the base of ridges or swellings of the surface test (e.g. *A. caelestis*, *A. crateriferum*). Cloacal apertures usually are elevated above the colony on conical prominences (Kott 1989). The test of *Aplidium* is gelatinous, but often is relatively firm, and sometimes is further strengthened by dense inclusions of embedded sand. Many species appear to sort the sand embedded in the test, large sand particles being found in the base and margins of the colony while smaller particles are around the branchial and cloacal apertures, where the test could be expected to be more flexible.

The cloacal cavities generally are shallow, with only a thin layer of surface test over them. Atrial apertures always are at the anterior end of the dorsal surface, and variations in their position usually are a result of contraction of body musculature. Deeper cloacal cavities sometimes develop, and the atrial opening into the base of the cloacal cavity with the atrial lip inserted above it is accommodated by the separation of the atrial lip from the aperture. Thicker surface test is accommodated by a long branchial siphon (e.g. *A. crateriferum*).

The genus *Sidnyum* Savigny, 1816 (type species *Sidnyum turbinatum* Savigny, 1816) is distinguished from *Aplidium* only by the 8-lobed (rather than 6-lobed) branchial apertures. The zooids form circular systems which open on the upper surface of soft, cushion-shaped or lobed colonies with translucent test, and with or without encrusting sand. The best known species of this genus are the type and the related *S. elegans* (see Berrill 1950), which both are common in some European locations. In addition to the 2 related European species, the known species with usually (but not always) 8 branchial lobes are:

Synoicum appendiculatum Michaelsen, 1923 from the Azores. Although assigned to *Sidnyum* by Monniot (1974), the species with its deeply curved oesophagus bilaterally symmetrical stomach with furrows (rather than folds), seems appropriately placed in the genus *Synoicum*.

Sidnyum pentatrema Monniot, 1972 from Bermuda and Guadaloupe (see Monniot 1983) appears to be an *Aplidium* species in which the number of branchial lobes varies from 6 to 9, although 8 is the number which occurs most often (Monniot 1972, 1983). These lobes are not equal in size, and probably several have subdivided to produce the higher number, which accordingly cannot be said to represent a reliable plesiomorphic character indicating generic status for the taxon.

Sidnyum pentatrema: Monniot and Monniot, 1987, known only from 2 small sand covered lobes from French Polynesia probably is convergent rather than conspecific with the Azores species.

Aplidium mernooensis (Brewin, 1956) from Chatham I., New Zealand has characters in common with both *S. pentatrema* and *S. appendiculatum*. Monniot (1972) concluded that *S. appendiculatum* from the Azores is distinct from *A. mernooensis*, but the relationships between the latter and the Tahitian *S. pentatrema*: Monniot and Monniot, 1987 and *A. mernooensis*: Monniot, 1987 from New Caledonia are not clear (see *A. filiforme* n.sp., below).

Aplidium amorphatum Kott, 1963 and *A. protectans* (Herdman, 1899) have (see below) 8 branchial lobes. Their other characters (including the stomach folds) conform with the genus *Aplidium*.

Sidnyum indicum Renganathan and Monniot, 1984, a massive gelatinous colony from the Indian Ocean, has thread-like zooids that have the usual characteristics of *Aplidium* including a folded stomach (see *A. protectans*, below).

Thus, of the 8 species that are possible candidates for the genus *Sidnyum*, 3 — *S. pentatrema* Monniot, 1972; *S. pentatrema*: Monniot and Monniot, 1987; and *A. mernooensis* (Brewin, 1956) — with 5 rows of stigmata and 5 stomach folds, probably are the result of convergent evolution. The number of branchial lobes in at least one of these species is unstable. The species appear at least as closely related to species of *Aplidium* as to one another. Of the other 5 known species, the 2 closely related and sympatric European ones do not seem to have closer relationships with the Australian *A. amorphatum* and *A. protectans*, and the Indian Ocean *A. indicum* than with other *Aplidium* species.

Further, in the diverse genus *Aplidium*, both adult and larval morphological differences between species and groups of species appear to

transcend (in evolutionary terms) the few differences between *Sidnyum* and *Aplidium*. Accordingly, in this work the genus *Sidnyum* is considered a synomym of *Aplidium*.

Aplidium has a close relationship with *Synoicum*. The difference between them disappears when, in some *Aplidium* species, the stomach wall is distended and the 5 folds flatten out. Further the larvae are similar, and it is probable that these two polyclinid genera are closely related phylogenetically.

Resolution of the taxonomy, and identification of species of the genus *Aplidium* has been, and continues to be, a problem. Owing to post-mortem changes and other artefacts of fixation and preservation, the reported appearance of living specimens is often difficult to reconcile with their changed appearance in preservative. In the preserved specimens, systems often are obscured by sand, and colours oxidise or are lost altogether. Zooids, already small and convergent, contract and withdraw from the surface, thus obscuring both their morphology and their arrangement in opaque and often distorted colonies. This confusion is compounded by a degree of plasticity in the shape of colonies which grow to accommodate a variety of substrates and conditions. Further the number of specimens available for examination does not always include a range of age groups or material from a variety of populations so that intraspecific variation is often not known, or has not been recognised. Difficulties also exist in finding reliable taxonomic characters in these small, simplified zooids, and in their crowded colonies.

The number of rows of stigmata, stomach folds, stigmata per row, and the configuration of the atrial aperture and lip, are important characters for species identification. Also of significance are characters of the colonies such as the distribution of pigment, consistency of the test, distribution and nature of test inclusions, form of the systems, shape of the colony and the presence or absence of a stalk. Usually of only limited significance at the species level are the relative lengths of different parts of the zooid (especially the posterior abdomen), the number of longitudinal muscle bands and the number and arrangement of testis follicles, which either are affected by the flexibility and contractability of the zooids, or by variations in form that occur with growth and sexual maturity.

In identifying species of this genus, particular care needs to be paid to the counting of stomach folds. The whole thickness of the stomach wall is pleated, and accordingly folds are internal as well as external. Internal pleats seen through the wall and counted with the external ones may explain the high intraspecific variation in the number of folds sometimes recorded. A transverse section of the stomach enables accurate counts to be made. The number of rows of stigmata is obscured when a part or the whole of the branchial sac is contracted. Inaccurate counts of the number of rows and the number per row occur when, in contracted sacs, stigmata are folded, and the interstigmatic bars and the perforations are crowded together. Fully relaxed branchial sacs are desirable for accurate determination of their structure, and dissection to expose the stigmata is essential, as shadows seen through the contracted body wall are not a reliable way to count the rows.

Nishikawa (1990) points out that the genus *Aplidium* is one of the largest in the Ascidiacea. *Aplidium* species abound in temperate as well as tropical seas. Because of the difficulties in resolving the taxonomy of species in this genus some of the approximately 200 recorded may be invalid. Others have been lumped together, more critical examination showing that many previously considered conspecific taxa are actually distinct from one another.

Most of the previous works on the *Aplidium* fauna of Australia are based on relatively small collections from limited areas, viz. from New South Wales (Herdman 1899), northwestern Australia (Hartmeyer 1919, Millar 1963), south-western Australia (Michaelsen 1930), Port Phillip Bay (Millar 1966), eastern and north-eastern Australia (Herdman 1886, Herdman and Riddell 1913, Kott 1966, 1972c), South Australia (Kott 1972a,b, 1975 and 1976). Kott (1963) dealt with Australia-wide collections. Sluiter (1909) in his report on the Siboga collection encountered only 5 species of *Aplidium* of which 4 occur in Australia. Only 25 species of *Aplidium* spp. have previously been reported from Australia.

The number of specimens available for examination in the present study has made it possible to more accurately determine species parameters and resolve synonymy. The identity of most of the 16 previously known indigenous Australian species and the 4 recorded also from the Western Pacific has been confirmed, however the 2 species said to be conspecific with species recorded from New Zealand, 3 from South Africa, and a pantropical species (*A. lobatum*), were wrongly assigned. No *Aplidium* species has been found to have a range from Australia to either South Africa or New Zealand, and the number of apparently

indigenous Australian species has been significantly increased as a result of the present review.

Aplidium, with 46 known species, including a relatively high indigenous component, now recorded from Australia, is one of the most diverse genera of the Ascidiacea in these waters (Tables 7–9).

Key to species of *Aplidium* recorded from Australia

1. Stomach folds more than 8 2
   Stomach folds not more than 8 25

2. Cloacal apertures few and terminal or central; parallel longitudinal or radial cloacal canals 3
   Cloacal apertures numerous and scattered over the colony surface; no long, parallel longitudinal or radial cloacal canals 9

3. Colonies flat-topped sandy lobes adhering to one another ..... *A. congregatum* n.sp.
   Colonies not flat-topped sandy lobes adhering to one another 4

4. Colony with thin, leathery stalk. *A. australiense*
   Colony without thin leathery stalk 5

5. Stomach folds less than 20 6
   Stomach folds more than 20 7

6. Stomach folds 10 ..... *A. brevilarvacium*
   Stomach folds more than 10 ..... *A. parvum*

7. Colony sessile or top-shaped, without a stalk... ..... *A. altarium*
   Colony not sessile or top-shaped, with a stalk..8

8. Head of colony with sand externally; larval trunk with epidermal vesicles ..... *A. geminatum* n.sp.
   Head of colony without sand externally; larval trunk without epidermal vesicles ..... *A. inflorescens* n.sp.

9. Stigmata in 5 rows 10
   Stigmata in more than 5 rows 11

10. Atrial aperture with a lip .. *A. minisculum* n.sp.
    Atrial aperture without a lip ..... *A. depressum*

11. Zooids in long conspicuously branching double-row systems 12
    Zooids not in long conspicuously branching double-row systems 14

12. Sand embedded throughout ..... *A. elatum*
    Sand not embedded throughout 13

13. Branchial siphon surrounded by wide band of white, opaque cells; larvae with single series of epidermal vesicles each side of anterior mid-line ..... *A. multiplicatum*
    Branchial siphon not surrounded by wide band of white, opaque cells; larvae with multiple series of epidermal vesicles each side of anterior mid-line ..... *A. opacum*

14. Stomach folds not more than 15 15
    Stomach folds more than 15 17

15. Sand embedded in the test 16
    Sand not embedded in the test ..... *A. fluorescum* n.sp.

16. Sand embedded in surface layer of test; zooids in conspicuous circular systems .... *A. jacksoni*
    Sand embedded in basal layer of test; zooids not in conspicuous circular systems ..... *A. triggsense*

17. Stigmata more than 20 per row; brood pouch present ..... *A. uteute*
    Stigmata less than 20 per row; brood pouch not present 18

18. Stigmata in more than 12 rows 19
    Stigmata in 12 rows or fewer 21

19. Stomach folds 18; stigmata not more than 8 per row ..... *A. gelasinum* n.sp.
    Stomach folds 20 or more; stigmata more than 8 per row 20

20. Stomach folds oblique ..... *A. gastrolineatum* n.sp.
    Stomach folds not oblique ..... *A. robustum* n.sp.

21. Stomach folds 30, oblique ..... *A. multilineatum* n.sp.
    Stomach folds less than 30, not oblique 22

22. Systems circular 23
    Systems not circular ..... *A. rosarium* n.sp.

23. Sand on upper surface of colony ..... *A. incubatum* n.sp.
    Sand not on upper surface of colony 24

24. Stigmata more than 10 per row ... *A. lodix* n.sp.
    Stigmata not more than 10 per row ..... *A. ornatum* n.sp.

25. Atrial lip separate from rim of aperture 26
    Atrial lip not separate from rim of aperture .35

26. Colonies undivided, upright and regular 27
    Colonies not undivided, upright and regular 26

27. Colony sandy externally ..... *A. magnilarvum* n.sp.
Colony not sandy externally ..... *A. coniferum*

28. Systems circular 29
Systems not circular 31

29. A single system per colony lobe ... *A. directum*
More than a single system per colony lobe . 30

30. Branchial siphon with bulging branchial sphincter ..... *A. crateriferum*
Branchial siphon without bulging branchial sphincter ..... *A. lunacratum* nom. nov.

31. Cloacal systems irregular; cloacal apertures at junction of 2 or 3 canals 32
Cloacal systems regular; cloacal apertures in centre of radially converging canals 33

32. Common cloacal canals surround circular to polygonal zooid-free areas ..... *A. lenticulum* n.sp.
Common cloacal canals do not surround circular to polygonal zooid-free areas ..... *A. caelestis*

33. Stomach folds 5 34
Stomach folds 8 ..... *A. griseum* n.sp.

34. Stigmata in 18 rows ..... *A. clivosum* n.sp.
Stigmata in 12 rows ..... *A. rubricollum*

35. Stigmata in 4 or 5 rows 36
Stigmata in more than 5 rows 39

36. Colony a 3 dimensional reticulum; 8 stomach folds ..... *A. acroporum* n.sp.
Colony not a 3 dimensional reticulum; 5 stomach folds 37

37. Stigmata in 4 rows ..... *A. distaplium* n.sp.
Stigmata in 5 rows 38

38. Stalks long; one system per terminal branch ..... *A. bacculum* n.sp.
Stalks not long; more than one system per terminal lobe ..... *A. filiforme* n.sp.

39. Sand sparse or absent from internal test 40
Sand moderate or crowded in internal test .. 42

40. Branchial lobes 8 41
Branchial lobes 6 .... *A. parastigmaticum* n.sp.

41. Parastigmatic vessels present .... *A amorphatum*
Parastigmatic vessles not present ..... *A. protectans*

42. Colony a single system . *A. paralineatum* n.sp.
Colony not a single system 43

43. Stigmata more than 10 per row ..... *A. macrolobatum* n.sp.
Stigmata less than 10 per row 44

Cloacal canals do not surround extensive irregular patches of zooid-free test; systems crowded; embedded sand crowded 45

45. Cloacal canals surround small circular zooid-free areas 46
Cloacal canals surround narrow zooid-free ridges ..... *A. ritteri*

46. Larva with median ampullae; southern Australian ..... *A. petrosum* n.sp.
Larvae without median ampullae; not southern Australian ..... *A. solidum*

Species recorded from waters adjacent to Australia

Aplidium cellis Monniot, 1987 has double rows of zooids around raised zooid-free areas of test as in *A. tabascum* n.sp., from which the species is distinguished by its smaller larva (less than 0.6mm trunk) and the sand which is said to completely encrust the surface, albeit it is less crowded over the cloacal canals. Although the colony resembles *A. lenticulum* n.sp. the zooids differ, having the atrial lip from the upper rim of the opening, similar to the zooids of *A. ritteri* (> *A. lobatum*: Monniot, 1987). The species may be conspecific with *A. lobatum* Savigny (see below).

Aplidium flavolineatum: Monniot 1987, from the Coral Sea, has zooids (with brood pouch, large thorax and short posterior abdomen), and possibly also the larvae (with epidermal vesicles around each adhesive organ attached to the epidermis by narrow stalks) like those of *A. altarium*. *Aplidium altarium* has only a limited number of systems in each colony, each consisting of double rows of zooids converging to central or terminal cloacal apertures. The Coral Sea specimen has circular systems and a brood pouch like *A. uteute*. However, the latter species has more numerous lateral vesicles in the larval trunk.

Aplidium lobatum Savigny, 1816 from the Gulf of Suez, later (as *A. africanum* Sluiter, 1905) reported from the Gulf of Aden, is said to be irregularly lobed but small (5 to 6mm thick), with yellowish white zooids in lines amongst the sand embedded in the transparent test. The upper surface is divided into flat-topped oval cushions which have deep furrows surrounding them. The cloacal canals into which the zooids open are in these furrows. Sand does not

adhere externally, stigmata are in 9 or 10 rows of about 12, the trifid atrial lip is part of the anterior rim of the aperture. The posterior abdomen is short, the male and female gonads are not present in the same zooid at the same time and the larval trunk is 0.5mm long (Michaelsen 1920). In his review of the species, Michaelsen added records from the Mediterranean (through the synonymy of *A. tremulum* Savigny, 1816), and suggested a range extending to Malaysia and Indonesia through synonymy with *Aplidium tremulum*: Sluiter, 1909. However, this requires confirmation as most assignations from the western Pacific by Tokioka (1967), Nishikawa (1984a), Monniot (1987) and Monniot and Monniot (1987) appear to be synonyms of *A. ritteri* (see below). *Aplidium lobatum*: Kott, 1963 is conspecific with *A. macrolobatum* n.sp. *Aplidium tabascum* n.sp. and *A. cellis* Monniot, 1987, with smaller lobes on the apertures, and elevated cushions surrounded by depressions into which the zooids open, have both colony and zooids like *A. lobatum* from Suez. Particularly *A. cellis*, with its embedded sand and small larva, is indistinguishable.

The small specimens from the Marianas (*A.* aff. *lobatum*: Tokioka, 1967), with the atrial lip separate from the aperture, is not this species. It is similar to *A. caelestis* or *A. nadaense* Nishikawa from Japan. Atlantic specimens assigned to *A. lobatum* (see Van Name, 1945) have fewer rows of stigmata than the types, the colonies are different, and they probably are not conspecific with the Red Sea specimens. Their similarity could well be the result of convergence.

Aplidium maru Monniot and Monniot, 1987, from French Polynesia, has a larva with median ampullae and, on each side, a band of lateral epidermal vesicles at the anterior end of the trunk (see Fig. 60). There is no other species in the group with similar larvae which also has circular to oval systems of zooids arranged around a protuberant cloacal aperture, 5 stomach folds and an atrial lip separate from the opening.

Aplidium mernooensis (Brewin 1956) from the subantarctic Chatham I., New Zealand (see also Millar 1982) is reported from the tropical New Caledonian waters by a single colony (Monniot 1987). The colony has sand externally but not internally. Its upper surface is lobed, each lobe containing a single circular system. Zooids have red thoraces, with 8 branchial lobes, 5 stomach folds and 5 rows of stigmata. The occurrence of this species in a tropical location is surprising and the identity of the New Caledonian specimen requires confirmation, especially in view of the possibility of convergence in species with zooids as small as these. The New Zealand specimens have almost twice as many stigmata as *A. filiforme* n.sp. (see below). The larvae of both the Chatham I. and New Caledonian specimens are larger than *A. filiforme* n.sp., but they are otherwise all similar to one another.

Aplidium multipapillatum Millar, 1975 from Hong Kong and New Caledonia (Monniot 1987) is characterised primarily by its larvae with 5 adhesive organs.

Aplidium nadaense (Nishikawa, 1980), a species probably indigenous to Japan has the atrial lip separate from the aperture, 13 to 15 rows of up to 8 stigmata, and 5 stomach folds. The colony is smooth-surfaced and the systems are not as conspicuous as they are in *A. caelestis*. Monniot and Monniot (1987) and Monniot (1987) assigned specimens, from French Polynesia and New Caledonia respectively, to this species. *Aplidium nadaense*: Monniot, 1987 from New Caledonia has 14 to 16 rows of stigmata, but branchial apertures are in furrows in the surface, between small polygonal areas, resembling *A. solidum*, which, however, does not have the atrial lip separated from the aperture. *Aplidium nadaense*: Monniot and Monniot, 1987 has a longer, narrower zooid but fewer rows of stigmata than the type. Neither the number of stigmata per row nor the form of the systems is reported. The small larva and other features of the zooid are similar to *A. lobatum*, but the long narrow posterior abdomen is not. Probably neither *A. nadaense*: Monniot 1987 nor *A. nadaense*: Monniot and Monniot 1987 are conspecific either with the Japanese species or any known Australian ones.

Aplidium uouo Monniot and Monniot, 1987 from French Polynesia resembles *Aplidium ritteri* in its long, winding systems, atrial lip from the upper border of the apertures, 10 rows of about 6 stigmata, 5 stomach folds, short posterior abdomen containing gonads of only one sex at a time, and a larva without median vesicles or ampullae and a band of lateral vesicles. It is distinguished only by the absence of embedded sand usually associated with *A. ritteri*, the band of lateral vesicles is not as wide, and the larval trunk (0.7mm long) is longer than that of *A. ritteri*.

branching, anastomosing stalks, usually with horizontal terminal branches that lie in the one horizontal plane. The whole upper surface and the sides of each terminal branch are covered with naked, saucer-shaped circular concavities of 2 to 3 mm diameter, separated from one another by raised sandy ridges. The base of each of these concavities consists of a thin layer of test overlying a shallow thoracic cloacal cavity with a central, sessile cloacal aperture. In the paratype colony (QM GH5431) some of the branches of the stalks, including the terminal ones, are often flattened vertical lamellae.

Zooids are in circular systems of about 10 around each cloacal cavity. Owing to the depressed, transparent, clear, naked test over each cloacal cavity the surface depressions appear deeper than actually they are. Sand is crowded throughout the remainder of the colony. The zooids, smaller than the sand grains, are embedded in the test between the crowded sand grains. Rigid open compartments in the test, which occur in

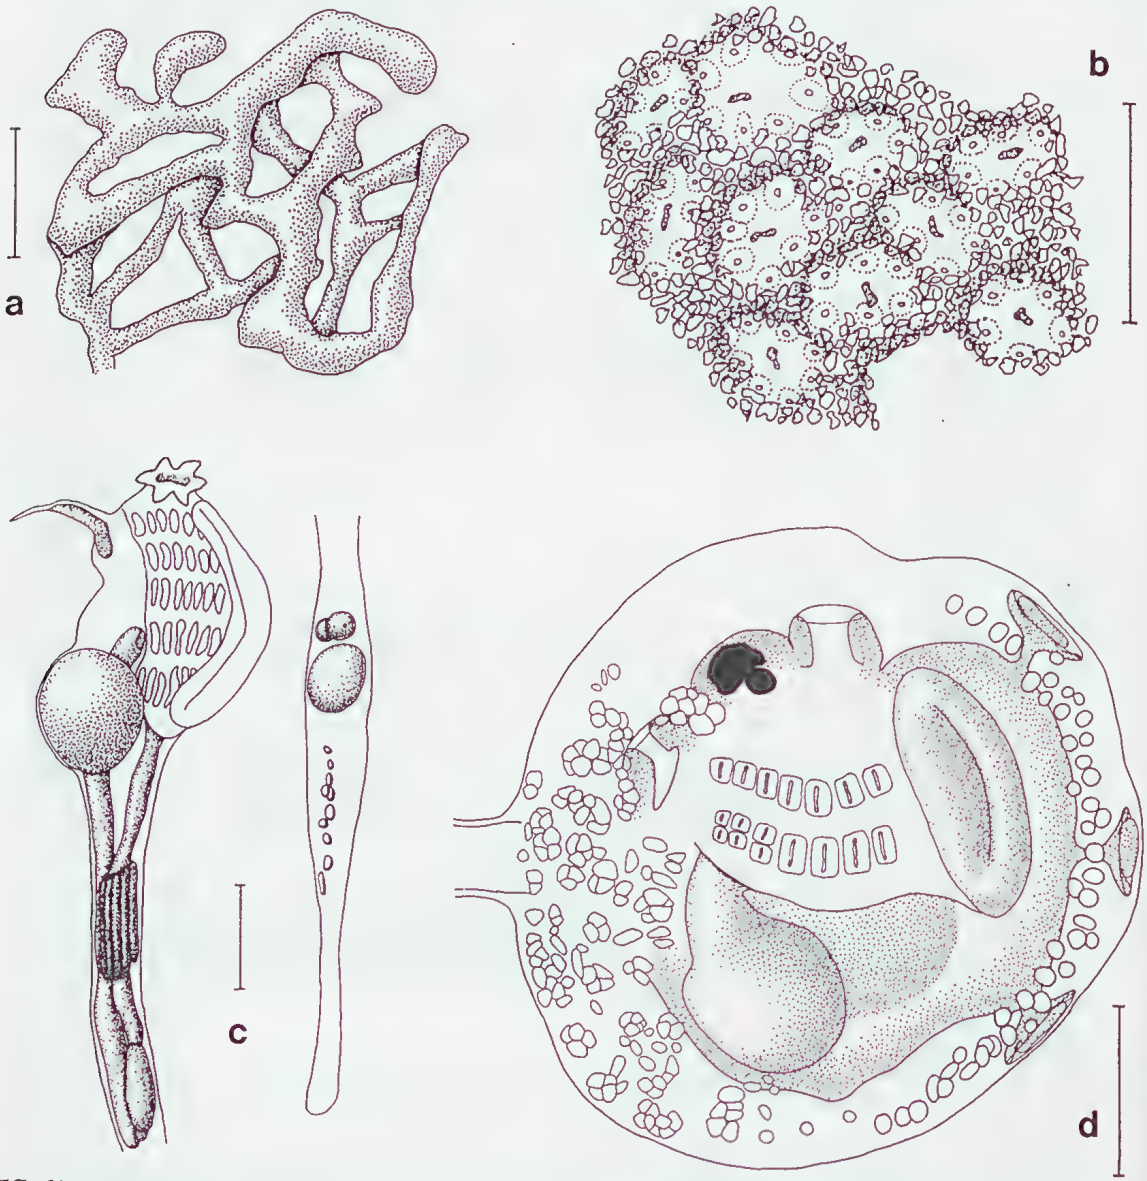

FIG. 61. *Aplidium acroporum* n.sp. — **a**, part of colony (paratype QM GH5443); **b**, surface of colony showing naked areas over cloacal cavities with branchial apertures around the margins (holotype QM GH4169); **c**, zooid, with embryo in atrial cavity and posterior abdomen separately (paratype QM GH5443); **d**, larval trunk, with large test cells (?) posteriorly (QM GH5341). Scales: **a**, 1cm; **b**, 5mm; **c**, 0.2mm; **d**, 0.1mm.

some aplousobranch species to accommodate the zooids, do not occur in the present species.

The maximum dimension of the available specimens is about 10cm and they are 5cm high. However, in no case was the entire colony taken, and it is probable that they are particularly extensive *in situ*. The branches toward the top of the colony have a diameter of 5mm, but the lower branches are narrower, and the basal vertical stalks taper like roots.

INTERNAL STRUCTURE: The zooids are particularly small, up to 2mm long, and thread like. The thorax, abdomen and posterior abdomen are of about equal length, except in those species in which the latter is contracted. The branchial and atrial siphons are short, the former with 6 (sometimes bifid) lobes, and the latter with a single pointed lip from the upper rim of the opening. There are 5 rows of stigmata with 6 or 7 in a row. The small stomach has 8 folds. A short posterior abdomen has 4 or 5 male follicles bunched in it in specimens collected in May. One colony (QM GH5431) collected in February has mature ova in the short posterior abdomen, and 2 embryos are incubated, one at the top of the abdomen and another completely obliterating the atrial cavity.

The larval trunk is spherical, 0.4 mm in diameter, and the tail is wound three-quarters of the way around it. There is a large cerebral vesicle with otolith and ocellus. Epidermal vesicles are in a band about 3 vesicles deep to form a conspicuous arc on each side around the anterior half of the trunk. These develop from a circle of epidermis around the adhesive organs, subsequently becoming detached and scattered in the test. Large morula corpuscles are scattered in the test over each side of the posterior half of the trunk. The 3 adhesive organs are wide but shallow, with short stalks.

REMARKS

Characteristics of the present species are the small zooids and the form of the colony, with its rigid, narrow, sandy branching stalks, and surface depressions separated by raised ridges which give the colony the appearance of the corallites of an acroporid coral.

The anastomosing horizontal terminal branches of this species, with zooid systems opening on the sides and upper surface, probably form a mat above the sandy substrate, with the rest of the reticulum (which lacks zooid openings), buried in the substrate. Such a growth form ensures that the colony is firmly anchored, and must add considerably to the consolidation and stability of the substrate.

The cloacal systems are smaller than similarly shaped ones of *A. lunacratum* nom. nov., from which the species is further distinguished by its 8 (rather than 5) stomach folds, 5 (rather than 9 or more) rows of stigmata and the atrial lip which is separate from the aperture in *A. lunacratum*.

PREVIOUSLY RECORDED: Western Australia (?Cape Boileau — Millar 1963). Northern Territory (Darwin — AM Y1396 Kott 1966). Indonesia (Sluiter, 1909).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are circular to oval cushions up to 3cm in greatest dimension, lightly attached to hard substrates such as coral skeletons as well as weed. In life the colonies are less flattened, sometimes almost spherical or top-shaped, narrowing basally. They are found either in large populations, their margins probably in contact, to form a mosaic-like covering over the substrate; or they are bunched together. In preservative most of the colonies from Western Australia collected in 1974 to 1979 are a purple colour. Apparently the colour is progressively lost when in preservative for longer, as some from the Abrolhos collected in 1963 (WAM 754-82) are beige transparent cushions. The colour of living colonies is recorded for only one of the Western Australian specimen lots (AMP1 60 QM GH5307), which is said to have been purple and white, although photographs of it are white. It is possible that the colour notes were taken after the specimen was collected, when some oxidation

had taken place. Living colonies from the Capricorn Group were described as 'brick' coloured with white in longitudinal lines down the sides of the colony, or 'pansy purple' (Ridgeway 1886) with beige or yellowish zooids, or 'brown ball ascidians'. The white lines referred to appear to have been calcareous faecal pellets in the cloacal canals. The specimens from Lizard I. and Myora are reported to have been 'maize yellow' (Ridgeway 1886) with a red dot each side of the apertures.

When present, the purple or brick pigment particles are crowded in the surface layer of the soft but turgid gelatinous test of the preserved colonies, becoming more sparse below the surface, and absent altogether from the basal test. Between the pigment particles, and after the pigment has faded, the test is clear and transparent. Sand is neither attached to, nor embedded in, the colony.

Usually a single, central, large, sessile and irregular common cloacal aperture is on the upper surface, and branching cloacal canals converge to it from the outer margin or the base of the upright colonies. Some colonies have up to 3 systems. Zooids, cream in preservative, are arranged in rows along each side of the cloacal canals. They are tightly enclosed in the firm test and are difficult to remove. Their large, white, atrial lips can be seen stretched out along the roof of the cloacal canals, and inserted around the rim of the cloacal apertures. White opaque vesicles in the surface test around the sides and upper surface are terminal ampullae of test vessels.

INTERNAL STRUCTURE: The zooids are about 6mm long when contracted, the thorax, abdomen and posterior abdomen each being about one-third of the total length. About 20 fine longitudinal muscles extend from the thorax along the

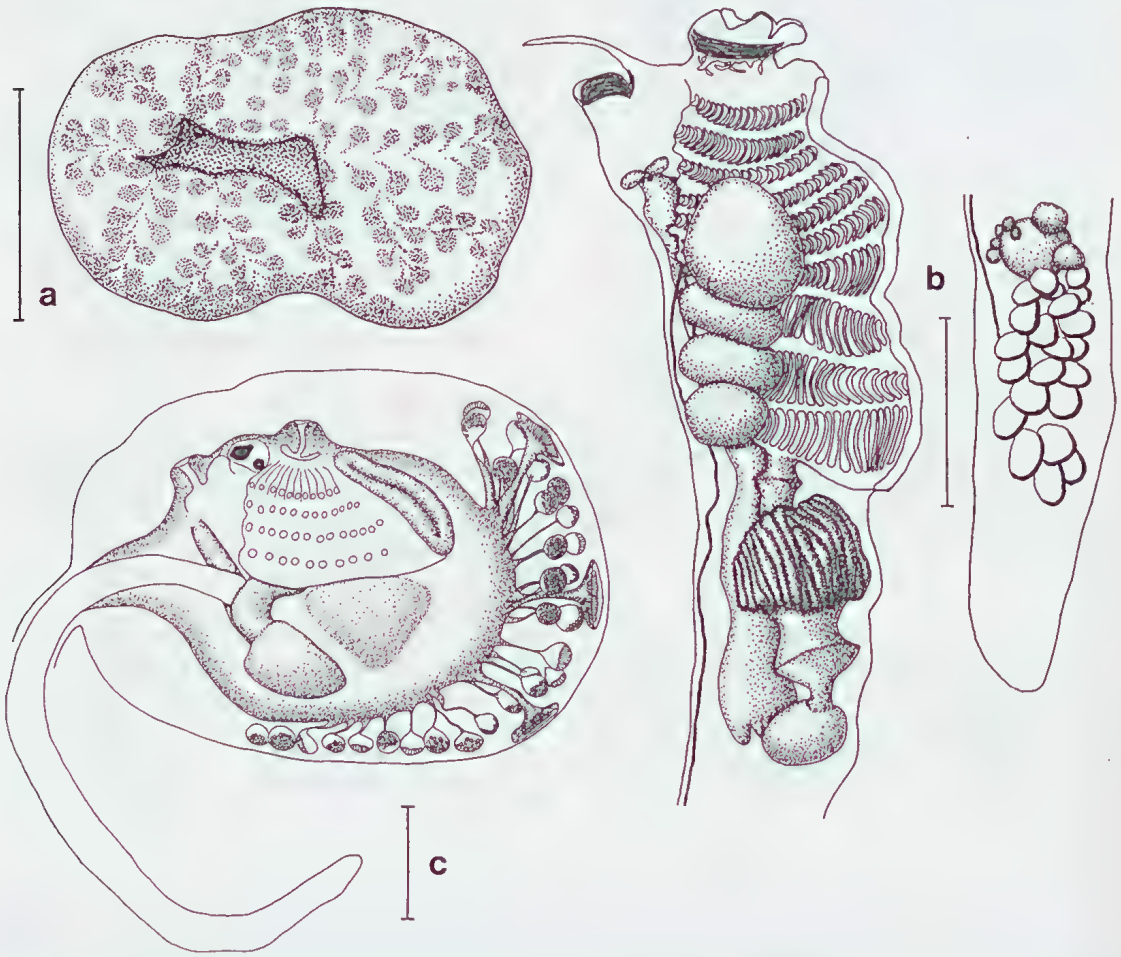

FIG. 62. *Aplidium altarium* — **a**, colony (QM GH5307); **b**, zooid, with posterior abdomen separately (AM Y1396); **c**, larva (WAM 79.75). Scales: **a**, 1cm; **b**, 1mm; **c**, 0.2mm.

length of the zooid, and even though all of the examined zooids are contracted, the muscles are inconspicuous. The branchial siphon is short. Only a short imperforate area is posterior to the prepharyngeal groove. The atrial tongue is of variable length, and is undivided or sometimes divided into 2 or 3 points. It arises from the anterior rim of the atrial aperture. The atrial aperture is a vertical slit, bounded on each side by a projecting convex lip which has muscles in its outer, convex, vertical margin. The homology of these muscles appears to be with the sphincter muscle usually found around the atrial aperture. The unusual configuration of the atrial sphincter in this species results from its component muscle bundle being drawn together by fine longitudinal muscles, one each in the middle of the anterior and posterior rims of the aperture, to form, respectively, the anterior and posterior extremities of a vertical aperture.

As well as being long, the branchial sac is wide, with up to 25 stigmata per row. However, despite its length, there are only 9 or 10 rows of stigmata. The stigmata are long. In the contracted, preserved zooids they usually are found folded horizontally along the centre of each row. The stigmata are fusiform, pointed at each end. They are only slightly reduced in length toward the dorsal and ventral mid-lines.

The oesophagus increases in diameter anterior to the stomach to form a prestomach. The stomach is wide, reduced in diameter at the cardiac end, with some oblique folds terminating against the suture line. It has 25 to 30 fine folds, sometimes interrupted along their length. The duodenum is wide, and the short mid-intestine narrows abruptly to enter the oval posterior stomach in the bend of the gut loop. Short rectal caeca are present at the proximal end of the ascending loop. The rectum extends half way up the branchial sac (opposite the fifth row of stigmata), but the contraction of the anterior part of the thorax can draw the anus up behind the atrial aperture. The anal opening is bounded by two large semicircular lips. The ovary is in the relatively short, stumpy posterior abdomen a short distance behind the gut loop, and 12 to 20 male follicles are clustered behind it. There is no constriction between the abdomen and the posterior abdomen.

Up to 2 embryos are in a brood pouch projecting from the postero-dorsal corner of the thorax in colonies collected in April and May from Western Australia (WAM 754.82 763.82 837.83 1030.83 871–2.83), and from the Capricorn Group in November (QM GH5307) and December (QM GH5559). Mature gonads are not present in colonies collected in August (WAM 1029.83). In the Darwin colonies, collected in October, up to 4 embryos are lined up in the atrial cavity, the largest a tailed larva. Specimens collected in October (QM GH5131) and November (Heron I.), May (Myora) and June (Lizard I.) have up to 3 embryos at various stages crowded into the atrial cavity, projecting dorsally from it when the thorax is contracted. These embryos distend the whole atrial cavity and are not in a postero-dorsal brood pouch as they are when only one embryo is present. Larvae are short and deep, with a trunk to 1mm long. As they mature they become almost spherical, the trunk about 1.0mm long with the tail wound about three-quarters of the way around it. Circles of 6 to 8 epidermal vesicles are around each of the adhesive organs and these remain attached by narrow stalks to the epidermis. About 5 epidermal vesicles are also attached to the trunk ectoderm in the median line ventrally, behind the adhesive organs. The 3 median adhesive organs at the anterior end of the trunk are small and shallow. A mass of blue pigment is in the haemocoelic cavity, especially dense in the posterior horns, although these are largely obliterated as the oozooid develops. Mature larvae with a spherical trunk have 4 rows of stigmata, and a relatively short yolk mass beneath the large, upright pharynx, with its vertical endostyle.

Remarks

The branching cloacal canals of these colonies resemble some species of *Polyclinum*. The mosaics formed by the closely spaced colonies resemble those of *Ritterella dispar*, and some species of *Diplosoma* (see Kott 1980). Nevertheless, the zooids are characteristic of *Aplidium*. It is possible that these lightly attached small colonies subdivide, and move to space themselves evenly over the substrate.

The zooid, sometimes with a brood pouch, and with bunched male follicles in a short posterior abdomen and numerous stomach folds, resembles *Aplidium uteute*. However, the latter species has zooids with longer, more barrel-shaped stomachs, arranged in circular systems, and the colonies are larger and more irregular than those of the present species. Further, although larvae of *A. uteute* have arcs of lateral vesicles, they also have median vesicles which do not occur in the present species. *Aplidium multiplicatum* has branching systems and similar larvae to the present species. However, *A. multiplicatum* colonies are larger, softer, the pigmentation is different, thoraces are nar-

rower and systems longer and more crowded. *Aplidium opacum* has more crowded systems, spreading colonies, narrower thoraces, more rows of stigmata and fewer stomach folds.

A. flavolineatum: Monniot (1987) from Chesterfield Reef has 12 rows of stigmata and about 30 stomach folds. Although Monniot does not record the number of stigmata per row the zooids are similar to the present species. However the colonies are sheet-like rather than being cushions or wedge-shaped lobes, the zooids are arranged in circles rather than radiating double rows, embryos are incubated in a brood pouch and larvae have median ampullae (like *A. uteute*, see below). Although the larvae have some similarities, the present species is not conspecific with the South African *A. flavolineatum* (see Millar 1962) which is sandy (rather than naked) and red (rather than a cream, yellow, purple or brown colour).

The most conspicuous feature of the present colonies, viz. the double-rows of zooids converging to the central or terminal cloacal apertures, were not observed either by Sluiter (1909) or Millar (1963) in specimens they assigned to *Aplidium altarium*. However, the shape of the colonies, the form of the stomach, and the short posterior abdomen without a constriction between it and the abdomen are similar in all descriptions. The large semicircular lips of the anal opening, and its unusual, relatively anterior, position are recorded by Sluiter for the type specimens, which also have an expansion in the oesophagus as in the present specimens. The 4 to 6 embryos reported to be in the atrial cavity (Sluiter 1909, Taf. V9a) are very much smaller than those in the newly recorded specimen — indeed they are smaller than is known for any species of *Aplidium* and possibly Sluiter misinterpreted these bodies. A further discrepancy between Sluiter's account of the type and the newly recorded specimens is that he recorded only 10 stigmata per row — however there often are discrepancies of this order in Sluiter's counts of stigmata.

Reexamination of specimens from Darwin (Kott 1966) shows that the number of stigmata per row and the shape of the colonies were recorded incorrectly. The colonies are cushions, rather than sheet-like and the branchial sacs have the same number of stigmata as the present newly recorded ones. These Darwin colonies appear to be conspecific with the newly recorded specimens and with the Indonesian type material (Sluiter 1909).

Specimens assigned to *A. altarium* from Zanzibar and Mozambique (Michaelsen 1919; Millar 1956) appear different from the present species, with more numerous stomach folds (about 40), and small larvae with only 4 large epidermal vesicles and no ampullae (see Millar 1956).

Aplidium amorphatum Kott, 1963
(Fig. 63)

Aplidium amorphatum Kott, 1963, p.101; 1975, p.6.

DISTRIBUTION

NEW RECORDS: Victoria (Deal I., QM GH ; South Gabo I., QM GH5155–6). New South Wales (Jervis Bay, QM GH5617–9).

PREVIOUSLY RECORDED: South Australia (Elliston Bay — SAM E2581 Kott 1975). Victoria (Bass Strait — AM U3918 Kott 1963). New South Wales (Eden — AM U3922 U3924 Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are soft, gelatinous cushions, about 8cm in diameter, almost spherical or dome-shaped. The test is translucent and the zooids can be seen through it arranged in circular systems of 9 or 10 in each circle, although in these preserved colonies they are generally withdrawn from the surface and the systems are obscured. Specimens from South Gabo I. (QM GH5155–6) are described by the collector as 'red rose' ascidians.

INTERNAL STRUCTURE: The zooids are large, the thorax and abdomen together being about 5mm long. In relaxed condition the thorax would be longer than the abdomen. The posterior abdomen is long, but when contracted is drawn up to the left side of the gut loop. The zooids are muscular with about 20 longitudinal bands on the thorax that extend along the ventral border of the abdomen and posterior abdomen. The branchial aperture has 8 pointed to shallow rounded lobes around the rim of the short siphon. The long, robust, tongue-like atrial lip, from the upper border of the opening, has a tridentate tip with each division of equal size. The pharynx has 15 rows of up to 16 long stigmata. Each of the rows is crossed by a parastigmatic vessel. An intermediate dorsal languet associated with each of these parastigmatic vessels alternates with, and is the same size as, the languets on the primary transverse vessels.

The oesophagus is about one third of the length of the abdomen. The large voluminous stomach occupies the middle third. It has 4 shallow glandular ridges in its internal wall. The usual duodenal and mid-intestinal regions and a pear-shaped posterior stomach are in the posterior third of the descending limb of the gut loop. A double series of testis follicles is in the posterior end of the posterior abdomen and the ovary is anterior to them.

The colony from Elliston Bay collected in February has a single, large, embryo being incubated in the atrial cavity, almost completely occluding the pharynx. The larval trunk is 1.2mm long, and the tail is wound only halfway around it. Ectodermal vesicles are crowded in the test around the anterior part of the trunk, obscuring the 3 adhesive organs in the anterior mid-line. They consist of wide lateral bands of vesicles, and some in the median line attached by 2 or 3 long branching stalks in each interspace between the adhesive organs. The developing adult organs are at the posterior end of the long trunk.

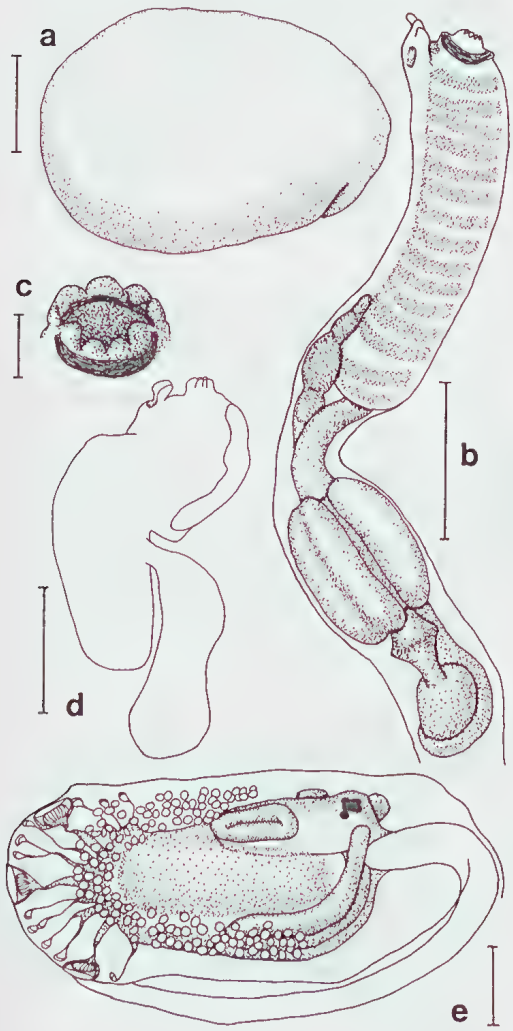

FIG. 63. *Aplidium amorphatum* — **a**, colony outline (SAM E2581); **b**, thorax and abdomen (holotype AM U3918); **c**, branchial aperture (holotype AM U3918); **d**, outline of contracted zooid, showing posterior abdomen pulled up alongside the abdomen (QM GH5617); **e**, larva (SAM E2581). Scales: **a**, 2cm; **b**, 1mm; **c**, **e**, 0.2mm; **d**, 2mm.

REMARKS

The distinctive aspects of this species are its soft, rounded colonies, large zooids in circular systems, 8 branchial lobes, parastigmatic vessels, large stomach with shallow glandular ridges, and the large larva filling the atrial cavity in which it is brooded. The species has a superficial resemblance to *Aplidium protectans* which also completely lacks sand, and has a similar rounded shape, circular systems, 8 branchial lobes, large zooids, and shallow stomach folds. However, in *A. protectans* the test is firmer, the systems are depressed into the surface test, rows of stigmata are more numerous, parastigmatic vessels are absent, and the range is tropical.

The wide ventral muscle which draws the posterior abdomen up alongside the posterior end of the abdomen is reminiscent of the muscle band in *Aplidium circumvolutum* which distorts the zooid in a similar way (see Miller 1982).

Aplidium australiense Kott, 1963
(Fig. 64)

Aplidium australiensis Kott, 1963, p.111 (part, type specimen from Shoreham).
Aplidium colelloides: Kott 1972a, p.15; 1972b, p.176; 1975, p.7.

DISTRIBUTION

NEW RECORDS: Western Australia (Recherche Archipelago, WAM 147.75). South Australia (Eyre Peninsula, SAM E2557; Great Australian Bight, SAM E2478; Nuyts Archipelago, SAM E2472 E2476 E2558; Hotspot, QM GH1325).

PREVIOUSLY RECORDED: South Australia (Great Australian Bight — Kott 1972b, 1975; St. Vincent Gulf — Kott 1972a; Investigator Strait — Kott 1972b). Victoria (Shoreham — AM Y1398 holotype Kott 1963).

The records suggest that the species occurs only off the southern Australian coast.

Description

EXTERNAL APPEARANCE: The colonies are long (up to 8cm), more or less elliptical heads to 6cm diameter on long (to 20cm) narrow, tough, sandy stalks narrowing to a basal holdfast of short, thick root-like branches. The test on the head is soft, gelatinous, translucent. The terminal end of the head sometimes is pointed.

In the larger preserved colonies there are 4 to 6 deep, longitudinal furrows or creases formed between deep folds of the surface of the colony. Common cloacal canals are at mid-thoracic level and extend into large cloacal spaces in the edge of the folds referred to above. Three or 4 large cloacal apertures are either sessile or on protuberant cones along the edge of the folds. Sometimes they seem to alternate from side to side of the edge of the fold. Branchial openings of zooids are on both sides of these folds, i.e. on their outer and inner surfaces, as well as in the base of the depressions between and under the folds. Branchial apertures are absent only from the edges of the folds over the large cloacal canals.

Zooids are seen to be in longitudinal rows near the top of the stalk. However, in preserved colonies the arrangement of zooids towards the middle and top of the head is obscure.

Relatively small heads (2cm long) on long (10cm) stalks (SAM E2558) suggest that heads may regenerate on persisting stalks. These smaller heads lack the deep creases of the larger ones, and the zooids are arranged in more or less conspicuous double rows, converging to large cloacal apertures — 3 or 4 randomly distributed around the sides of the head, and 2 or 3 on the top of the head.

INTERNAL STRUCTURE: Zooids are particularly long and thread-like, their posterior ends curving down into the stalk. The rim of the branchial apertures is divided into 6 large, rounded lobes. The atrial aperture is a small sessile opening in the middle of the dorsal border of the thorax with a small pointed languet from the upper rim of the opening. About 10 longitudinal muscle bands on the thorax extend the length of the zooid, joining into a single wide ventral band along the long posterior abdomen.

Stigmata are in 15 rows with about 15 per row, although both the number of rows and the number per row are difficult to count owing to contraction of the small zooids. Twelve to 16 deep, longitudinal folds are in the stomach wall. The number varies with the size of the zooids. Testis follicles are in a double series in the posterior end of the posterior abdomen.

One large embryo or tailed larva and sometimes also what appears to be an infertile ovum are in the posterior part of the atrial cavity in colonies collected in September (SAM E2557) and in October (Kott 1972b). Specimens collected in March (SAM E2476) have mature male gonads.

The larval trunk is 1.5mm long. Its anterior end is obscured by a cloud of minute epidermal vesicles along each side of the base of the adhesive organs. The tail is wound three-quarters of the way around the trunk.

Remarks

The colonies of this species, with their long, narrow, hard, sandy stalks and long gelatinous heads with small, crowded zooids and deep longitudinal creases, are distinctive.

Despite Herdman's (1886) speculation that *Aplidium colelloides* (Herdman, 1886) from South Africa had a short stalk, Millar (1962) established that it has a long (up to 6cm), narrow, hard stalk like that of the present species and reminiscent also of the long-stalks of species of *Sycozoa* and *Pseudodistoma*. Kott (1972a,b; 1975) in assigning South Australian specimens to the South African species, ignored the fact that the former have larger colonies with external creases on the head, more numerous stomach folds, and a larval trunk twice the size of the South African specimens. The large colonies that characterise the Australian species also have more crowded zooids less conspicuously arranged in long, oval systems (Millar 1962).

The larger colonies, deep creases, complex crowded systems as well as the long, narrow, hard stalks help to distinguish the species from *A. geminatum* n.sp. which has double rows of zooids, but short and thick stalks, less crowded zooids, more numerous stomach folds, longer, more conspicuous and often 3-lobed atrial tongues, and different larvae.

The type specimen of the present species from Shoreham (AM Y1398) is a head which has lost its stalk. The other specimens assigned to this species by Kott (1963) are colonies of

A. geminatum n.sp., to which the larva figured by Kott (1963, Fig. 25) also belongs.

Aplidium bacculum n.sp.
(Fig. 65. Plate 10e)

DISTRIBUTION
TYPE LOCALITY: South Australia (Yorke Peninsula, Edithburgh, 35°9.7S 137°47.4E, 12m, coll. AIMS Bioactivity Group 6.2.89, holotype QM GH 5434).
FURTHER RECORD: South Australia (Thorny Passage, SAM E2568).

DESCRIPTION
EXTERNAL APPEARANCE: The colony is a compact mass of parallel, long (3cm), narrow (to 5mm) sandy stalks, that branch once or twice along their length and adhere to one another. Their terminal free ends are flattened, horizontal, and level with one another to form a more or less even platform. They have a cloacal aperture in the centre of each terminal flat tip. This opens from a shallow, circular, cloacal cavity which is surrounded by about 10 zooids. Branchial apertures open around the upper margin of the terminal flat surface, and atrial apertures open into the cloacal cavity. A single cloacal system is in each terminal branch. The specimens from Thorny Passage have the terminal test inflated over each zooid, and the central common cloacal apertures protrude slightly.

Sand is crowded over the surface of each stalk, and also is embedded throughout the internal test, but is absent from the surface over the terminal end of each lobe. The small thread-like zooids are difficult to remove from their narrow longitudinal spaces in the hard, sandy colony.

INTERNAL STRUCTURE: Zooids extend the whole length of the sandy stalk, but the thorax and abdomen are together only about 3mm of which the abdomen is about two-thirds. The branchial aperture has 6 rounded lobes. A fleshy atrial lip, divided into 3 pointed lobes, extends from the upper border of the atrial aperture. Longitudinal muscles on the thorax are moderately strong, but they become finer as they extend back along the ventral surface of abdomen and posterior abdomen in a wide band of delicate muscles.

Stigmata are in 5 rows of about 6 stigmata per row, but these were difficult to count owing to contraction. The oesophagus is relatively long,

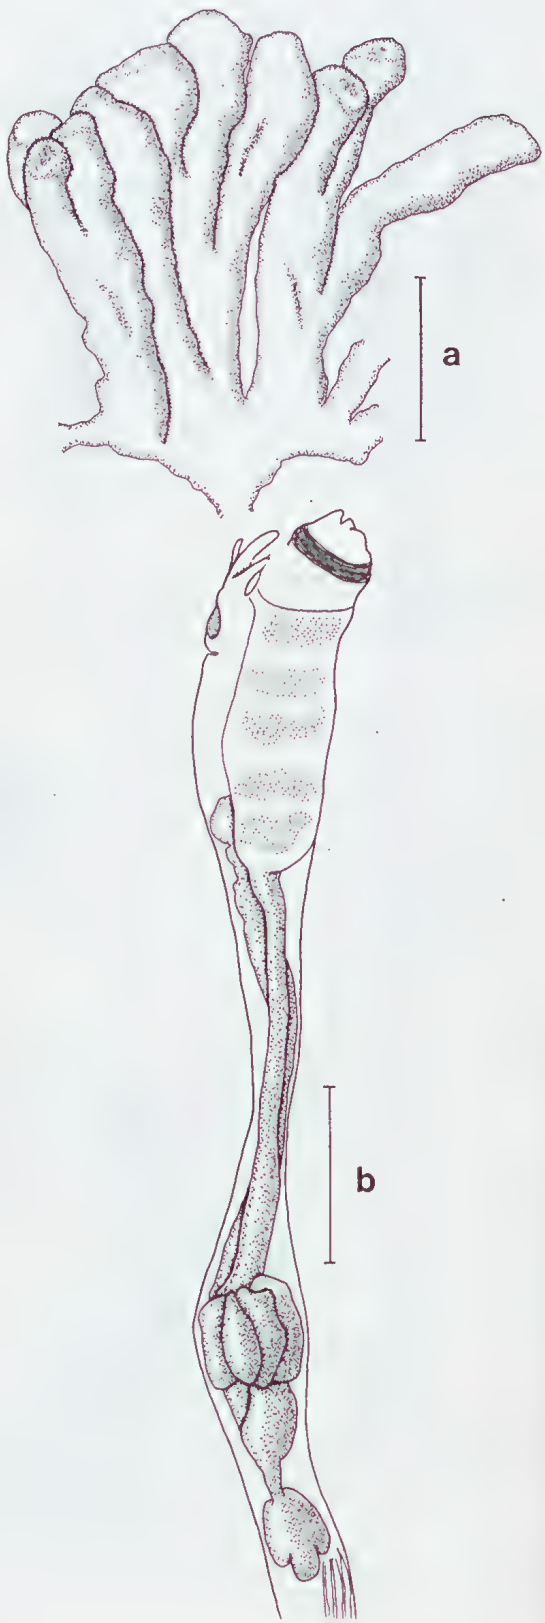

FIG. 65. *Aplidium bacculum* n.sp. (holotype QM GH5434) — **a**, colony; **b**, thorax and abdomen. Scales: **a**, 1cm; **b**, 0.5mm.

the small stomach being two-thirds of the way down the abdomen. The stomach wall has 5 deep folds. The duodenal area reduces in diameter to a short mid-intestine which opens into an oval posterior stomach in the descending limb of the gut loop. There is a small rectal valve at the proximal end of the rectum. Gonads are not developed in the available material.

REMARKS

Superficially, the sandy stalks of this species differ from those of *Ritterella* spp. and *Monniotus* spp. (which have no sand internally) principally in having embedded sand crowded in the internal test. Despite the long oesophagus, however, zooids are characteristic of *Aplidium* and open into a well developed cloacal cavity rather than directly to the exterior as in *Ritterella*. The form of the colony, and the long oesophagus (which probably is associated with the length of the colony lobes), together with the small zooids with only 5 rows of stigmata, characterise the species. Externally, the sandy lobes of the colony, especially the one from Thorny Passage with the test inflated over the anterior end of each zooid, and the protruding central cloacal aperture, resemble *Synoicum stewartense* Michaelsen, 1924 (see Millar 1982).

Other *Aplidium* species with 5 rows of stigmata viz. *A. filiforme* n.sp. and *A. depressum* lack the long stalks and long oesophagus of the present species.

Aplidium brevilarvacium Kott, 1963
(Fig. 66. Plate 10f,g)

Aplidium brevilarvacium Kott, 1963, p.113.
Aplidium digitatum Kott, 1975, p.7.

DISTRIBUTION

NEW RECORDS: South Australia (Ward I., QM GH2412; Top Gallant I., QM GH953; Investigator Group, QM GH1311 GH2413). Queensland (Heron I., QM GH961).

PREVIOUSLY RECORDED: Western Australia (Pt. Peron; Cape Naturaliste — AM U3926 syntypes *A. brevilarvacium* Kott, 1963). South Australia (Northern Great Australian Bight – QM G7508 AM Y1982 paratypes *A. digitatum* Kott, 1975).

The record from Heron I. is anomalous (see Remarks, below).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are rounded heads (0.5 to 1.5cm in diameter) on thick stalks, 0.5 to 6.0cm long, branching 2 or 3 times along their length, and up to about 0.5cm in diameter at the base. These sometimes arise from a basal test mass. Zooids are arranged in longitudinal rows along each side of cloacal canals that extend the length of the head, converging to 2 or 3 large, terminal cloacal apertures. The outer surface of both head and stalk is even, without wrinkles or protuberances.

There is a layer of sand in the outer surface that may obscure the zooids and their branchial openings. Sand is present also in the internal test. The anterior ends of the zooids are perpendicular to the outer surface and posteriorly they curve down into the stalk of the colony, criss-crossing one another as they go. In life the colonies are white to a sandy pink colour.

INTERNAL STRUCTURE: Zooids are robust. When contracted the thorax and abdomen are of equal length and together about 2mm long. About 12 very fine longitudinal muscles from the thorax run the length of the zooid. The branchial lobes are rounded. The atrial opening is sessile, with a fleshy, pointed lip from the anterior rim of the opening which sometimes is divided into 2 at the tip. The pointed dorsal languets are to the left of the mid-dorsal line, opposite the third row of stigmata. Stigmata are relatively short and oval, about 10 per row, and in 14 rows. The stomach, halfway down the abdomen has 10 deep longitudinal folds. The duodenum is long, and the oval posterior stomach is separated from the duodenum and rectum respectively by short lengths of proximal and distal mid-intestine. The posterior abdomen is narrow, up to 1cm long.

In the type specimens from Cape Naturaliste (collected in January) and the newly recorded South Australian specimens (collected in April) there is a large tailed embryo in the atrial cavity and sometimes a large (possibly non-fertile) ovum as well. The larval trunk is about 0.9mm deep, but only about 0.6mm long. It has an ocellus and an otolith, 3 medium stalked adhesive organs, and the tail is wound one and a half times around it. Epidermal vesicles are present along each side of the adhesive organs.

REMARKS

The colonies from Heron I. appear to have only one or 2 terminal cloacal apertures, instead of the more numerous openings in the South Australian colonies. However the zooids have the same number of rows of stigmata and stomach folds, and are not distinguishable from the southern or western Australian ones. These Heron I. colonies may

represent a population at the northern extremity of the range of this otherwise temperate indigenous species.

Externally, the colonies of this species, and particularly the specimens from Heron I. with one or 2 systems per lobe resemble *Distaplia australiensis* (see Kott 1990). Colonies also resemble *Aplidium geminatum* n.sp. which, however, has more numerous (20), fine stomach folds, appreciably larger colonies, and less branched and more wrinkled stalks.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies form robust, always sandy, investing sheets up to 20cm

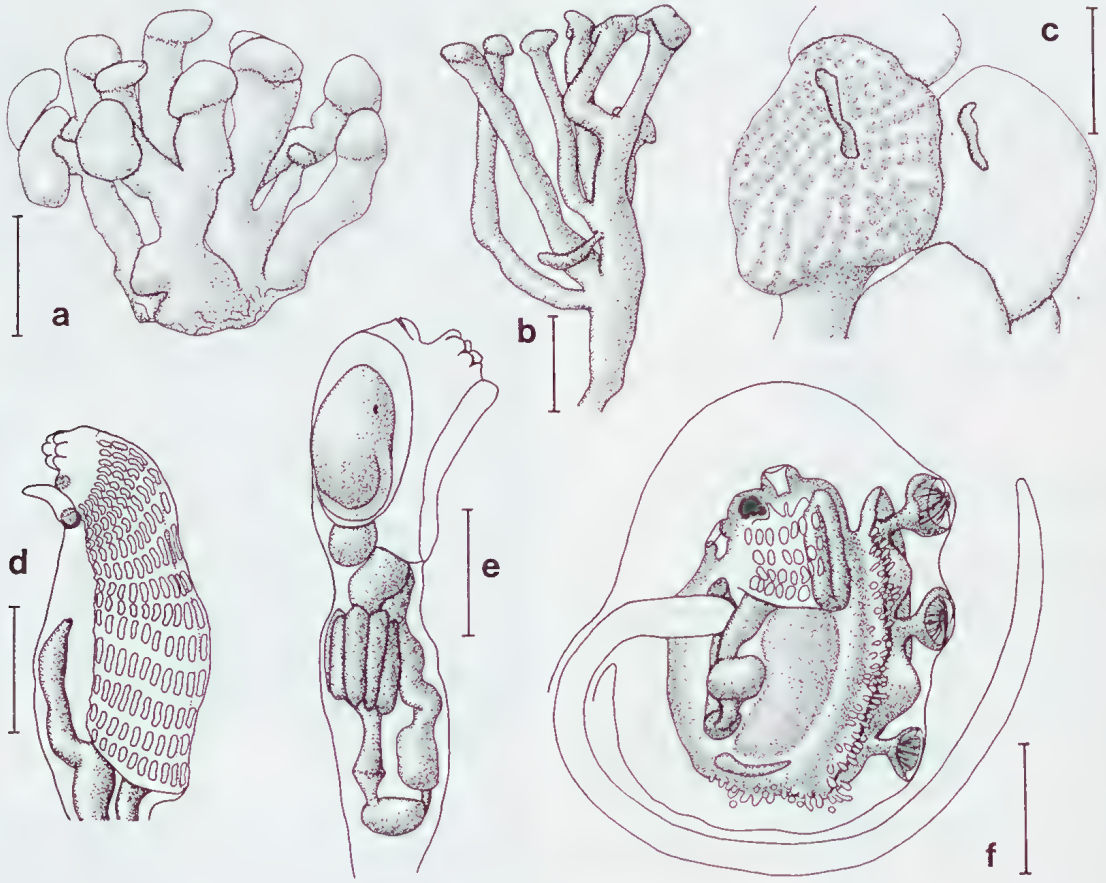

FIG. 66. *Aplidium brevilarvacium* — **a**, **b**, parts of colonies (QM GH953, G7508); **c**, details of a zooid system, with double rows of zooids converging to a terminal cloacal cavity (QM GH961); **d**, thorax (QM GH2412); **e**, thorax and abdomen (QM GH953); **f**, larva, showing arcs of lateral vesicles and median ampullae (syntypes AM U3926). Scales: **a**, **b**, 2cm; **c**, 5mm; **d**, **e**, 0.5mm; **f**, 0.2mm.

in maximum extent and up to 1cm thick. A row of zooids is along each side of the cloacal canals that extend between or around long, narrow areas of zooid-free test. Large sessile common cloacal apertures are at the junction of several canals and they often are elevated by the large cavity beneath them. The surface of the colony is depressed where relatively thin, usually transparent, naked test overlies the cloacal canals. Oval granular bodies about 0.1mm long, and some shade of brown to almost black are in the test and line the sides, base and walls of the cloacal canals, and often are in the surface as well. The grey to brown colour of the colonies results from these bodies and the included sand, sometimes in small clumps. Both the oval bodies and the clumps of sand appear to have been interpreted as faecal pellets. Sand is embedded throughout the test except in the thin transparent surface layer over the cloacal canals. Colonies have been described as 'sandy grey' or 'drab, with fawn zooids', 'sandy grey with yellow zooids', 'grey encrusting ascidian'. Living zooids are yellow, or orange. The test over the cloacal canals is irridescent in

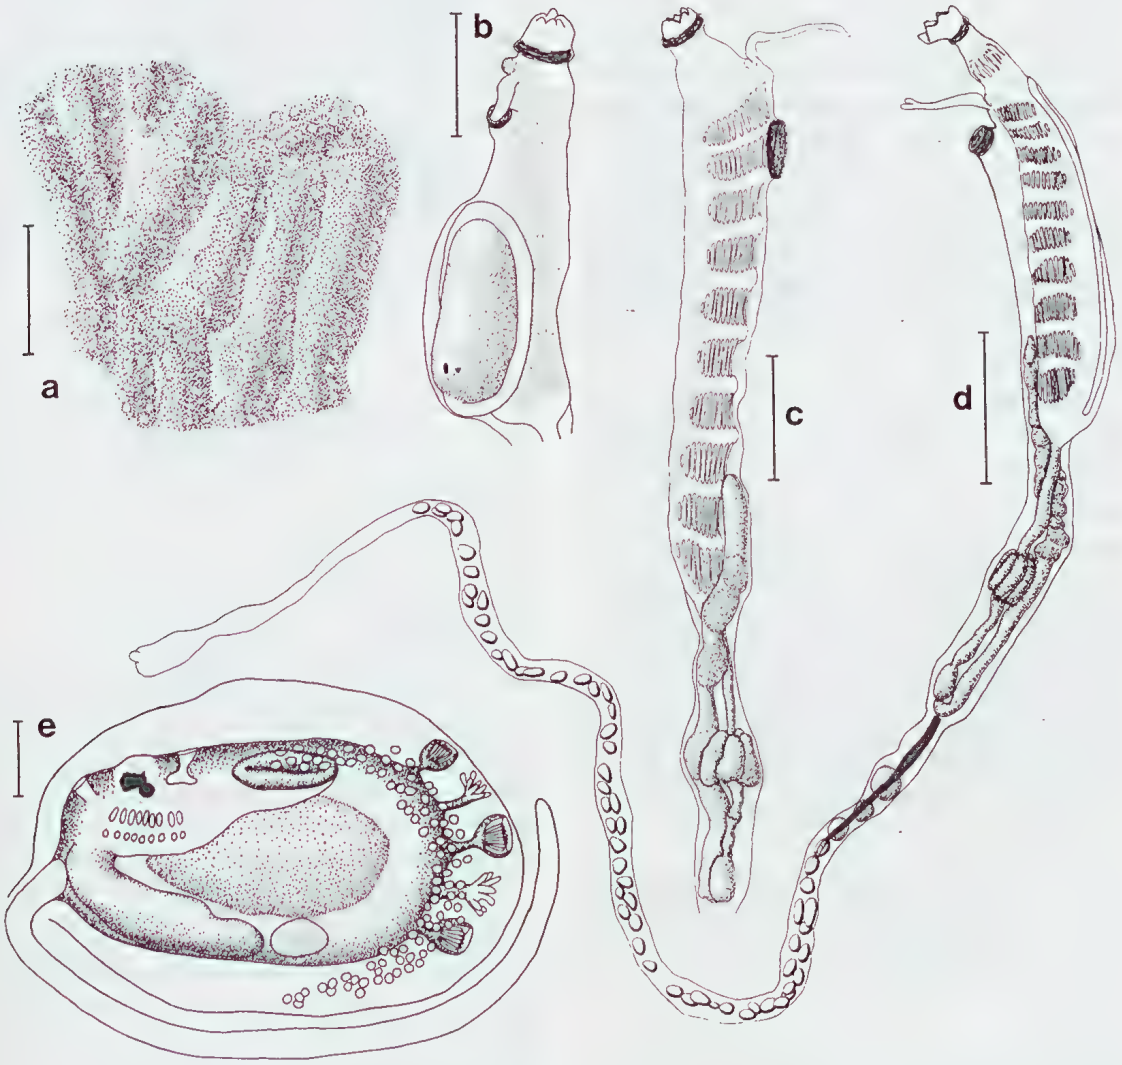

FIG. 67. *Aplidium caelestis* — **a**, colony (QM GH5437); **b**, thorax with embryo being incubated (QM GH5150); **c**, thorax and abdomen (QM GH5647); **d**, whole zooid (QM GH5633); **e**, larva (QM GH5647). Scales: **a**, 5mm; **b**, **c**, 0.5mm; **d**, 1mm; **e**, 0.1mm.

living specimens. A colony from Heron I. (QM GH5661) had blue cells in the surface test between the rows of zooids of the living colony — as in the type from New Caledonia. *Prochloron* is often present on the surface (see Kott *et al.*, 1984: *Aplidium* sp. 1). Two colonies have red and green symbiotic cells embedded amongst the sand in the floor of the common cloacal canals. These are pink in preservative. Sand always is present in the basal half of the colony, and in the ridges between the double rows of zooids.

INTERNAL STRUCTURE: The zooids are long and thin (thorax and abdomen together to 5mm), but robust, with strong longitudinal muscles that extend their full length, along the ventrum of abdomen and posterior abdomen. The thorax and abdomen, of about equal length, are together about 3mm. The branchial siphon has 6 rounded lobes and a single conspicuous bulging sphincter muscle at their base. A long prebranchial area is posterior to the tentacles. The atrial aperture, a short distance down the dorsal surface, also has a conspicuous sphincter muscle. A robust, but not very long, pointed atrial lip, usually not divided, arises from the body wall anterior to the aperture. The atrial aperture at the level of the second or third row of stigmata opens into the sides or base of the cloacal canal.

Stigmata are in 10 to 18 rows, with 6 to 14 the maximum number per row. Expanses of unperforated pharynx are along each side of the mid-dorsal and mid-ventral lines. The oesophagus and post-pyloric part of the gut loop are relatively long for this genus, the gut loop being about the same length as the thorax when both are extended. The small stomach, halfway down the abdomen, has 5 distinct folds, although these sometimes flatten and occasionally it is difficult to see traces of any folds in the stomach wall. The duodenum, mid-intestine and posterior stomach are characteristic of the genus. Gonads are in the centre of the abdomen and consist of an irregular row of testis follicles with an anterior ovary a little distance behind the gut loop.

A single embryo with a trunk 0.65mm long and median ampullae alternating with the adhesive organs is in the atrial cavity of specimens taken in March and August from Heron I.

REMARKS

The zooids of this species, with their well-formed branchial siphons, sphincter muscles, atrial lips separate from the apertures, and long and narrow thoraces, resemble *A. crateriferum*, *A. griseum* n.sp., *A. lenticulum* n.sp., *A. lunacratum* nom. nov. and *A. clivosum* n.sp. The long, rather straight double row systems with long canals surrounding ridges of solid sandy test, sometimes can be seen in *A. ritteri*, but its atrial lip is not separate from the aperture. The oval granular bodies are present also in *A. lenticulum* n.sp., which has cloacal canals around raised polygonal areas rather than between the long ridges of the present species. The larvae also appear to be similar to those of *A. lenticulum* n.sp. The type specimen of *A. caelestis* Monniot, 1987 from New Caledonia has the same almost smooth stomach, narrow thorax, separate atrial lip, long double rows of zooids. The test is entirely encrusted with sand as it usually is in the newly recorded specimens. Although the transparent test over the cloacal canals is not always sky-blue in living specimens as it is in the type, it sometimes is. Colour and the number of rows of stigmata appear to be variable characters in this widespread species.

Kott (1963), interpreting the oval bodies as faecal pellets, assigned specimens of this species to *A. hypurgon* (Michaelsen, 1924), a New Zealand temperate species.

South Australia (Elliston Bay — SAM E2585 Kott 1972b).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are large, to 4cm thick and to 15cm or more in maximum dimension. Some are of even thickness attached by the whole of the basal surface. Others converge toward the basal attachment area, or have irregular processes that may project into the substrate or around rocks and rubble. One colony (WAM 1021.83) is upright, rather flattened and divided into 2 lobes, about 15cm high, with systems evenly distributed over the both sides of the upright lobes.

The base and sides of the colonies have sand adhering to the surface. Sand usually is present on the zooid-free raised areas of the surface surrounding single systems, or groups of systems. The test over the systems usually is naked. Embedded sand is absent at thoracic level where zooids curve around the shallow cloacal cavities, but is present throughout the remainder of the test. In some colonies it can be seen projecting in from the periphery of each system as narrow wedges between the double rows of zooids.

The cloacal canals converge from the periphery of each system, to the large central cloacal cavity. A cloacal aperture raised on a conical protuberance (up to 5mm diameter across the base) is in the centre of each system. Zooids are arranged in double rows, one row along each side of the canals. In preserved colonies the surface is depressed over the systems, although it is not unusual for 3 or 4 systems to be present in one large depression, each system with its protruding common cloacal aperture. Systems are not always circular, often being irregularly shaped, the cloacal aperture being excentric with longer canals on one side than on the other. The diameter of the systems in this species is variable, ranging from 0.5 to 1cm, often in one colony.

In some colonies the whole upper surface is horizontal, and depressed within a rounded marginal rim. In others there is no sharp division between the margin and a convex upper surface.

In photographs, living colonies are pink, 'light wine' or bluish red. In preservative they are a translucent bluish-red. The colour is conspicuous on the upper surface over the systems and around the cloacal apertures.

INTERNAL STRUCTURE: In contracted zooids the thorax and abdomen together are from 3 to 6mm long. Long, thread-like posterior abdomina extend down through the crowded sand in the lower half of the colony.

About 12 fine longitudinal thoracic muscles extend posteriorly along the whole length of the zooids. The branchial siphon is long, with a narrow, bulging sphincter muscle behind the branchial lobes. Some fine circular muscles are on the remainder of the siphon, but they do not form a sphincter. The branchial tentacles are about halfway up the branchial siphon, with a long prepharyngeal area between them and the prepharyngeal groove. The diameter of the siphon bulges out in the vicinity of the branchial tentacles between the anterior sphincter and the prepharyngeal groove. A single, pointed atrial lip, sometimes bifid or trifid at the tip, arises from the body wall just anterior to the atrial siphon, which, depending on the state of contraction of its sphincter muscle, is either a sessile, circular opening, or is on a short, cylindrical siphon. The atrial siphon is well anterior, opposite the second row of stigmata.

In the branchial sac are 16 to 18 rows of up to 12 stigmata. A wide unperforated band of pharyngeal wall is present each side of the endostyle.

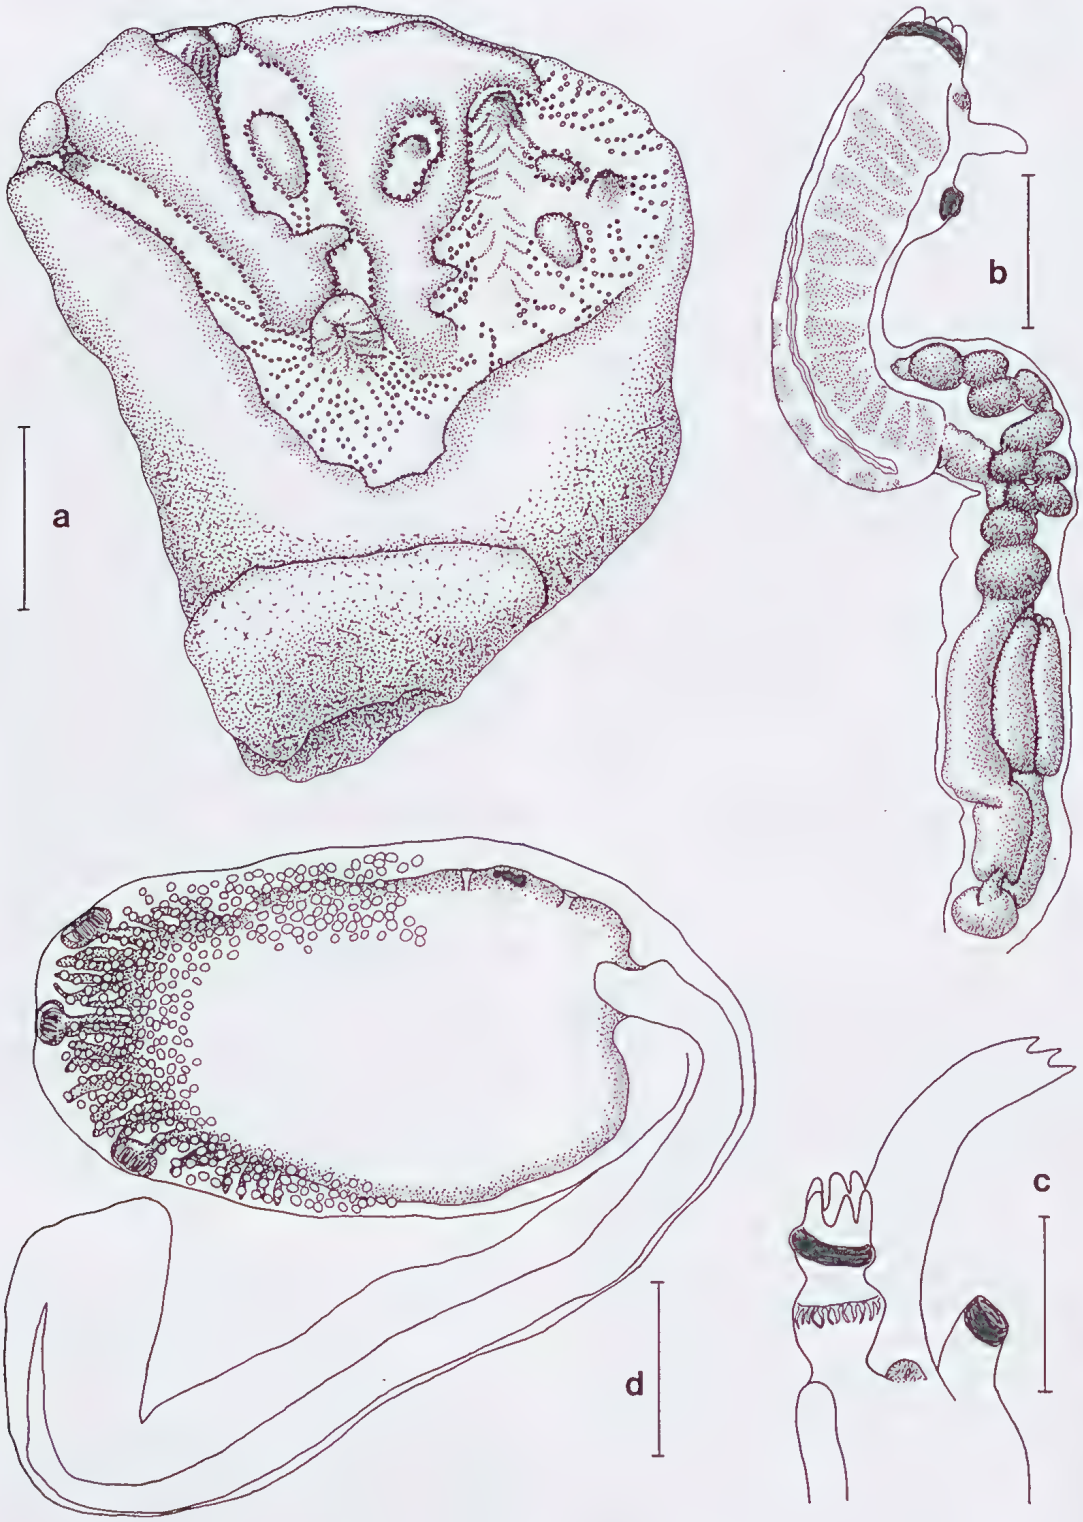
The abdomen is almost as long as the thorax. The oesophagus is long and narrow. The small stomach has 5 deep folds in its wall. A long duodenum is continuous with a narrow proximal part of the mid-intestine. A small oval posterior stomach is in the distal part of the descending limb of the gut loop. A short, narrow distal section of the mid-intestine is between the posterior stomach and rectum in the bend of the gut loop. A distinct rectal valve is present. The anal opening is opposite the fourth most posterior row of stigmata.

A single or double series of male follicles is in the posterior part of the posterior abdomen.

A large embryo (trunk 1.5 to 2.5mm long) is in the posterior half of the atrial cavity of specimens collected in March at Busselton (QM GH5469), and January at Kangaroo I. (QM GH5432). The tail extends only to the anterior end of the trunk which has crowded hair-like ampullae obscuring the anterior end. Embryos and larvae are heavily pigmented (red and opaque).

REMARKS

The species is distinguished by 2 characters which although they occur separately in other species, seldom are found together as they are in the present one — the atrial lip is close to, but separated from the aperture, and the double rows of zooids converge to the cloacal aperture. It also has a group of characters which it shares with *A. crateriferum* and the temperate and partly sympatric *A. lunacratum* nom. nov., viz. the bulky sandy colonies, protuberant cloacal apertures, narrow



a
b
c
d

zooids with 5 well-formed stomach folds, and the atrial lip separate from the aperture.

The zooid systems are not always so deeply depressed into the surface as they are in *A. crateriferum*, and *A. lunacratum* nom. nov. has sand in the test over the cloacal cavity and in the protuberant cone of the cloacal aperture. Both the latter species have their zooids arranged in a single circle around each common cloaca. In *A. crateriferum* the atrial lip is not close to the aperture as it is in the present species and *A. lunacratum* does not have the same bulging branchial sphincter and long siphon. In *A. lunacratum* the thoracic muscle bands, and in *A. crateriferum* the number of rows of stigmata are more numerous. The larvae of *A. clivosum* are in the same size range as those of *A. lunacratum* but larger than those of *A. crateriferum*. Larvae of the present species differ from *A. lunacratum* in having fewer epidermal vesicles and more ampullae.

Aplidium pantherinum (Sluiter, 1898) and its synonyms from South Africa (see Millar 1962) have a smaller larval trunk, and although they have narrow thoraces and about 17 rows of stigmata like the present species, the atrial tongue is not separate from the aperture.

Aplidium clivosum has possibly more variation in its external appearance than most other species of *Aplidium*. The size of the systems varies, as does the number per colony, the amount of embedded sand, the colour and the depth of surface depressions. These variations are not geographically based however and the whole range of morphological variations occurs in tropical as well as temperate waters.

In view of its wide range in Australian waters, it is probable that it will be found to occur in the Western Pacific. It is possible that some of the specimens assigned to *A. crateriferum* by Van Name (1918) from the Philippines are of this species.

Aplidium congregatum n.sp.
(Fig. 69)

DISTRIBUTION

TYPE LOCALITY: Queensland (North Stradbroke I., Point Lookout, coll. A. Rozefelds 17.11.78, holotype QM GH5584).

FURTHER RECORDS: None.

Specimens are found tucked into narrow rocky crevices at the type locality.

DESCRIPTION

EXTERNAL APPEARANCE: Sandy flat-topped lobes 1.5 to 2cm diameter around the upper surface, narrow toward the base where they are joined through common test. The edges of the flat upper surface fuse with adjacent lobes. A layer of sand adheres to the outside of the stalks and sides of the lobes, but is absent from the upper surface. Internally sand grains are scattered sparsely amongst the zooids. Zooids are crowded and parallel in the test. They may be in rows along each side of long canals that converge to the sessile cloacal apertures on the flat upper surface.

INTERNAL STRUCTURE: Zooids are long and narrow, up to 5mm long, of which the thorax and abdomen together comprise about half, and the thorax is about twice the length of the small abdomen. About 16 fine longitudinal muscles extend separately along the length of the zooid and are not gathered into bands on either side of the abdomen or the posterior abdomen. A distinct sphincter muscle is at the base of the 6 narrow, pointed lobes fringing the branchial aperture. The atrial aperture is at the anterior end of the dorsal surface with the forked atrial tongue extending from the anterior rim of the opening. Fine muscle fibres extend along the length of the atrial lip. The stigmata are in 11 rows of up to 12. The oesophagus is moderately long and narrow. The stomach is small and narrow with 12 longitudinal folds in its wall. There is the usual narrow mid-intestine, interrupted at the end of the descending limb of the gut loop by an oval posterior stomach. Small rectal caecaare at the proximal end of the rectum.

A large (4 or 5 oocytes) ovary is at the proximal end of the posterior abdomen and the testis follicles in a single or paired series are behind it in the long, narrow posterior abdomen. The holotype has up to 6 embryos being incubated in a developmental series lined up in the atrial cavity, tending to stretch the thorax longitudinally. Tailed larvae have a trunk 0.5mm long with the tail wound three quarters of the way around it. Conical median ampullae (4) alternate with the median adhesive organs. An arc of scattered epidermal vesicles (about 3 or 4 deep) is around the lateral line on each side of the adhesive organs and extending posterior to them along the dorsal and ventral border of the larval trunk. An ocellus and an otolith are present.

FIG. 68. *Aplidium clivosum* n.sp. — **a**, colony (QM GH5669); **b**, thorax and abdomen (QM GH5670); **c**, branchial aperture, atrial aperture and atrial lip showing sphincter muscles (SAM E2564); **d**, larva (QM GH5469). Scales: **a**, 1cm; **b**, 0.5mm; **c**, 1.0mm; **d**, 0.4mm.

REMARKS

The species is found in similar habitats and in the same geographic location as other flat-topped sandy, lobed species, all superficially resembling one another, viz. *Aplidium incubatum* n.sp., *A. directum* and *Botryllus stewartense* (see Kott 1990). The flat topped lobes of *A. congregatum* have more complex systems of crowded zooids than the others; *Aplidium directum* is distinguished by its tougher colonies with distinct circular systems, only 5 stomach folds and an atrial lip separate from the opening; *Aplidium incubatum* n.sp. tends to divide into separate lobes each with a single system, its zooids have 25 stomach folds, and the larvae have numerous vesicles but no ampullae.

The larvae of the present species resemble those of *A. opacum* which has investing, naked colonies; and *A. geminatum* n.sp. which has stalked heads with long cloacal canals converging to terminal cloacal apertures.

Zooids of the present species share some characters with those of *Aplidium fluorescum* n.sp., but both larvae and colonies are different.

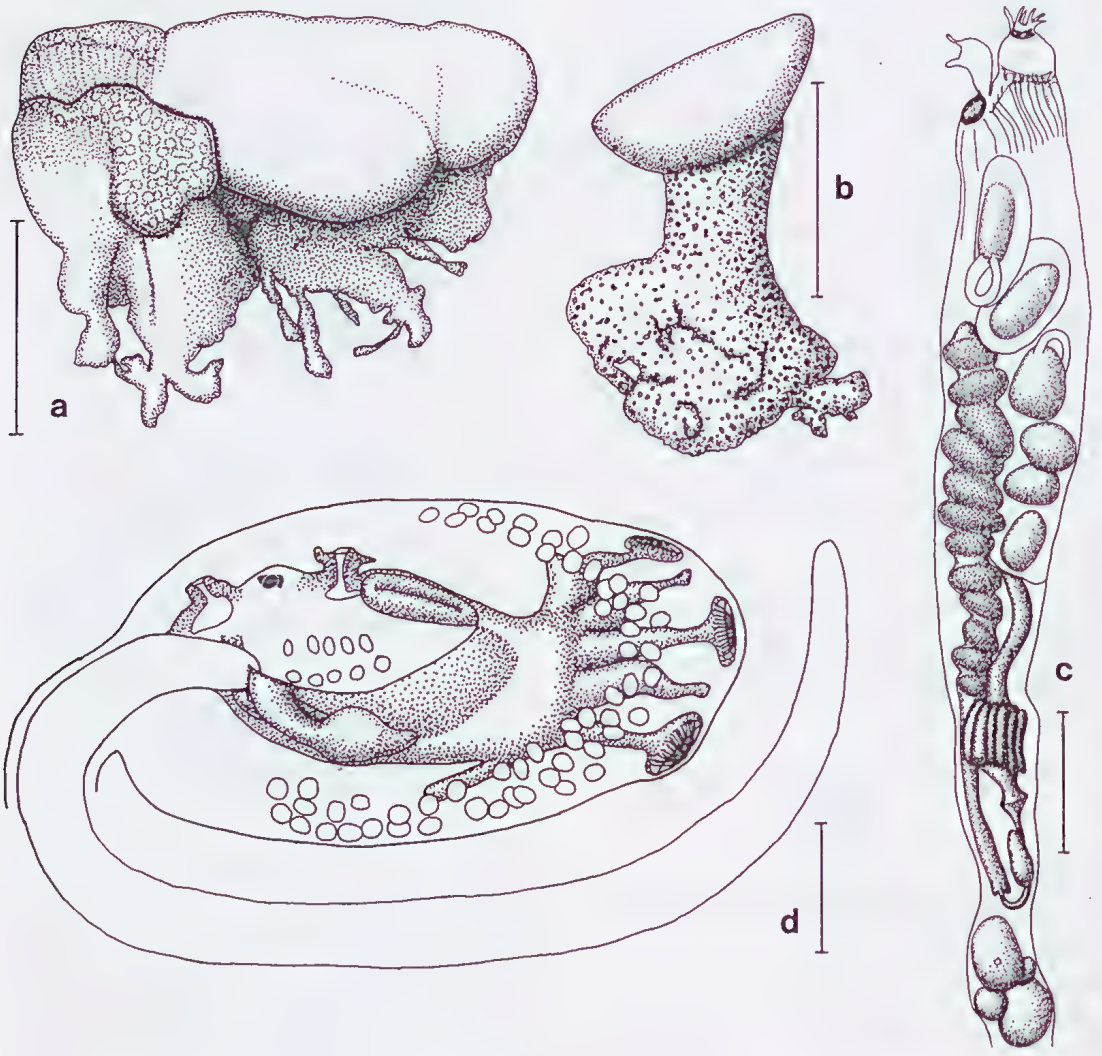


FIG. 69. *Aplidium congregatum* n.sp. (holotype QM GH5584) — **a**, **b**, colonies with positions of zooids shown in part of a colony lobe; **c**, thorax, abdomen, part of posterior abdomen and embryos in atrial cavity; **d**, larva. Scales: **a**, **b**, 1cm; **c**, 0.5mm; **d**, 0.1mm.

Aplidium coniferum Kott, 1963
(Fig. 70)

Aplidium coniferum Kott, 1963, p.102.

DISTRIBUTION

NEW RECORDS: South Australia (Elliston, SA E2580). Tasmania (off Devonport, AM E309; Huon Channel, TM D2074). Victoria (Bass Strait, QM G11861 GH5605, MV H462; Cape Everard, AM E6231–2; Gabo I., SAM E2592).

PREVIOUSLY RECORDED: New South Wales (Montague North, Twofold Bay, AM U3921 Kott 1963).

The species is known from depths to 400m (AM E6231–2).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are upright spherical to egg-shaped lobes, largely naked and without sand in the thin layer of smooth surface test. A basal hard sandy holdfast is probably rooted in sand. Sand is present in moderate concentrations internally. Zooids appear crowded in circular, oval to elongate systems, as well as some in double rows. However, the test is hard, whitish and almost opaque in preservative and it is difficult to determine the exact arrangement of the zooids. The shallow common cloacal cavities are relatively limited. They are surrounded by the fine, thread-like zooids, which are perpendicular at the surface, but cross one another posteriorly in the centre of the colony.

INTERNAL STRUCTURE: Zooids are narrow, and long. The branchial siphon is short, with 6 rounded lobes, but the prebranchial area is relatively long. The thorax and abdomen are each about 2mm even when contracted, and the posterior abdomen is many times that length. The atrial lip is small, pointed and arises from the body wall opposite the first row of stigmata. The atrial aperture is a small round opening, well removed from the lip, opposite the fifth or sixth row of stigmata. There is a pointed papilla posterior to the atrial aperture. About 2 longitudinal muscle bands are on the thorax and continue in wide bands along each side of abdomen and posterior abdomen. Stigmata are in 22 rows of 8 per row. The oesophagus also is long, and wrinkled when contracted. The stomach wall has 5 deep folds. There is a long duodenum and mid-intestine, and a small oval posterior stomach in the descending limb of the gut loop. Rectal caeca are not well developed.

A series of male follicles is in the posterior half of the posterior abdomen, and the small cluster of oocytes is just anterior to the male follicles. A large embryo sometimes is found being incubated in the atrial cavity (QM G11861). The larval trunk is 0.65mm long. It has lateral ampullae on each side near the base of the 4 median ampullae, the

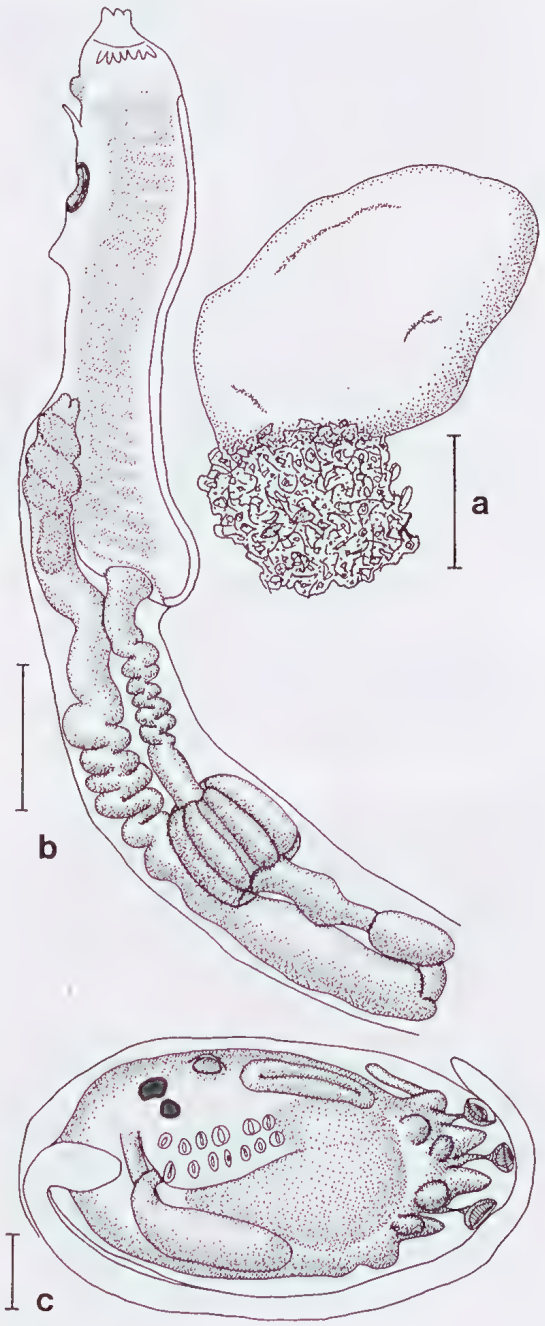

FIG. 70. *Aplidium coniferum* — **a**, colony (QM GH797); **b**, thorax and abdomen (MV H462); **c**, larva (QM G11861). Scales: **a**, 2cm; **b**, 0.5mm; **c**, 0.1mm.

latter alternating with the adhesive organs. The tail is wound about two-thirds of the distance around the trunk.

REMARKS

The large colony with embedded rather than surface sand and basal sandy holdfast, the long and narrow oesophagus, small and isolated atrial lip, and long thorax, are distinctive. The stomach folds are well formed, confirming that it is a species of *Aplidium* rather than *Synoicum*, which it resembles in having a dorsal papilla. The crowded systems distinguish the species from others such as *A. crateriferum* which, also has a long, narrow thorax, and separate atrial lip.

A colony from Bass Strait (AM E309) characteristic of this species, with sandy basal stalk, naked, upright, ovoid colony, and long narrow posterior abdomina criss-crossing internally, originally was assigned to *A. jacksoni* by Kott 1963. Despite her interpretation that the zooids were similar to those of *A. jacksoni*, this was not confirmed on reexamination of the specimen. The zooids are juvenile vegetative ones and neither stomach nor branchial sacs are developed.

Aplidium crateriferum (Sluiter, 1909)
(Fig. 71. Plate 13a–c)

Amaroucium crateriferum Sluiter, 1909, p.103.
Not Van Name 1918, p.163. **Not** Tokioka, 1967, p.40.
Aplidium crateriferum: Millar, 1975, p.242.

DISTRIBUTION

NEW RECORDS: Western Australia (Flinders Shoal near Onslow, QM GH5403; Exmouth, QM GH5398). Queensland (Capricorn Group, QM GH5158–9 GH5567; central section Great Barrier Reef, QM GH5422).

PREVIOUSLY RECORDED: Philippines (Sluiter 1909, Van Name 1918, Millar 1975).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are bulky, gelatinous and translucent but firm. The surface is smooth, and raised in high rounded ridges around irregular surface depressions. One to 3 large conical elevations with a terminal common cloacal aperture arise from each depression. Single apertures are sometimes more or less central but often at one or the other end. A shallow but extensive cloacal cavity is beneath the rela-

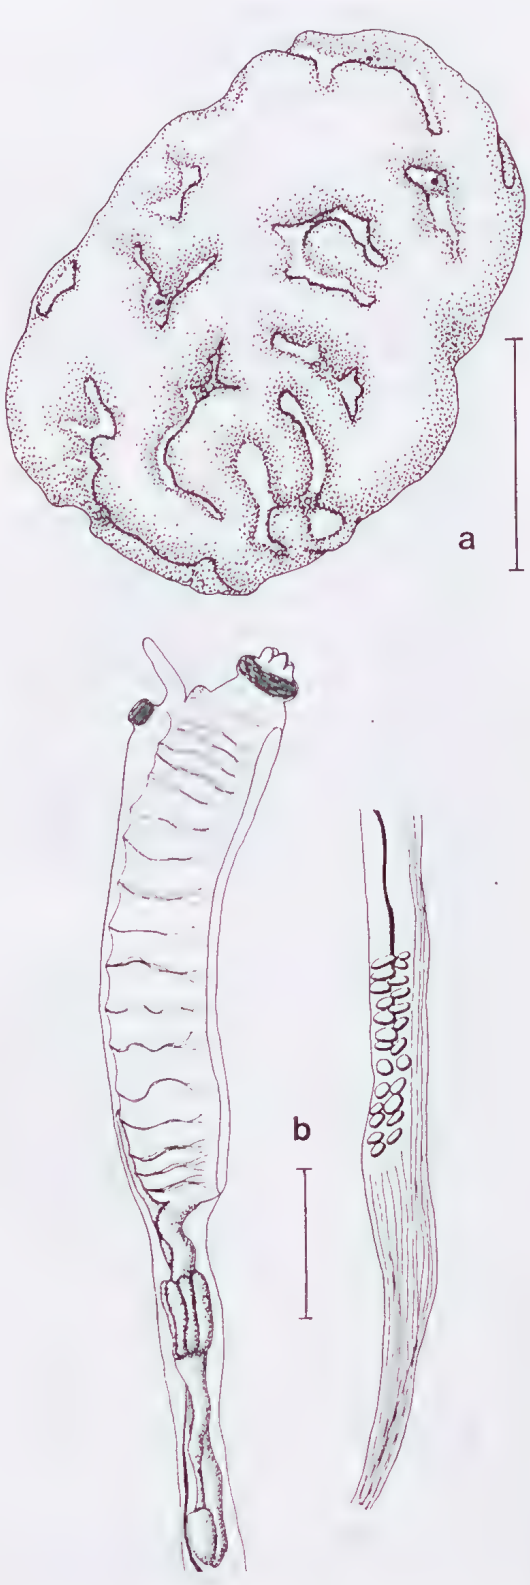

FIG. 71. *Aplidium crateriferum* — **a**, colony (QM GH5158); **b**, zooid (Heron I.). Scales: **a**, 2cm; **b**, 0.5mm.

tively thin surface test in the floor of each depression. Zooids surround each cloacal cavity, their branchial apertures at the base of the surface ridges, and protected by them. The atrial apertures are directed laterally to open into the cloacal cavity.

In some colonies a little sand is in the surface test around the apertures, but otherwise embedded sand is not present, and the surface is naked. In other colonies, sand is scattered throughout the test, amongst the zooids as well as in the zooid-free areas, and is on the external surface of the high ridges, although the surface of each depressed area is naked (QM GH5403).

Living colonies are said to be grey with red zooids, although photographs of specimens following their removal from the substrate are brown and yellow. In preservative the zooids, test and preservative are bluish-pink.

INTERNAL STRUCTURE: The zooids are long and thread-like, with the thorax (to 5mm) twice the length of the abdomen. The posterior abdomen is many times the length of the rest of the zooid. A long, conspicuous branchial siphon has a narrow bulging sphincter muscle at the top, near the base of the branchial lobes. This sphincter appears to have a blood sinus associated with it, and it is invariably pink and translucent.

There is a long pre-branchial area between the branchial tentacles and prepharyngeal groove and this effectively increases the length of the branchial siphon. The branchial tentacles cause a bulge about halfway down the siphon. Imperforate areas are anterior to the stigmata, and along each side of the endostyle. The atrial lip is usually a single pointed but quite fleshy lobe from the body wall anterior to the opening. The atrial aperture also has a sphincter muscle. About 15 fine longitudinal muscles are on the thorax and extend the whole length of the zooid. Fine transverse muscles are in the transverse vessels, but not in the parietal body wall. There are 18 to 21 short rows of up to 14 oval stigmata on the left and up to 10 on the right side of the branchial sac. The maximum number of stigmata (8 to 14) is in the fifth to eighth rows. Up to 4 more stigmata are on the left than the right. On the left the triangular dorsal languets are opposite the third to fourth stigmata i.e. almost halfway across the pharyngeal wall in the smaller, narrower zooids.

The short gut loop has the usual parts, with a slightly longer oesophagus than usual, and a relatively small stomach, with 5 distinct, deep folds in its wall. The posterior stomach also is short. Two conspicuous rectal caeca form a valve at the proximal end of the rectum. The posterior abdomen is long and thin. Two irregular longitudinal series of testis follicles are about halfway down it.

Single large embryos are in the thoraces of zooids collected in November, but not in May. The larvae are amongst the largest known for *Aplidium*, with the trunk 2mm long. The tail winds about three-quarters of the way around it. The long slender stalks of the 3 median adhesive organs are obscured by crowded epidermal vesicles which develop from the anterior part of the larval trunk.

REMARKS

The large, firm gelatinous colonies with surface depressions over the systems are one of the most conspicuous aspects of this species. The colonies are reminiscent of the colonies of *Lissoclinum patella* (see Kott 1980), *Synoicum castellatum* (see above) and *Aplidium clivosum*.

The sandy species *Aplidium caelestis*, with zooid openings protected by sand-filled swellings on the surface test, has similar narrow zooids with their atrial lip separate from the opening but they do not have the conspicuous surface depressions and circular systems of the present species.

The mostly temperate *Aplidium clivosum* also has similar zooids which open into deep surface depressions. However, it has zooids in double rows converging to the protruding common cloacal apertures, and fewer (14 to 18) rows of stigmata.

Sluiter's type specimen, from the Philippines, a large, fleshy mass, maximum dimension 10cm and up to 1.5cm thick with characteristic surface depressions and projecting cloacal apertures, closely resembles the present colonies. Millar (1975) describes similar colonies from this location. Other colonies from the type locality (Van Name 1918) are irregular with deep folds, but only shallow depressions, large systems with irregularly distributed zooids opening onto the flattened upper surface of the colony, and the surface thickly encrusted with foreign particles. These do not seem to be conspecific with the present species and are more like specimens of *Aplidium caelestis* (see below), which has similar zooids, but double row systems and embedded sand.

Tokioka's (1967) specimens from the Palau Is also appear to belong to some other species. They lack the characteristic surface depressions and the atrial lips extend from the upper rim of the opening rather than being separated from it as in the present species.

The narrow branchial sac, with wide bands of imperforate pharynx dorsally and ventrally is a characteristic of this species referred to by Sluiter (1909) in his description of the type. It should be noted that his figure of the branchial sac of the type (Sluiter 1909, pl.V7b) has been reversed — the larger number of stigmata and the dorsal languets are on the left, not on the right.

However, Sluiter appears to have overlooked the position of the atrial aperture and the sphincter muscles of both apertures, and miscounted the number of stomach folds (see Millar 1975). Sluiter has not always been accurate in his count of stomach folds (see *A. pantherinum*: Millar, 1962).

Aplidium depressum Sluiter, 1909
(Fig. 72)

Aplidium depressum Sluiter, 1909, p.102. Hartmeyer 1909, p.1499. Van Name, 1918, p.167. Kott, 1963, p.95. Kott and Goodbody, 1982, p. 515. **Not** Kott 1976, p. 60; 1981, p. 160.

DISTRIBUTION

NEW RECORDS: Queensland (Capricorn Group, QM GH890 GH916 GH2275 GH5680 GH5682 GH5690 GH5692 GH5693–702 GH5705–6).

PREVIOUSLY RECORDED: Queensland (Bargara — Kott 1963). Indonesia (Sluiter 1909; Van Name 1918). Hong Kong (QM G12796 Kott and Goodbody 1982).

These transparent, investing sheets, are probably more common than the records suggest. They are difficult to remove from the substrate and possibly are often overlooked by collectors.

DESCRIPTION

EXTERNAL APPEARANCE: Some colonies are thin, investing gelatinous sheets with a smooth upper surface, or they are irregular with the surface divided by shallow creases, or raised into convoluted ridges with common cloacal apertures along the ridges. One colony (QM GH5695) is a small cushion, trimmed to fit the back of a small crab on which it was found. In preservative, the small zooids are irregularly distributed and randomly oriented, usually lying at angles to one another. The test is translucent to glassy, firm and colourless. In life the zooids are maize yellow or orange to beige or pinkish beige, but they become white in preservative. *Prochloron* is found in the cloacal cavity and on the surface of some colonies (QM GH5682; see also Kott *et al.* 1984). Sand grains are sparsely scattered through the test, occasionally becoming crowded toward the base.

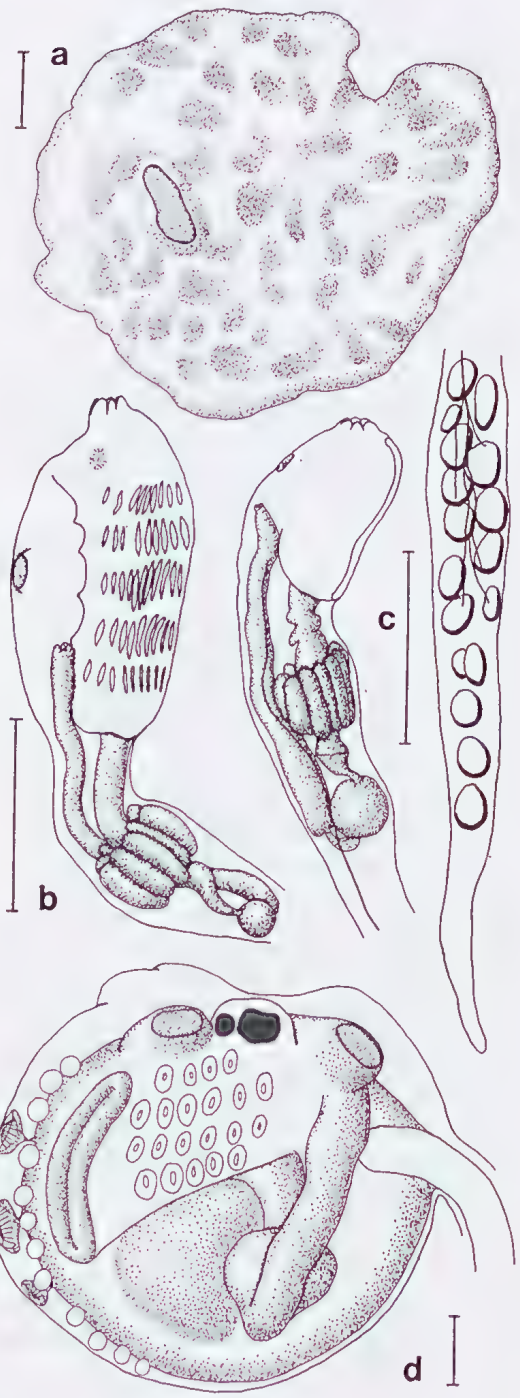

FIG. 72. *Aplidium depressum* — **a**, colony (QM GH890); **b**, **c**, thorax and abdomen, posterior abdomen separately (QM GH5697 QM GH5688); **d**, larval trunk (QM GH5693). Scales: **a**, 1mm; **b**, **c**, 0.5mm; **d**, 0.05mm.

Minute test cells appear as evenly spaced grains in the test.

INTERNAL STRUCTURE: Zooids are small, being no more than 3mm overall. The thorax and abdomen are of about equal length, and together are slightly shorter than the posterior abdomen which usually is relatively slender, tapering to its posterior end. The branchial aperture has 6 lobes. The atrial aperture is a single circular opening, sometimes on a short siphon, halfway down the thorax. There is no atrial lip. Stigmata are in 5 rows of up to 10, their length reducing at the dorsal end of each row.

The stomach wall has 11 distinct folds. A short thick duodenum and oval posterior stomach are in the post-pyloric part of the descending limb of the gut loop. The posterior abdomen is relatively short with a small ovary anterior to one or 2 rows of testis follicles. Up to 3 embryos are in the atrial cavity of colonies collected from Bargara in August and from the Capricorn Group from August to March (QM GH2276 GH5680 GH5683 GH5693–4 GH5702–3).

The larvae are amongst the smallest aplousobranch larvae known, with a spherical trunk only about 0.35mm in diameter. The greater part of the trunk is occupied by the developing adult organs — gut and pharynx. However, the cerebral vesicle is large in relation to the size of the trunk. A row of 7 or 8 epidermal vesicles is on each side of the median adhesive organs. Conspicuous test cells are in the surface of the larval test, tending to obscure the internal structure of the larva.

REMARKS

The principal characters of the present species are the transparent gelatinous test, the beige, yellow or pink zooids, the lack of an atrial lip, the 5 rows of stigmata, the relatively numerous stomach folds (12) and the minute spherical larval trunk.

The type specimen (Sluiter 1909) was gelatinous, with violet zooids seen through the test. Systems were not observed, although cloacal apertures were. The atrial siphon, without an atrial lip, is halfway down the thorax. Sluiter reported 9 rows of up to 14 stigmata in the branchial sac and numerous narrow folds in the stomach wall. Thus there is a discrepancy in the number of rows of stigmata and the colour between Sluiter's description and the newly examined material. There also is a discrepancy in the numbers of rows of stigmata in Van Name's (1918) specimens, with 6 or 7 rows of stigmata. Both Van Name and Sluiter may have had difficulty in determining the exact number of rows of stigmata in these small zooids, for most of the other characters conform with the newly recorded material. The ragged colony from Fiji (QM GH86) assigned to this species by Kott (1981), has been reexamined. It has, as reported, 8 rows of stigmata and a minute stomach with about 12 folds. There also is a narrow atrial lip from the upper border of the aperture which Kott overlooked. The colony is not conspecific with the present species. The colony (QM G12796) from Hong Kong (Kott and Goodbody 1982) appears to be correctly assigned.

Aplidium directum Kott, 1972
(Fig. 73)

Aplidium directum Kott, 1972c, p.246.

DISTRIBUTION

NEW RECORDS: Queensland (Dunwich, QM GH5517 GH5519; Cape Moreton, QM GH5614).

PREVIOUSLY RECORDED: New South Wales (Cronulla — AM Y1110–1 Kott 1972c).

The specimens are dredged from 6m to 140m from the sea floor.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are flat-topped, upright lobes, either separate or joined to a common base to form irregular, sandy masses up to 2.5cm high. The common base often is thin and keel-like and probably is buried in the substrate. Each separate lobe is about 1cm diameter, with a raised rim around its upper margin, surrounding a central depression containing a common cloacal aperture. Zooids are around the shallow common cloacal cavity beneath this depression.

Crowded sand particles are all over the surface of the colony and embedded throughout the test. Smaller sand grains only are on the surface in the terminal depression around the common cloacal aperture. In one extensive colony (QM GH5517) these smaller grains in the centre of each terminal lobe are black, apparently coal particles. Larger siliceous sand particles mixed with sparse black grains to give a grey colour are all over the remainder of the colony.

INTERNAL STRUCTURE: Zooids are thin and thread-like. The thorax and abdomen are of about equal length and together about 6mm. The branchial siphon has 6 distinct lobes. The atrial lip arises from the body wall just anterior to the aperture, which projects slightly on a short siphon

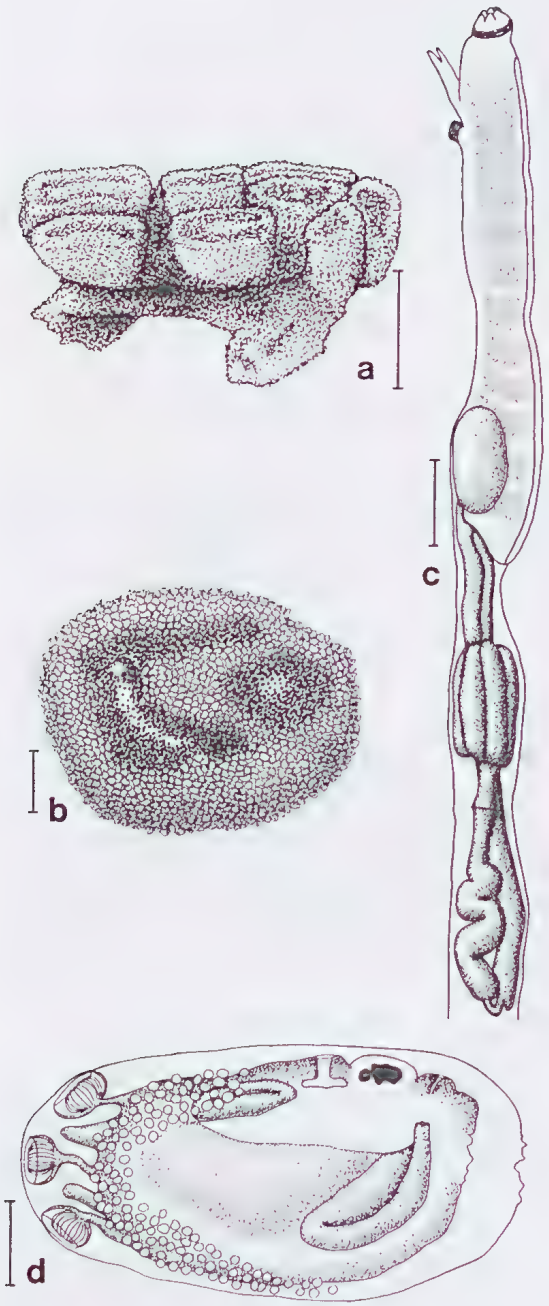

FIG. 73. *Aplidium directum* (QM GH5517) — **a**, colony; **b**, top of colony lobe showing depressions into which systems open with smaller grains of embedded sand; **c**, thorax, abdomen and embryo in atrial cavity; **d**, larval trunk. Scales: **a**, 1cm; **b**, 2mm; **c**, 0.5mm; **d**, 0.1mm.

with a sphincter muscle. The tip of the atrial lip is pointed or bidentate. There is a long unperforated band of pharyngeal wall both anterior and posterior to the perforated area. Short, wide stigmata are in 10 to 13 rows of up to 14 per row. The oesophagus is a narrow vertical tube. The stomach, also relatively long and narrow, has 5 well-defined folds. In extended zooids the post-pyloric part of the gut loop is relatively long. The descending limb has a long narrow duodenum and mid-intestine, but a relatively thick and slightly spiralling extent of gut in the lower one-third of the descending limb is in the position usually occupied by the short posterior stomach, well developed rectal caeca are at the proximal end of the rectum.

One or 2 embryos are in the posterior part of the atrial cavity in the material from Dunwich (collected in August), but not in the other specimen lot from Cape Moreton taken in the same month (QM GH5614). The larval trunk is about 0.5 to 0.6mm long. It has a conical median ampulla in each of the interspaces between the adhesive organs. An arc of epidermal vesicles is on each side of the median line around the anterior half of the larval trunk. The tail is wound about two-thirds of the way around the trunk. Ocellus and otolith are present.

REMARKS

The colony of this species resembles that of *Synoicum obscurum* and *Aplidium filiforme* n.sp. in the quantity of sand present, the size of the zooids, and the circular systems in lobes rising from the upper surface. *Aplidium filiforme* n.sp. is distinguished by having only 5 rows of stigmata a shorter branchial sac, a longer oesophagus, shallower stomach folds, 4 or 5 systems per colony lobe, and larvae without median ampullae.

The species is found in association with others superficially similar and sandy, viz. *Aplidium incubatum* n.sp., and *Botryllus stewartense* (see Kott 1985).

Larvae are not known from the New South Wales population — the type specimens of this species. However the similar morphology of these and the material from Moreton Bay indicate that they are conspecific.

Aplidium distaplium n.sp.
(Fig. 74)

DISTRIBUTION

TYPE LOCALITY: Victoria (Bass Strait, off Ninety Mile Beach, 10 km SW Seaspray, 560m off shore, calce-

narite reef 12m, fast currents, coll. J.E. Watson 21.3.80, holotype QM G12728; paratype QM G12729).
FURTHER RECORD: South Australia (Reevesby I., QM GH5602).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are solid, sandy irregular masses. Sand is crowded throughout, obscuring the small zooids and their arrangement. Zooids are tightly enclosed in the sandy test.

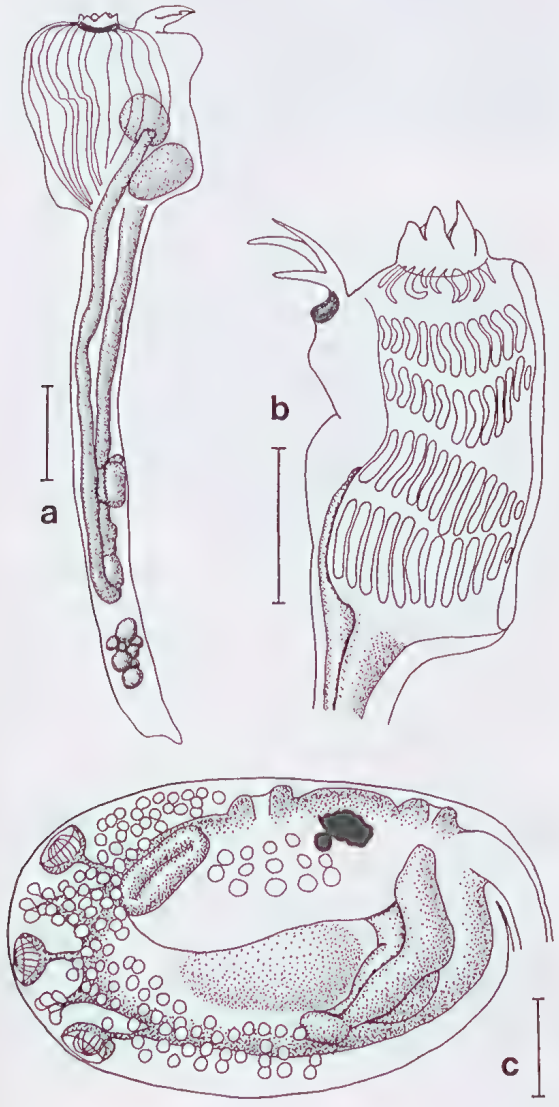

FIG. 74. *Aplidium distaplium* n.sp. — **a**, zooid, showing small posterior abdomen, long oesophagus (holotype QM G12728); **b**, thorax (paratype QM G12729); **c**, larval trunk (holotype QM G12728). Scales: **a**, **b**, 0.5mm; **c**, 0.1mm.

INTERNAL STRUCTURE: Zooids are minute, the thorax, abdomen and posterior abdomen together being about 4mm long, of which the abdomen is about half the length, the thorax and posterior abdomen being relatively short. The 6 branchial lobes are triangular and the siphon is short. A flat atrial tongue, undivided, bi-, or tripartite, extends out from the upper rim of the small aperture. About 15 muscle bands extend from the thorax, although they are fine, and the zooid is delicate.

Stigmata are in 4 rows of 12, and these rows are arranged in 2 pairs as in *Sycozoa* (see Kott 1990). The oesophagus is an unusually long vertical tube, and the 5-folded stomach is in the posterior half of the abdomen. The post-pyloric part of the descending limb of the gut loop (with the usual duodenum, mid-intestine and posterior stomach) is not as long as the oesophagus.

Sometimes the posterior abdomen is short, with only an ovary developed. In the male phase it is longer, with a double row of male follicles.

Embryos (up to 4) are incubated in the atrial cavity. The larval trunk is 0.52mm long. A large conical median ampullae with epidermal vesicles branching off it is in each interspace between the adhesive organs. Also there is a median dorsal ampulla and a ventral one. Epidermal vesicles are also scattered in an arc in the test around the anterior half of the trunk on each side. The tail is wound about three-quarters of the way around the trunk on each side of the median line.

REMARKS

The species resembles *A. solidum* in its solid hard sandy colony, although the larval trunk of the present species is longer. The presence of 4 rows of stigmata rather than 5, is unusual in this genus. In the related genus *Synoicum* only *S. bowerbanki* has a similar number of rows of stigmata (see above).

Aplidium elatum Kott, 1972

Aplidium elatum Kott, 1972b, p.177

DISTRIBUTION
NEW RECORDS: None.
PREVIOUSLY RECORDED: South Australia (Elliston Bay — SAM E905 E906 Kott 1972b).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies form tall, undulating fan-shaped lamellae, 1cm thick to 6cm high. Sand is present throughout, and the colony is hard. Common cloacal apertures are randomly

distributed over the surface and zooids are along each side of the cloacal canals converging to them. The surface test is raised slightly over the anterior ends of each of the zooids.

INTERNAL STRUCTURE: The anterior part of thoraces and the endostyles are orange in preservative. Zooids are about 3mm long, the thorax and posterior abdomen approximately equal in length and slightly longer than the abdomen. The branchial lobes are sharply pointed. The atrial aperture, opposite the fourth to sixth row of stigmata has a large lip divided into 3 large, muscular, leaf-like lobes from its anterior rim. The muscles in the atrial lip are longitudinal, extending down the centre of each lobe. About 12 longitudinal thoracic muscles extend posteriorly in 2 bands along each side of the zooid. Stigmata are in 8 rows of about 8. The stomach is short with about 15 longitudinal folds. The usual duodenum and mid-intestine interrupted by a posterior stomach comprise the post-pyloric part of the descending limb of the gut loop. Gonads are in 2 series in the posterior abdomen. Larvae are not known.

REMARKS

The sandy colonies of this species resemble those of *A. petrosum* n.sp. and *A. solidum*, although they are neither as branched, nor as extensive. The zooids, with their large atrial lips from the upper border of the opening, and 15 stomach folds resemble *A. opacum*, as does their arrangement in double rows of zooids converging to the common cloacal apertures.

Aplidium filiforme n.sp.
(Fig. 75)

Aplidium thomsoni: Kott, 1963, p.97 (part, specimens from Cockburn Sound). **Not** *A. thomsoni* Brewin 1950a.

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I. Blue Pools, coll. D. Parry 9.11.86, holotype QM GH5527; 9.11.85, paratype QM GH5528).

FURTHER RECORDS: Western Australia (Cockburn Sound — Kott 1963). Queensland (Capricorn Group, QM GH5511 GH5515 GH5523 GH5554–5).

DESCRIPTION

EXTERNAL APPEARANCE: The colony consists of upright, flat-topped sandy lobes that rise from the surface of a common basal mass, and aggregate together along their length through the sand attached to the surface test. They form a sandy platform up to 4cm in maximum dimension and about 1cm high. Groups of 4 or 5 systems open onto the upper surface of each lobe. In some colonies the tops of a number of lobes seem to fuse to form a cushion-like platform, with crowded systems opening on its upper surface. Each system consists of a wide, sessile cloacal aperture in the centre surrounded by branchial apertures obscured by the sand which is embedded in the test. Sand is not always present around the cloacal openings. The systems are usually quite conspicuous, even when sand is present on the upper surface, for the branchial apertures have small sand particles outlining them, while large sand grains are embedded around the outside of each system and in the centre around the common cloacal aperture. Living zooids have orange thoraces.

INTERNAL STRUCTURE: The zooids are minute, thread-like, about 0.3mm thick and about 7mm long. The thorax and abdomen together are about 3mm long and the posterior abdomen is at least twice that length. The branchial siphon is short although the branchial sphincter is large, bulging and conspicuous. The atrial aperture, with a short, stumpy tripartite lobe from the upper rim of the opening, is antero-dorsal. The 5 rows of stigmata have no more than 6 per row, although these could not be counted accurately. The oesophageal neck is longer than the post-pyloric part of the gut loop. The stomach has 5 distinct folds.

Ovary and testis are not mature in the one zooid at the same time. The ovary, when present, is a short distance from the posterior end of the gut loop — in the middle of the anterior third of the posterior abdomen. When the testis follicles are mature they are in a single row in the middle third of the posterior abdomen.

In the holotype colony 3 embryos are lined up in the atrial cavity. The most anterior of these is a tailed larva. The trunk length is surprisingly variable being 0.32 to 0.6mm. The adhesive organs are in the anterior mid-line. Epidermal vesicles, scattered 2 or 3 deep, in a long narrow arc along each side of the median line, branch off common stalks. Median vesicles also branch off one or 2 common stalks in each interspace between the adhesive organs. The arc of lateral vesicles extends well postero-ventrally and postero-dorsally.

REMARKS

This species, with its unusual lobed colony, small zooids with 5 rows of stigmata, 5 stomach folds, orange thorax and colourless abdomen and

posterior abdomen resembles *Aplidium mernooensis* (Brewin, 1956) from Chatham I., New Zealand and one colony from New Caledonia (Monniot 1987). Like the type, the specimens from New Caledonia have single systems of zooids in each lobe of the colony, and 8 branchial lobes. Although Brewin records the height off the substrate of *A. mernooensis* as only 2mm, its zooids are said to be 8mm long. Thus it appears that the base of the colony was embedded in the

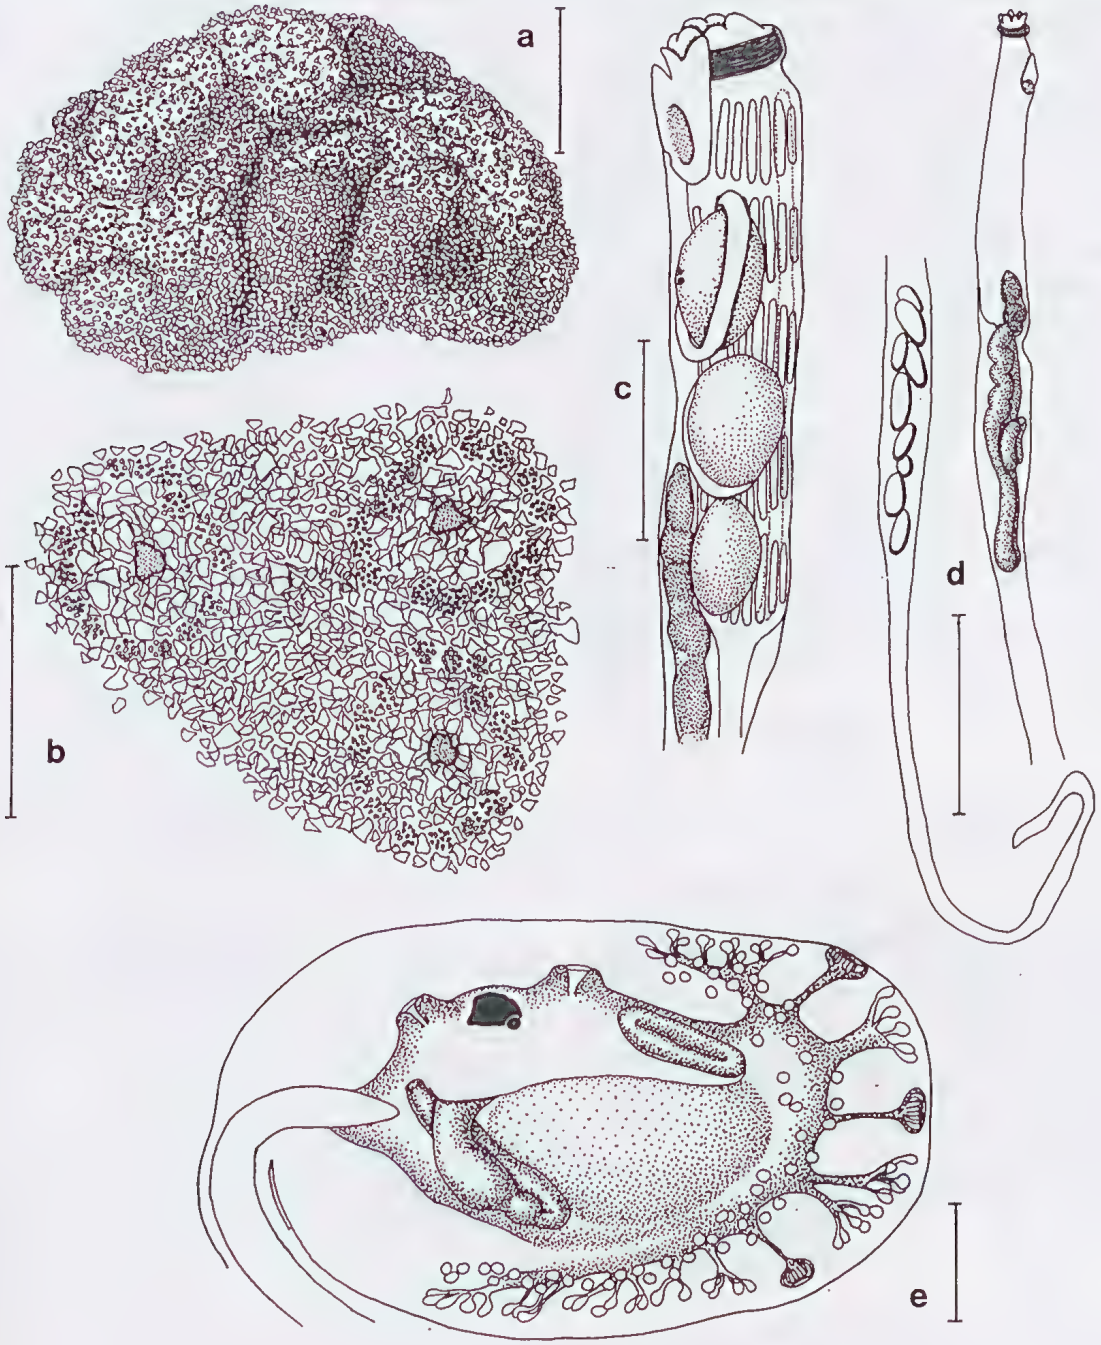

FIG. 75. *Aplidium filiforme* n.sp. — **a**, whole colony (QM GH5523); **b**, upper surface of colony lobes showing systems (QM GH5515); **c**, thorax with embryos in atrial cavity (QM GH5515); **d**, outline of whole zooid (QM GH5515); **e**, larval trunk (QM GH5555). Scales: **a**, 1cm; **b**, 5mm; **c**, 0.5mm; **d**, 1mm; **e**, 0.1mm.

substrate, and that it is much the same size as the present species. However, the present species has more than one system per colony lobe to distinguish it, and although *A. mernooensis* has sand externally, it lacks the embedded sand of *A. filiforme*. There also are more numerous stigmata in the Chatham I. colonies than in *A. filiforme*. Larvae from the New Caledonian colony (*A. mernooensis*: Monniot, 1987) have a trunk 0.65mm long with a wide lateral band of vesicles obscuring the anterior end of the trunk similar to the vesicles in *A. caelestis*, *A. clivosum*, *A. craterif-erum*, and *A. griseum* n.sp. The vesicles in the narrow lateral arc of the present species are less numerous and are spread over a smaller area at the anterior end of the trunk.

The large bulging branchial siphon known in *A. crateriferum* and *A. clivosum* is an unusual character not usually present in species with zooids as small as those in the present species. Monniot (1987) records a strong branchial spincter in the New Caledonian specimen. The larvae and zooids of the present species are among the smallest known in the genus.

Aplidium bacculum also has only 5 rows of stigmata, but its terminal heads, onto which zooids open, are naked, its systems less regular, its stalks longer and the oesophagus about two-thirds of the length of the abdomen.

Aplidium fluorescum n.sp.
(Fig. 76)

Aplidium multiplicatum: Kott, 1963, p.103 (part specimen from Sarina).

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I., NE Point, rubble fauna, low tide, coll. P. Kott 4.5.85, holotype QM GH5243; Heron I., NE reef, rubble fauna, coll. P. Kott 14.11.85, paratypes QM GH5244; coll. P. Kott May 1987, paratypes QM GH5245; NE Heron reef, coll. P. Kott 2.11.86, paratypes QM GH5246; Heron I., The Canyons, coll. P. Kott 13.11.85, paratypes QM GH5247).

FURTHER RECORDS: Queensland (Sarina, AM Y1448; Lizard I, QM GH5630; Capricorn Group, QM GH5318–24).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are small, rounded to dome-shaped cushions, to about 1cm in maximum thickness. Only the colony from Sarina (AM Y1448) forms extensive investing sheets. Living test is translucent, or opaque-whitish, with green fluorescent particles around the branchial apertures and in the surface test. These particles give an azure-blue sheen to the colony. Zooids are 'buff pink', or 'maize yellow' (Ridgeway 1886), or pinkish white, with an orange stomach. In preservative the zooids are beige to white and the test is almost opaque, or translucent to glassy. One of the living specimens (holotype) was described as a 'translucent fluorescent potato'.

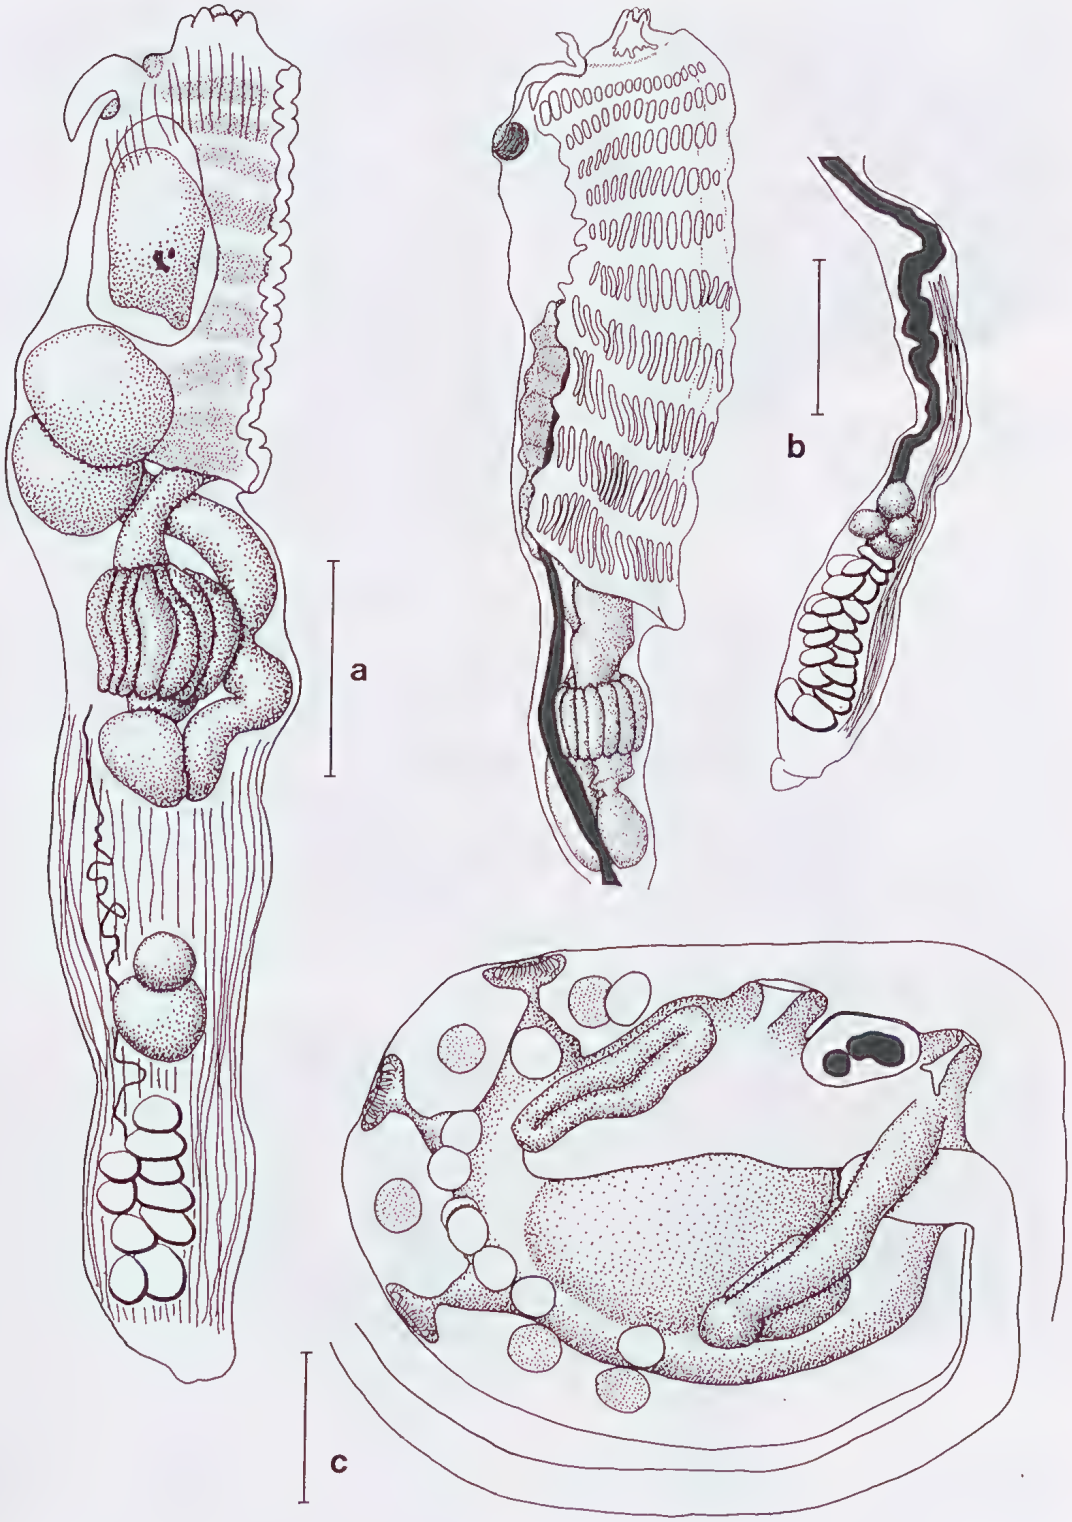
The test is firm and naked, and there is neither adherent nor embedded sand. The systems are circular, although often they are obscure in preserved specimens, with the zooids lying at various angles to one another in the firm test.

INTERNAL STRUCTURE: Zooids are about 6mm long when relaxed, the thorax and posterior abdomen of about equal length and the abdomen only a fifth of the total length. The branchial lobes are small and pointed and the branchial aperture almost sessile. The small and undivided atrial tongue arises from the upper border of the opening, which has a sphincter muscle. Fifteen to 20 longitudinal muscle bands are on each side of the thorax, and extend the length of the zooid, evenly spaced around it rather than forming a band on each side of the abdomen and posterior abdomen. The branchial sac has 10 rows of up to 16 stigmata. The moderately long stomach has 12 to 14 deep folds in its wall. The duodenum and proximal sections of the mid-intestine are wide, the latter being only slightly constricted from the oval posterior stomach.

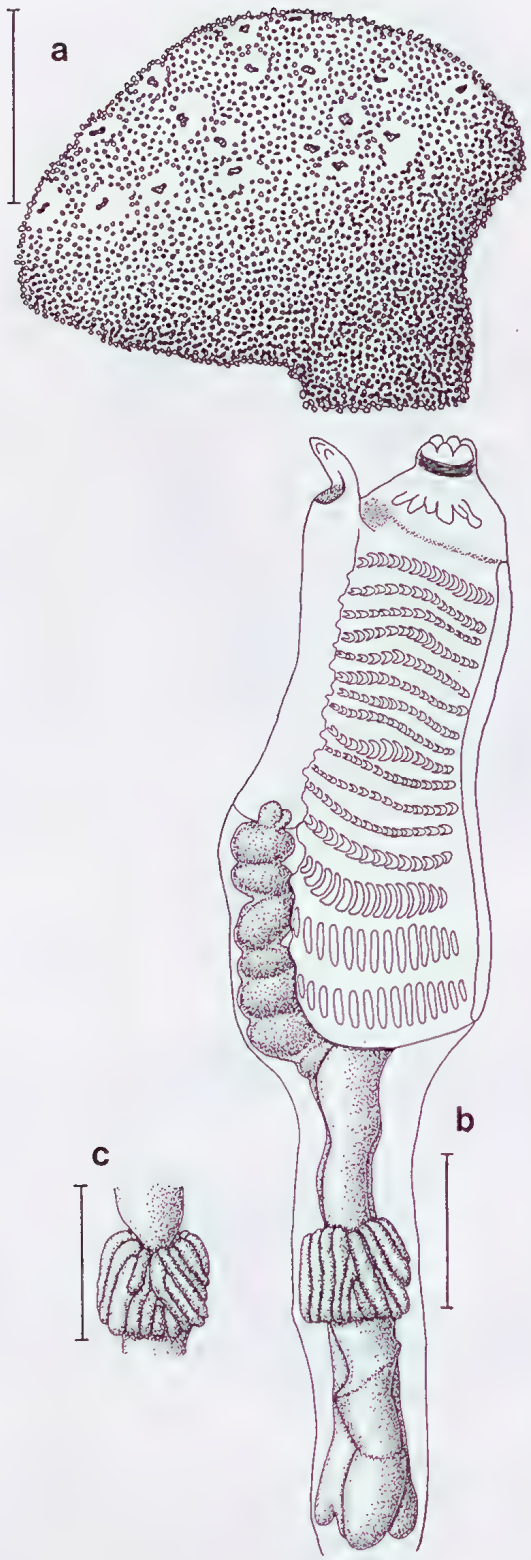
Gonads are absent from the anterior half of the posterior abdomen, which is relatively short and thick and only occasionally larger than the thorax. The ovary is about halfway down the posterior abdomen, with the testis follicles in 2 irregular series posterior to it.

With only one exception (May 1987) the colonies from the Capricorn Group, all collected in April, May, August and November, have zooids with 2 or 3 embryos lined up in the atrial cavity. The larvae are small, the trunk being about 0.5mm long. They have the tail wound slightly more than halfway around the trunk. An ocellus and an otolith are present in the cerebral vesicle. There are 3 median adhesive organs on narrow stalks at the anterior end of the trunk, and up to 9 particu-

FIG. 76. *Aplidium fluorescum* n.sp. — **a**, **b**, zooids (paratypes QM GH5247 GH5244); **c**, larva (paratype QM GH5247). Scales: **a**, **b**, 0.5mm; **c**, 0.1mm.



a
b
c



larly large, spherical ectodermal vesicles separate from the lateral line on each side. Up to 3 embryos are in the Sarina specimens collected in August. Their larvae differ from the Capricorn Group ones only in having one more (total 10) epidermal vesicles in each of the lateral arcs. Ectodermal ampullae are never present.

REMARKS

The species is distinguished from others with naked colonies by its small zooids with the small atrial lip from the anterior rim of the opening and by the number of stomach folds and rows of stigmata. *Aplidium gelasinum* n.sp. is distinguished by its narrow thorax with only 8 stigmata per row. Its small larvae are also distinctive, and although similar ectodermal vesicles occur in other species (e.g. *A. multiplicatum*), there are fewer in the present species than in any others known.

Aplidium gastrolineatum n.sp.
(Fig. 77)

Aplidium flavolineatum: Kott, 1972b, p.177 (part, specimen from Waldegrave I.).

DISTRIBUTION

TYPE LOCALITY: South Australia (1km NW of Waldegrave I., Anxious Bay, 33°33'S, 134°46'E, rocky bottom, slow current, 23m, coll. S. Shepherd 11.5.71, holotype SAM E2584).

FURTHER RECORDS: South Australia (Pearson I. QM GH1292; Flinders I., QM GH2305).

DISTRIBUTION

EXTERNAL APPEARANCE: The holotype colony is an almost spherical cushion, 2.5cm diameter and 2cm high. It is fixed basally by a relatively broad sandy area. A thick layer of sand is present around the outer surface, being absent only from the circular depressed areas into which the systems open. Protruding common cloacal apertures are in the centre of each of these depressions. Zooids are in circles around each common cloacal aperture. The colony from Pearson I. lacks sand on the upper surface although it is present around the sides and base. It has the same circular systems and protuberant cloacal apertures. Sand is not embedded internally. The test is soft, white and translucent, and both colonies are distorted.

FIG. 77. *Aplidium gastrolineatum* n.sp. (holotype SAM E2584) — **a**, colony; **b**, thorax and abdomen; **c**, stomach from the left side. Scales: **a**, 1cm; **b**, 0.5mm; **c**, 0.5mm.

The zooids are tightly embedded in the test and a sheath of it, containing white opaque cells, clings to the zooids when they are removed. The living colonies are described as having a pink matrix with white zooids.

INTERNAL STRUCTURE: The zooids are robust, and the thorax and abdomen together are about 4mm long. The relaxed thorax is longer than the abdomen. The 10 fine longitudinal muscle bands on the thorax extend the length of the zooid in a wide band on each side. The 6 rounded branchial lobes are distinct. The atrial lip extends out from the upper rim of the aperture at the anterior end of the dorsal surface. It is thick and fleshy, with its tip divided into 3 rounded lobes. The stigmata are in 16 rows of up to 14. The stomach is relatively small, its diameter not markedly greater than that of the duodenum. Its wall has 24 mostly oblique folds. The stomach wall is more or less divided into 4 quarters with the folds in each quarter running obliquely to meet those of the adjacent quarters dorsally and ventrally, and in the middle of the mesial and lateral aspects. Three folds on the left side of the mid-dorsal line of the stomach, and 3 on the right of the mid-dorsal line do not reach the posterior end of the stomach, and further oblique folds in the middle of each side do not reach the anterior end. The duodenum and proximal end of the mid-intestine are wide. Rectal caeca are at the proximal end of the rectum.

Larvae are present in South Australian specimens collected in October (Kott 1972b, p.174 Fig. 30). They have a larval trunk 0.8mm long, and median and lateral ampullae between the adhesive organs. They lack epidermal vesicles.

REMARKS

The naked circular depressions each with a central protruding cloacal aperture, into which the systems open, are reminiscent of the surface of *Aplidium lunacratum* nom. nov. However, the latter species has only 5 stomach folds, and its atrial lip arises from the body wall anterior to the aperture, rather than from its anterior rim.

Aplidium incubatum n.sp. from Queensland also has circular systems opening into conspicuously naked surface areas. However, it has the surface of the colony partially divided, each division containing a system, and it has parallel longitudinal stomach folds.

Kott (1963, 1972a–c, 1975) erroneously assigned various specimens to the South African species *A. flavolineatum* Sluiter, 1898 on the basis of the number of gastric folds. Re-examination of these specimens has shown that they have other characters which distinguish them from one another, and from the African species (see *A. multilineatum* n.sp., *A. robustum* n.sp., *A. multiplicatum*, *A. uteute* and the present species). The present species is distinguished from the African *A. flavolineatum* by its oblique stomach folds and more numerous rows of stigmata. *Aplidium robustum* n.sp., which has similar numbers of stigmata and stomach folds, has more crowded systems and sessile cloacal apertures.

Aplidium gelasinum n.sp.
(Fig. 78)

DISTRIBUTION

TYPE LOCALITY: Queensland (far Northern Great Barrier Reef, Tydeman Reef, coll. AIMS Bioactivity Group 23.4.87 Q66 B2089, holotype QM GH5333).

FURTHER RECORDS: None.

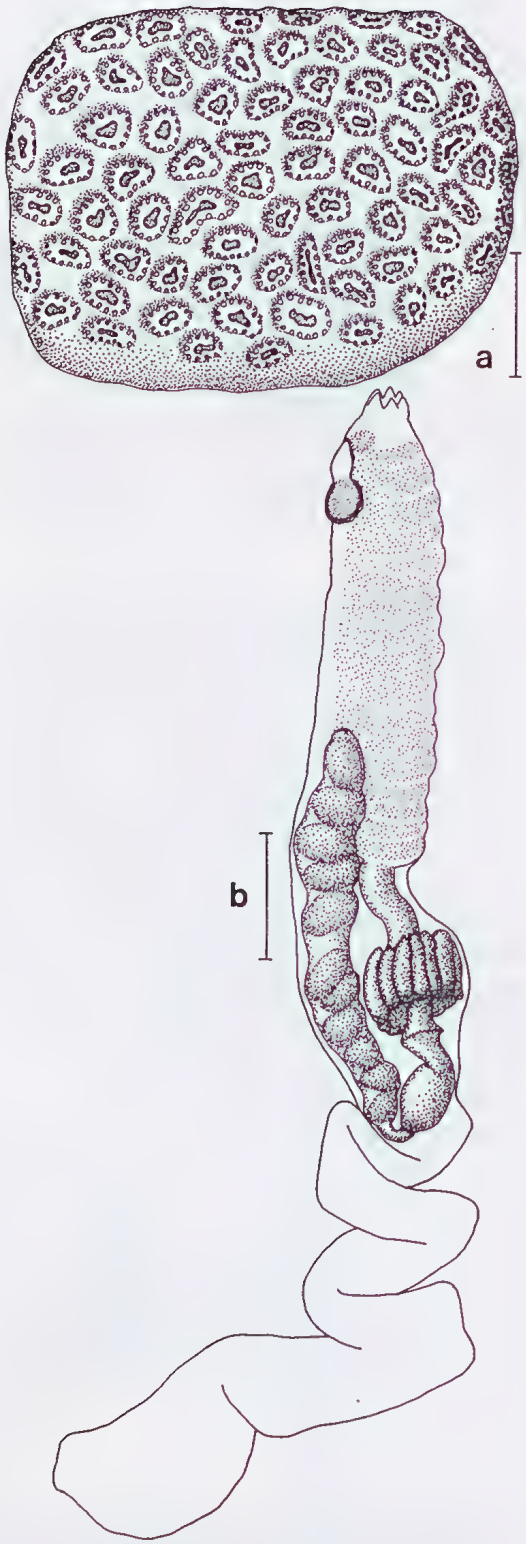
DESCRIPTION

EXTERNAL APPEARANCE: The colony is a flat-topped cushion; 7cm in maximum dimension and 1cm high. In preservative, it has a white opaque deposit in the surface test, which emphasises the circular zooid systems, being more opaque around the outside of each system where the surface is raised into a rounded rim and the test is thicker — not being interrupted by either zooids or cloacal cavity. Each system is about 3mm diameter. The cloacal cavity is circular with a central protuberant aperture. White deposit is concentrated in the surface layer of test. Internally the test is gelatinous and translucent. The zooids are firmly embedded and the sheath of test immediately surrounding each contains opaque, white cells. The specimen is reported to have been orange with orange zooids in life.

INTERNAL STRUCTURE: The zooids have a long posterior abdomen, although the thorax and abdomen together are only about 3mm. The atrial lip, from the upper rim of the opening, has from one to 3 points. Stigmata are in 16 rows of only about 8 per row. The small, relatively short stomach has 16 to 18 longitudinal parallel folds. Duodenum, mid-intestine and posterior stomach are of the usual form. When contracted the posterior abdomen is pulled up into a coil behind the abdomen. Gonads are not mature in this specimen, and larvae are not known.

REMARKS

Superficially, the regular circular systems in this opaque, white colony resemble *Distaplia prolifera* Kott, 1990 and *Morchellium pannosum*.



The crowded small, regular circular systems also resemble those of *A. lunacratum* nom. nov., although the latter species is distinguished by its external layer of sand between the systems and its fewer stomach folds. *Aplidium protectans* has circular systems, but 8 branchial lobes, more numerous rows of stigmata, and fewer stomach folds. *Aplidium fluorescum* and *A. uteute* have naked cushion-like colonies with circular systems, and numerous stomach folds like the present species. However they are softer colonies, have more stigmata per row and lack the surface depressions of the present species.

Aplidium geminatum n.sp.
(Fig. 79)

Aplidium australiensis Kott, 1963, p.111 (part, specimens from Port Lincoln and Western Port).

DISTRIBUTION

TYPE LOCALITY: South Australia (Price I., Avoid Bay, coll. S. Shepherd 9.4.87, holotype QM GH4175; Port Bonython jetty, 6m, coll. G.A. Powell, paratype QM GH4229).

FURTHER RECORDS: Tasmania (Bass Strait, SAM E2593); South Australia (Port Lincoln — Kott 1963); Victoria (Westernport — AM U3914 Kott 1963).

Although other records are from relatively shallow water, the specimen from Bass Strait is from 92m.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies consist of spherical to oval heads (3 to 6cm diameter), each on a thick, sandy stalk, occurring singly or in clumps. Long, more or less parallel, sometimes branching cloacal canals are along the sides of the heads. Zooids are arranged in double rows, a row along each side of the canal. The canals open to a number of large cloacal openings around the upper margin of the head, or to a few terminal apertures. A wide zooid-free strip of test is between adjacent double rows of zooids. A layer of sand is present on the outer surface of the colony, including the stalk. It is absent only from a bare area around the cloacal apertures on the top of the head. Sand is not present internally. The contracted, preserved colonies have a conspicuously transversely wrinkled sandy stalk.

FIG. 78. *Aplidium gelasinum* n.sp. (holotype QM GH5333) — a, colony from upper surface; b, zooid. Scales: a, 1cm; b, 0.5mm.

The anterior ends of the zooids are perpendicular to the surface, but the posterior ends curve down into the stalk and cross one another.

INTERNAL STRUCTURE: Zooids are robust, the thorax and abdomen together being about 3mm long when contracted. The posterior abdomen is longer and varies in length. About 12 longitudinal thoracic muscles extend posteriorly, forming a wide band along each side of the abdomen and posterior abdomen. The 6-lobed branchial siphon is short. The atrial aperture is a conspicuous, anteriorly oriented opening with a large, conspicuous atrial lip, deeply divided into 3 long pointed lobes, produced from the upper rim of the aperture. In some zooids 5 or 6 conical points project from the body wall in a transverse row just behind the atrial aperture. Longitudinal thoracic muscles lie between these projections.

Fifteen rows of 10 to 12 large, oval stigmata are present in the wide pharynx. The relatively long barrel-shaped stomach has 20 to 23 parallel longitudinal folds. The duodenal area is relatively long and roomy, and an oval posterior stomach is in the descending limb of the gut loop near its bend.

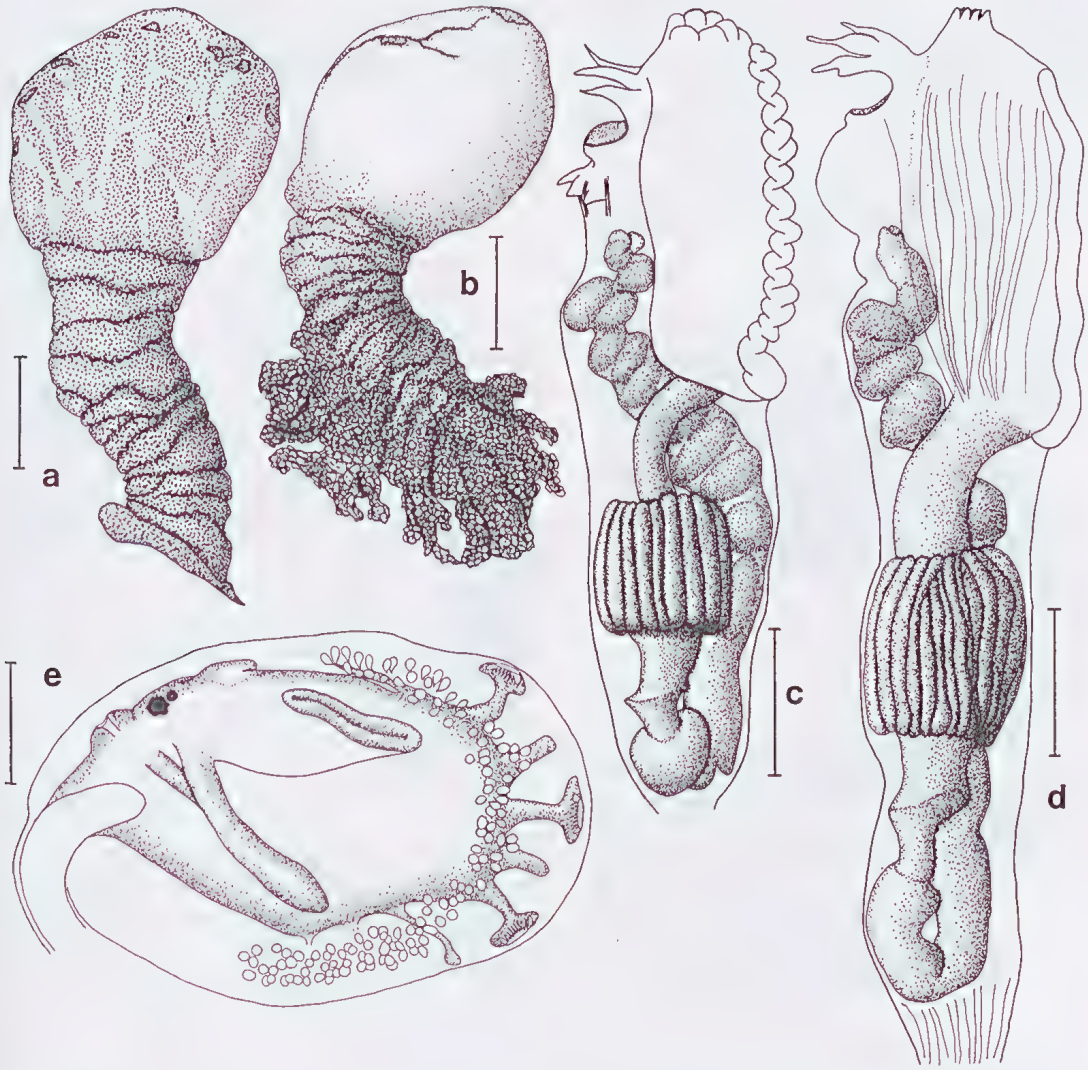


FIG. 79. *Aplidium geminatum* — **a**, **b**, colonies both showing thick sandy transversely wrinkled stalk (**a**, QM GH4175, indicating arrangement of zooids in vertical rows with a number of terminal cloacal apertures; **b**, SAM E2593 with 2 terminal cloacal apertures); **c**, **d**, thorax and abdomen (**c**, SAM E2593 showing transverse row of dorsal papillae; **d**, QM GH4175); **e**, larval trunk (AM specimen from Port Lincoln). Scales: **a**, **b**, 1cm; **c**, **d**, 0.5mm; **e**, 0.2mm.

Gonads are in the long posterior abdomen. Larvae are not present in the newly recorded specimens taken in February and April. However, they are present in the type material collected in September and November (see Kott 1963). The larval trunk is 0.9mm long with a band of numerous epidermal vesicles from the antero-lateral ridges along each side of the 3 median adhesive organs and the median ampullae that alternate with them.

REMARKS

The stalked colonies with parallel, double row systems down each side resemble *Sycozoa* and some *Distaplia* species (e.g. *D. australiensis*). Amongst *Aplidium* the species has some characters it shares with *A. australiense* and *A. brevilarvacium*, notably the stalked colonies with double row systems converging to relatively few common cloacal apertures. Of these two species, *A. brevilarvacium*, with its common cloacal aperture on the upper surface of the head, and relatively few cloacal canals, most closely resembles the present species. However, the zooids of both *A. australiense* and *A. brevilarvacium* are smaller than in the present species and they have fewer stomach folds, and fewer stigmata. There are other differences in the size and shape of the colonies (see species descriptions below). A conspicuous character of the present species is the large atrial lip with its 3 long pointed lobes.

The protruding dorsal papillae in a transverse row behind the atrial aperture are at the level of, and may be homologous with, the dorsal median papillae present in species of *Polyclinum* and *Synoicum*.

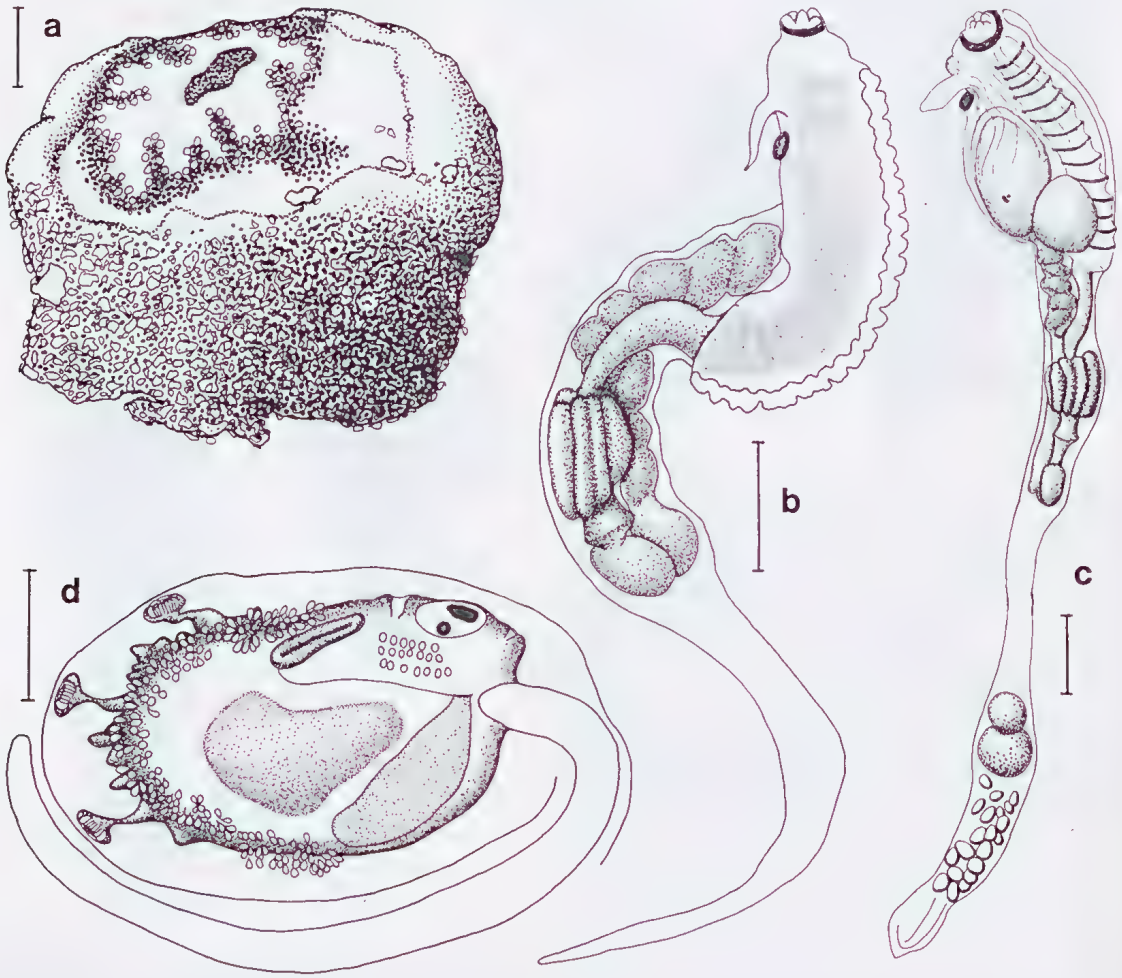

FIG. 80. *Aplidium griseum* n.sp. — **a**, colony (QM GH5171); **b**, **c**, zooids (holotype QM GH5212 GH5172); **d**, larva (QM GH5213). Scales: **a**, 2mm; **b**, **c**, 0.5mm; **d**, 0.2mm.

The larvae resemble those of *Aplidium opacum* with a band of numerous epidermal vesicles along each side of the median adhesive organs, similar numbers of stomach folds, and a similar large atrial lip. The form of the colonies and systems differ from those of the present species, and the zooids have fewer rows of stigmata.

Aplidium griseum n.sp.
(Fig. 80)

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I., under rubble, near reef edge, low tide, coll. P. Kott May 1985, holotype QM GH5212; May 1985, 1987, paratypes QM GH5214 GH5215).

FURTHER RECORDS: Queensland (Capricorn Group, QM GH5171–3 GH5213 GH5216–7 GH5529–31 GH5613 GH5668).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are small, upright (to 1.0cm high), almost cylindrical (to 1cm diameter), flat-topped lobes. Embedded sand is crowded in the lower half of the lobe and becomes less crowded in the top half. Sand is present also on a ridge around the periphery of the upper surface of each lobe, and is crowded into a line around each system where the branchial apertures open at the base of marginal ridges. As well as the peripheral ridge around the upper surface of each lobe the marginal ridges are on the upper surface separating the systems from one another. The thin threadlike zooids are in irregular or circular systems around 2 or 3 sessile common cloacal apertures on the upper surface of each lobe. Radial extensions from the peripheral test extend in toward the centre of a system and have zooids along each side. The regular circles of zooids are thus interrupted and the number of zooids in a system is increased.

Living colonies are 'Indian-', or 'prune purple' to 'blackish' or 'light translucent lavender', or 'Prouts brown' externally and 'poppy red' internally. Zooids are 'vermilion' (see Ridgeway 1886). In life, red pigment in the atrial lips can be seen through the translucent test. The preservative sometimes is stained reddish-orange. Brown spherical cells are in the test of preserved specimens.

INTERNAL STRUCTURE: The delicate zooids have fine longitudinal muscles extending their whole length. The branchial lobes are rounded and petal-shaped. The atrial lip from the body wall anterior to the small rounded aperture is narrow and pointed. Opaque brown pigment particles are around the zooid openings and along the endostyle. These particles probably cause the red colour in the living zooids. The thorax, is longer than the abdomen with 13 rows of up to 16 stigmata per row. The small stomach in the middle of the abdomen has 8 or 9 deep folds in its wall. Of these 2 or 3 do not extend the whole length of the stomach. Caeca at the proximal end of the rectum form a rectal valve.

The posterior abdomen is long and thin, with an anterior ovary and double row of male follicles in its posterior two-thirds.

In specimens collected in May, a tailed larva and a second less advanced embryo are in the atrial cavity. The larval trunk is 0.85mm long, with small, pointed median ampullae in each interspace between the 3 adhesive organs. The whole anterior end of the trunk is obscured by an arc of scattered epidermal vesicles in the larval test along each side of the mid-line.

REMARKS

The species is distinguished by its upright colonies, small stomach with 8 folds in the stomach wall, relatively wide thoraces with numerous (16) stigmata per row, and delicate musculature in the body wall.

Incomplete stomach folds that do not extend the full length of the stomach are known in other species of this genus e.g. *Aplidium multipapillatum* Millar, 1975. The latter species also has a similar number of stigmata in each row, but it has more stomach folds than the present species. Colonies resemble those of *Aplidium craterif-erum* and *A. clivosum*, with systems opening into depressions on the surface of the robust colonies. However, the present species has more stomach folds.

The larva is like that of *Aplidium ritteri* with scattered vesicles around the anterior end, although the trunk of the present species is larger.

Aplidium incubatum n.sp.
(Fig. 81)

DISTRIBUTION

TYPE LOCALITY: Queensland (Point Lookout, in crevices on rocky platform, high tide, coll. P. Kott 12.5.87, holotype QM GH5309; paratypes QM GH5310).

FURTHER RECORDS: Queensland (Point Lookout, QM GH5311–2; Cape Moreton, QM GH5615).

The records are from 0 to 10m, from rocky substrates.

DESCRIPTION

EXTERNAL APPEARANCE: The colonies vary in shape from extensive plates up to 2cm in maximum diameter to upright mushroom-shaped more or less flat-topped lobes (up to 1cm high). Sometimes the base of the colony is drawn out into a long, flattened extension which fits into narrow crevices and sometimes narrow stolons join the separate lobes of a colony to one another, or function as root-like processes fixing the colony in the substrate. Small circular systems of up to 10 zooids, and 5mm diameter are crowded in the colony and open on the upper surface. Large, sessile common cloacal apertures are in the centre of each system. The test above the systems is naked, pinkish-white and translucent. Sometimes sand is on the surface test separating single, or groups of, systems from one another.

Sand also is present on the surface test around the sides and base of the colony and varying amounts are embedded in the test amongst the zooids. The test is firm and transparent in preservative. In life, colonies are pink around the periphery of the systems, or red-orange with orange or salmon coloured zooids.

INTERNAL STRUCTURE: The zooids are robust, but the thorax and abdomen together are only about 2mm long, the thorax slightly longer than the abdomen. The posterior abdomen occupies about half the length of the zooid. The 6 branchial lobes are large and fleshy, with a small, pointed papilla in the centre of each lobe, sometimes

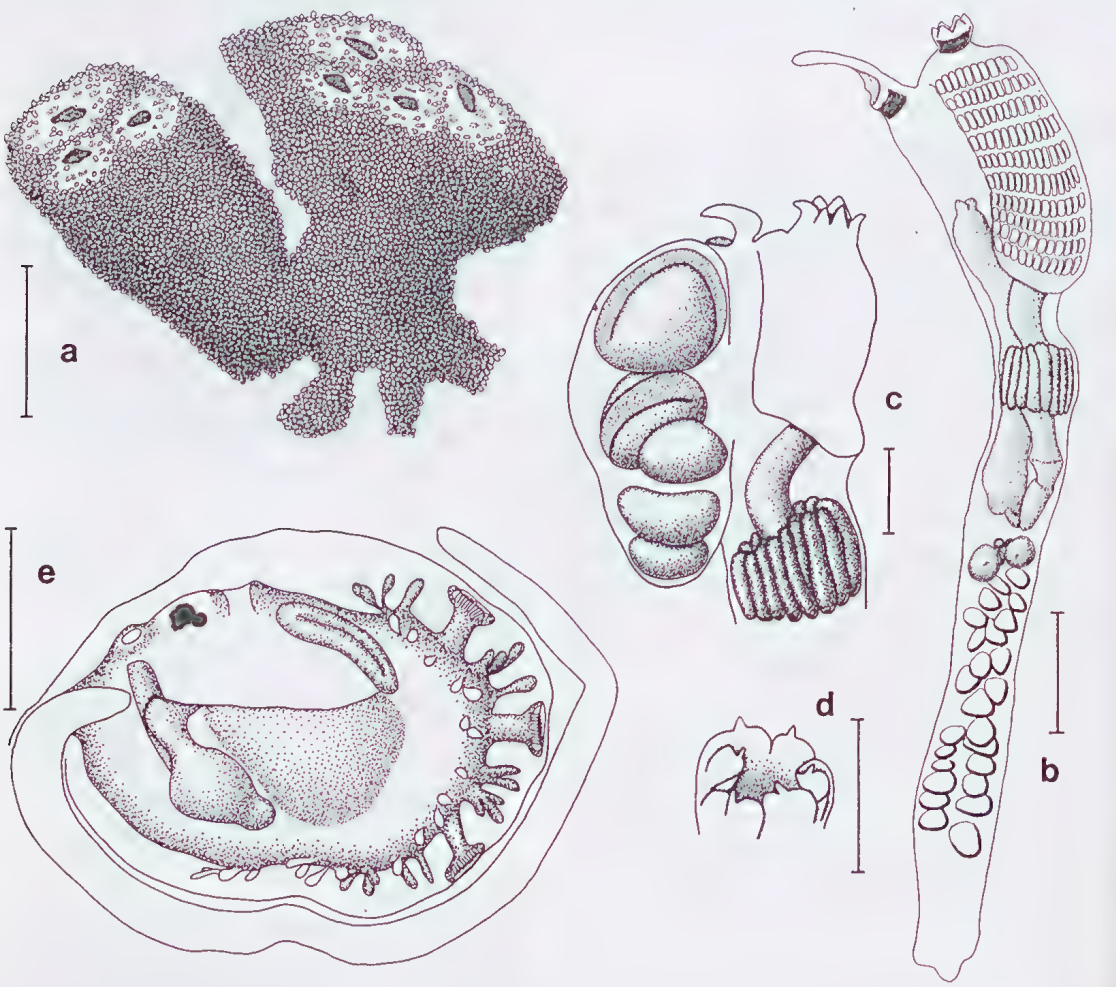

FIG. 81. *Aplidium incubatum* n.sp. — **a**, colony (holotype QM GH5309); **b**, whole zooid (paratype QM GH5310); **c**, anterior part of zooid with embryos in brood pouch (holotype QM GH5309); **d**, branchial lobes (paratype QM GH5310); **e**, larva (holotype QM GH5310). Scales: **a**, 5mm; **b–d**, 0.5mm; **e**, 0.2mm.

slightly depressed into its surface. The atrial lip is produced from the upper rim of the opening and is single or divided into 2 or 3 lobes. Twelve thick, conspicuous muscles are in the thoracic wall and extend the length of the zooid in a narrow band on each side. Broad, rectangular stigmata are in 9 or 10 rows with up to 15 per row.

The stomach has 25 folds in its wall. The oesophagus and post-pyloric part of the descending limb of the gut loop are of moderate length, an ovary is in the anterior part of the abdomen behind the gut loop, and the male follicles are in a long, irregular and rather loose bunch occupying most of the posterior abdomen.

Zooids of the holotype each have a large brood pouch, constricted off from the postero-dorsal corner of the thorax, with up to 6 embryos in a developmental sequence, lined up in it. The most advanced tailed larva is uppermost. It has a trunk 0.55mm long, and a tail wound three quarters of the way around it. About 16 epidermal vesicles are in a single arc on each side of the mid-line around the anterior half of the trunk.

A total of 7 epidermal vesicles in the interspace between the upper and middle adhesive organs branch off 2 common basal stalks, and 5 branch of 2 basal stalks in the lower interspace.

REMARKS

A. uteute and the present species have circular systems, a brood pouch and similarly arranged epidermal vesicles. However, the larvae of the present species lack the median vesicles, the zooids have fewer stomach folds and fewer stigmata per row than *A. uteute*, and the test has embedded sand, which *A. uteute* does not have. *Aplidium ornatum* n.sp. has sand around the border of the colony, like the present species, but is distinguished by its more numerous and scattered larval epidermal vesicles and lack of a brood pouch.

Aplidium inflorescens n.sp.
(Fig. 82)

? *Aplidium opacum* Kott, 1963, p.108 (part, lobed specimen from Balnarring Beach).

DISTRIBUTION

TYPE LOCALITY: South Australia (SW Point, Grindal I., NNE Cape Catastrophe 18m, coll. L. Hobbs, H. Brandon on RV *Ngeria* 29.9.89, holotype SAM E2588).

FURTHER RECORD: Victoria (? Balnarring Beach — AM Y1401 Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: The colony consists of multiple stalked heads branching from a sandy common base. Heads are hemispherical to 2.5cm diameter, and the thick stalks are of slightly less diameter and up to 1.5cm long. Sparse sand is embedded in, and is present on the surface of, the stalk, increasing in abundance toward the base. Sand is absent from the head. Zooids are arranged in double rows converging to a few common cloacal apertures on the terminal surface of each lobe.

INTERNAL STRUCTURE: The zooids are of moderate length, the thorax and abdomen together being about 4mm. The posterior abdomen is long and thread-like. The atrial lip is from the anterior rim of the aperture. It is undivided and usually its median longitudinal muscles are contracted causing the edge to be frilled. Stigmata are in 15 rows with 14 or 15 per row. The oesophagus has a slight prestomach enlargement. The stomach wall has 20 folds.

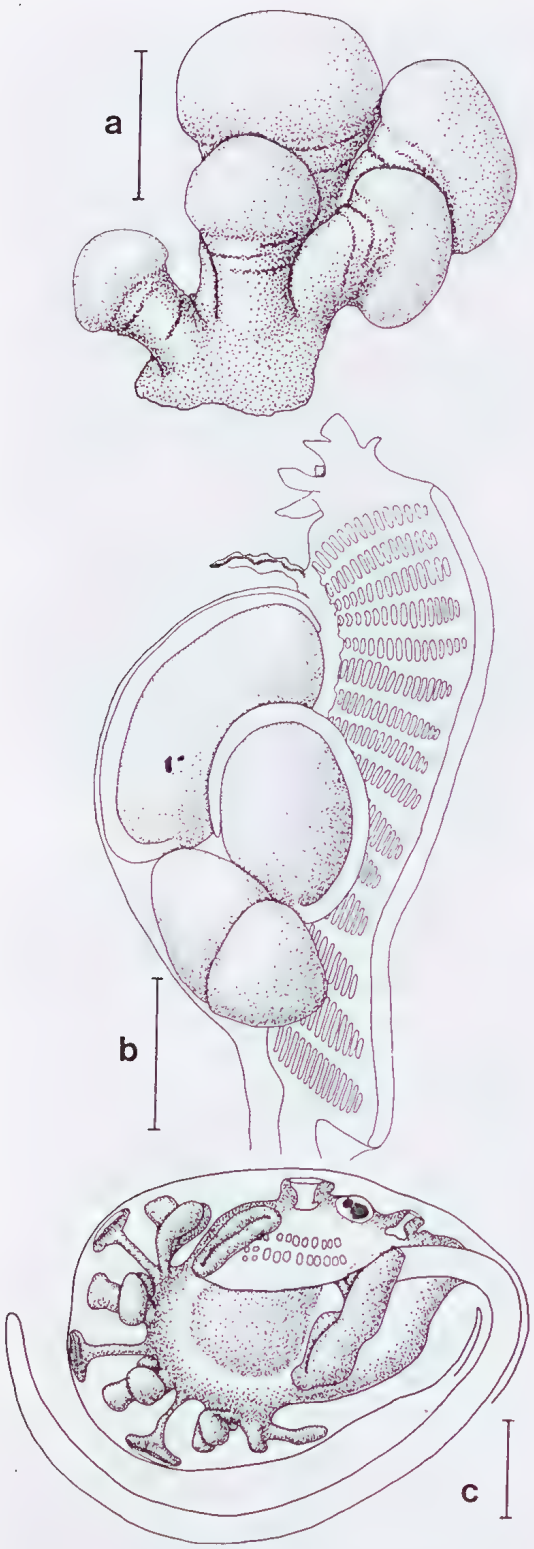
Up to 4 embryos are crowded in the atrial cavity of the type specimen. In the contracted zooid this causes the dorsal surface to protrude. Larvae are large, the trunk almost 0.9mm long, with median and lateral ampullae alternating with the adhesive organs. There are no epidermal vesicles.

REMARKS

The colony of this species with its thick basal stalks and longitudinal rows of zooids converging to terminal cloacal apertures, resembles *Aplidium geminatum*, which also has a similar number of stomach folds, and is recorded from South Australian waters. The present species lacks the layer of external sand characteristic of *A. geminatum*, and its stalks are shorter, thicker, more branched and not so wrinkled. Further, the larvae of the present species lack the arc of crowded epidermal vesicles found in *A. geminatum*. They have, instead, well-formed lateral ampullae.

Aplidium brevilarvacium has similar cloacal systems but the heads are smaller and sandy, the stalks thinner and longer, and the stomach has only 10 folds, thus is readily distinguished from the present species.

The larvae of the present species are similar to those of *A. coniferum*, which is distinguished by its large undivided upright colony, and its zooids with only 5 stomach folds. *Aplidium lodix* n.sp. has a similar larva without vesicles, and with median and lateral ampullae, but its colonies are extensive and investing with branching rows of



zooids converging to the randomly distributed common cloacal systems.

The colony assigned to *A. opacum* by Kott (1963) is in vegetative condition, and although the colony resembles that of the present species, zooids are not available to confirm its identity.

Aplidium jacksoni Kott, 1963
(Fig. 83)

Aplidium jacksoni Kott, 1963, p.110 (part, holotype).

DISTRIBUTION
NEW RECORDS: None.
PREVIOUSLY RECORDED: New South Wales (Port Jackson — AM U3917 Kott 1963).

DESCRIPTION
EXTERNAL APPEARANCE: The colony is a circular slab, about 12cm diameter and 2cm thick. Sand is embedded thickly in the surface layer of test, but is not present externally adhering to the outer surface. Sand is sparse in the lower half of the colony. Circular cloacal spaces are just below the surface, covered over by a thin layer of test, and with large, irregular, sessile cloacal apertures in the centre. Zooids are in wide circles of about 8 to 12 surrounding the cloacal cavities. Each branchial aperture opens on or inside a small upstanding papilla, which has one or more of the ventral branchial lobes embedded in it.

INTERNAL STRUCTURE: The zooids are robust, with a short thorax and a long posterior abdomen. The atrial aperture has a small pointed lip from the upper border of the opening. Branchial lobes are small and pointed. Stigmata are in 12 rows of 16. The wide stomach is relatively short with about 12 regular, parallel longitudinal folds. Two rows of male follicles are in the long, robust posterior abdomen. Larvae are not known.

REMARKS
Although it is not impossible that *A. jacksoni* occurs in Bass Strait, a naked, stalked, colony from off Devonport (Tasmania), assigned to this species by Kott (1963), is not conspecific. It is in the vegetative phase, and appears to be a colony of *A. coniferum* (see above).

FIG. 82. *Aplidium inflorescens* n.sp. (holotype SAM E2588) — **a**, colony; **b**, thorax showing embryos being incubated; **c**, larva. Scales: **a**, 2cm; **b**, 0.5mm; **c**, 0.2mm.

The present species is characterised by its distinct circular systems, with the position of the branchial openings indicated by a papilla on the surface of the colony. The zooids have some characters in common with *A. triggsense* which, however, has more crowded zooids and sand embedded in the basal layer of test rather than the surface.

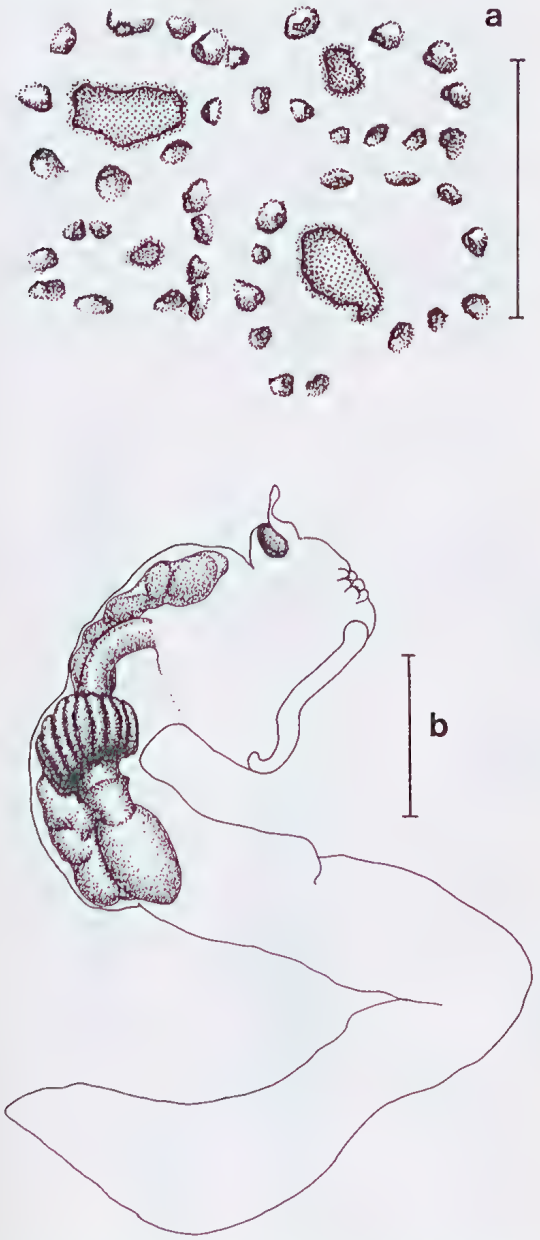


FIG. 83. *Aplidium jacksoni* (holotype AM U3917) — a, surface of part of colony showing large sessile common cloacal apertures surrounded by the branchial apertures on small papillae; b, zooid. Scales: a, 5mm; b, 0.5mm.

(Fig. 84. Plate 13d–f)

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I. under coral slab 3m, coll. N. Coleman 26.11.74 AMPI 141, holotype QM GH5060. Heron I., coll. P. Fredrickson May 1975, paratype QM GH5061.

FURTHER RECORDS: Western Australia (Carnac I., QM G9475; Rockingham, QM GH5457). South Australia (Topgallant I, QM GH941). Queensland (Capricorn Group QM GH1497).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are robust sheets or slabs up to 20cm in maximum extent and to 2cm thick. The upper surface is divided into flat-topped, circular, oval or polygonal zooid-free elevations of varying diameter up to 1cm. These are separated from one another by narrow depressions. In the base of each depression is the thin layer of test forming the roof of the common cloacal canals. The zooids open along each side of these common cloacal canals in the angle between the base and sides of the depression. The ventral surface of each zooid is in the solid test beneath each elevated area, atrial apertures are in the base or sides of the cloacal canals and atrial lips are in the test above the canals. Sand is packed in the lower half of the colony and around the outer margin, but the upper half of the colony is completely or partially free of sand.

The sand occasionally spreads from the lower half of the colony into the test around the zooids and above them, into the outer margin of each elevation, thus protecting the branchial openings. Sometimes some small clumps of sand are scattered in the surface of each elevation and these may also be present in small papillae projecting from the upper surface. The sand is also occasionally present in the surface test above the cloacal canals, and around the large common cloacal apertures which appear to occur randomly at the junctions of cloacal canals. The cloacal apertures are conspicuous, projecting from the surface of the colony, with a large cloacal chamber beneath them. Brownish oval bodies (about 0.1mm long) are in the test especially crowded around the cloacal canals, in their base, walls and roof. They become more sparse toward the base of the colony. These contain granular material, but they do not appear to be faecal pellets.

In life colonies are said to have been black, greenish-black, red, aqua-blue (South Australian

specimens) translucent gels, although all photographed specimens appear to be cream and red.

INTERNAL STRUCTURE: Zooids are robust. The thorax and abdomen are together about 3mm long, and of about equal length, but the posterior abdomen is at least twice the length of the rest of the zooid.

The branchial siphon is long with a large sphincter around the base of the lobes. Fine longitudinal muscle bands number about 12 on the thorax. The atrial lip arises from the body wall opposite the first row of stigmata, and the atrial siphon surrounded by a sphincter muscle, is opposite the fifth or sixth row. The tip of the atrial lip is invariably entire and pointed. The atrial lip is particularly long and broad. Zooids located in the vicinity of a cloacal aperture have their atrial lips inserted into the test around the rim of the opening.

An extent of unperforated pharynx is between the tentacular ring and the first row of stigmata. Also, bands of unperforated pharynx lie along each side of the endostyle, the perforated part being a relatively narrow part of the dorsum of the pharynx. Stigmata are in 16 to 20 rows of up to 8 per row.

The stomach has 5 folds although when inflated only slight anterior and posterior protrusions remain.

The posterior abdomen is long and thin, the test follicles in one or 2 series are usually separated from the posterior end of the abdomen by an interval of various lengths. The ovary is at the anterior end of the male follicles. It increases in size as it moves up into the atrial cavity from 0.7 to 1mm. It is a long, pointed, egg-shape, rounded at one end and tapering to a blunt point at the other. Embryos are present in the atrial cavities of specimens from Rockingham (collected in

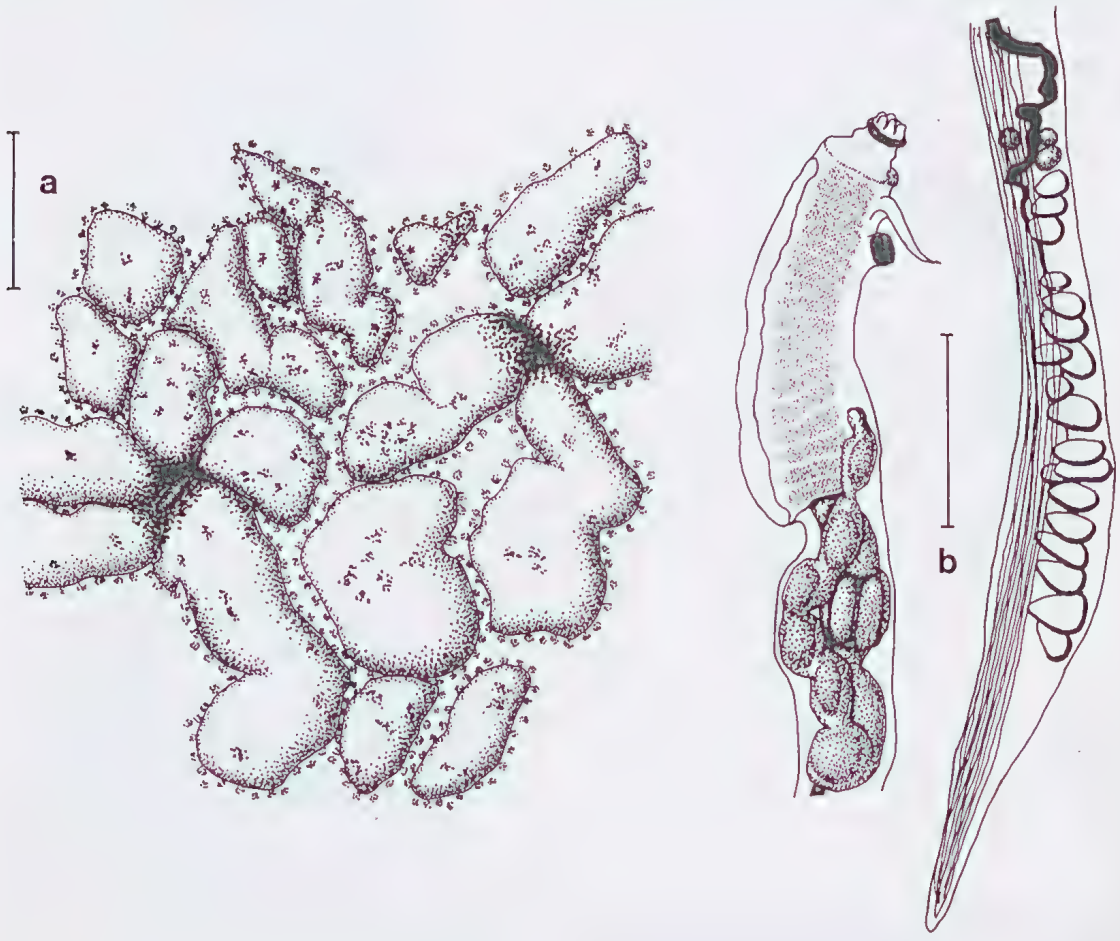

FIG. 84. *Aplidium lenticulum* (paratype QM GH5067) — **a**, part of colony surface; **b**, zooid. Scales: **a**, 5mm; **b**, 1mm.

March). Tailed larvae are in a Heron I. specimen collected in May (QM GH5061). They have median ampullae alternating with the adhesive organs, and a mass of epidermal vesicles obscuring the anterior end of the 1mm trunk. Only one embryo is incubated at a time in the posterior half of the atrial cavity.

REMARKS

As well as the narrow zooids with long thoraces, long branchial apertures and atrial siphons separated from the atrial lip by 3 or 4 rows of stigmata, the gelatinous, flat-topped elevations on the surface, surrounded by the cloacal canals and zooid openings, are characteristic.

The species is the opposite of such species as *A. clivosum* and *A. lunacratum* nom. nov. which, although they have similar zooids, have zooid-free surface elevations of the test that surround the systems rather than being surrounded by the systems as in the present species.

A line of sand outlines the zooid-free areas of test where the branchial apertures open to the surface also in *Aplidium tabascum* n.sp., although in the present species the sand grains in the margins of the elevated areas form a crowded band rather than a single line. Also the cloacal cavities of *A. tabascum* are more extensive, and the atrial lip is from the rim of the aperture and not separate from it as it is in the present species. *Aplidium solidum* has similar, though smaller systems, more embedded sand, and a different zooid.

The surface elevations and similar systems are found also in *A. cellis* Monniot 1987 from New Caledonia but its atrial lip is not separate from the opening, and the larvae of the 2 species differ.

Aplidium caelestis has similar zooids and oval bodies embedded in the surface test as the present species. However its long, crowded meandering systems separated by long, thin ridges, rather than the circular double rows surrounding polygonal areas, and the sandy colonies with surface as well as embedded sand, distinguish it.

The nature and role of the oval bodies is not known, although it is possible that they have sometimes been mistaken for faecal pellets (see *A. caelestis*, above).

Aplidium lodix n.sp.
(Fig. 85)

DISTRIBUTION

TYPE LOCALITY: Victoria (Western Port, Crawfish Rock, coll. J.E. Watson 14.11.78, holoytpe QM G12712).

FURTHER RECORD: South Australia (Perforated I., QM GH4144).

DESCRIPTION

EXTERNAL APPEARANCE: The colony is a large sheet investing pebbles on an irregular substrate. It is uneven in thickness from 0.5 to 1cm. The maximum dimension of the colony is 6cm, and it is irregularly indented and lobed around the margin and smooth and even on the upper surface. The test is firm and translucent, without sand on the upper surface, although there is some on the base. There is no embedded sand. Moderately crowded zooids are arranged in circular to stellate systems. In preservative it is greyish, with whitish zooids.

INTERNAL STRUCTURE: Zooids are robust, to 6mm in length, with thorax, abdomen and posterior abdomen each about one third of the total length. The 6 branchial lobes are conspicuous and rounded. The atrial tongue arises from the anterior rim of the aperture. Numerous stigmata are present in 10 rows, although the exact number was impossible to count. The stomach has about 25 longitudinal, parallel folds.

Up to 6 crowded embryos are incubated in the atrial cavity. Larvae from the holotype have trunks 0.65 to 0.75mm long, with the tail wound half-way around. Ocellus and otolith are present. A lateral ampulla is on each side of each of the 4 median ampullae which alternate with the adhesive organs. A ventral median ampulla projects posteriorly, but there are no epidermal vesicles.

REMARKS

Superficially the preserved colony resembles *Aplidium opacum*. However, the latter species has more crowded zooids arranged in double branching rows, and its larva differs from the present species in having epidermal vesicles and lacking lateral ampullae. *Aplidium robustum* n.sp. is another temperate species with a similarly shaped and naked colony, circular systems of varying size, and robust zooids with about 20 stomach folds. It has up to 16 rows of stigmata, its thorax is longer than that of the present species and its larva has clumps of dorsal and ventral vesicles which are not present in *A. lodix*.

Aplidium inflorescens has lateral and median larval ampullae, lacks epidermal vesicles, but is distinguished from the present species by the form of its systems with apical common cloacal apertures.

DISTRIBUTION
NEW RECORDS: Western Australia (Cervantes, WAM 237–9.87); South Australia (Great Australian Bight, SAM E2563; Kangaroo I, QM GH5429; Beachport, QM GH5448; Cape Jaffa, SAM E2553 E2560 E2565, QM GH5446). Victoria (Portland Harbour, MV F59370).
PREVIOUSLY RECORDED: New South Wales (Manning River — AM G12216 holotype *A. ordinatum* Herman and Riddell, 1913).

The discontinuity in the records probably reflects collecting effort.

DESCRIPTION
EXTERNAL APPEARANCE: Colonies are irregular sandy mats, or upright wedges and lamellae up to 1cm thick with zooids opening on both sides, or cylindrical lobes of various sizes arising from common basal test with zooids opening only on the upper surface. Zooids are in evenly spaced circular systems of 5mm diameter. Branchial apertures are in a circle around the periphery of each system and a circular cloacal cavity is in the centre beneath the naked concavities on the surface of the colony. Crowded and relatively large sand grains adhere to the ridges between the systems, and usually to the outside of the conical common cloacal protuberance that rises from the centre of each surface concavity. A little fine sand is embedded in the naked test in the concavity around the base of each cloacal protuberance. Radial bands of red pigment from the cloacal aperture to the circumference of each depression are in the surface test. Sand is crowded throughout the remainder of the test. Zooids lie amongst the embedded sand. They are perpendicular at the surface but more posteriorly they cross one another. In thin lamellae or sheet-like colonies they bend at right angles so that the long narrow posterior abdomina extend through the fine sand in the middle layer of each colony lobe toward its point of fixation, or to where it branches off a

FIG. 85. *Aplidium lodix* n.sp. (holotype G12712) — **a**, colony with systems indicated on part of the surface; **b**, thorax and abdomen; **c**, larva. Scales: **a**, 1cm; **b**, 0.5mm; **c**, 0.2mm.

Scales: **a**, 5mm; **b–d**, 1mm; **e**, 0.2mm.

basal plate. When such lamellae are broken across, the posterior abdomina can sometimes be pulled out in tufts like fine hair-like threads.

INTERNAL STRUCTURE: The zooids are muscular and often are contracted, although the posterior abdomen always is relatively long (up to 1cm or more). When relaxed, the thorax is 3 or 4mm long, and the abdomen about half of that length. Dark pigment cells are in the tip of the atrial siphon and in the branchial siphon of preserved zooids. Longitudinal musculature is strong with about 25 bands on the thorax.

The branchial siphon is short with 6 relatively shallow lobes around the aperture. It has circular muscles in a wide band along its length, and there is no narrow, bulging sphincter muscle. The atrial tongue is fleshy and pointed to long, wide and strap-like, with parallel longitudinal muscles. It arises from the body wall opposite the first row of stigmata, anterior to the atrial siphon which is opposite the second to third rows. A ring of muscles is around the forward pointing atrial aperture on its short siphon which opens into the base of the cloacal cavity around its outer margin. The prebranchial area between the prepharyngeal band and tentacular ring is wide, as is the imperforate pre-stigmatal and post-stigmatal parts of the pharynx. Also a wide band of unperforated pharyngeal wall is along each side of the endostyle.

Stigmata are in 10 to 15 rows of 12 to 15 per row. The stomach is small with 5 shallow folds, sometimes (if the stomach is flattened or inflated) difficult to distinguish and reduced to longitudinal glandular areas internally. The anal opening is opposite the seventh row of stigmata. Spherical to oval male follicles are in a long single or double series in the middle third of the long posterior abdomen. The ovary is just anterior to the testis follicles.

A single embryo is in the posterior half of the atrial cavity of specimens collected in January (SAM E2563). The larval trunk is 2.2mm long, more or less cigar-shaped, with the ocellus and otolith near its posterior end. Two median ampullae, one in each interspace, alternate with the adhesive organs. The anterior end of the trunk is obscured by numerous ectodermal vesicles that extend in bands, one along each side of the ventral and dorsal mid-lines from outside the base of the ventral and dorsal adhesive organs, respectively. The larva is pigmented red and is opaque.

REMARKS

Like *Synoicum castellatum*, the present species has large circular sytems, protruding cloacal apertures, atrial lips separate from the apertures, stomach folds flattened, and occasionally the stomach in the 'atopogaster' condition — with horizontal folds. However the internal glandular areas are all parallel and longitudinal and none are irregular as they are in the large stomach of *S. castellatum*. The present species also has close similarities with other *Aplidium* spp. It has the same long larval trunk (in the vicinity of 2mm) and a long narrow zooid with the atrial lip separate from the opening as in *A. crateriferum* and *A. clivosum* but it lacks their narrow, bulging branchial sphincters, has fewer rows of stigmata, and its systems are smaller. *Aplidium lunacratum* has circular systems (as in *A. crateriferum*) rather than stellate ones (as in *A. clivosum*).

Despite the circular systems of the present species being different from those of the sympatric *A. clivosum*, in which the double rows of zooids converge to the cloacal apertures, preserved colonies are readily confused with one another. Both species have naked surface depressions with central protuberant cloacal apertures and red test. In both the colony shape varies, and variable quantities of sand are on the upper surface. In *A. lunacratum* there seems always to be a single system per depression, as in some specimens of *A. clivosum* (SAM E2564–5). As well as the form of the cloacal systems the present species can be distinguished by its larger zooids, with more muscles, and fewer rows of stigmata but more per row (10 to 14 rows of up to 15). *Aplidium acroporum* has similar systems but smaller zooids, with only 5 rows of stigmata, 8 stomach folds and the atrial lip arising from the anterior rim of the aperture. *Aplidium protectans* has similar circular systems, a large roomy stomach, and larvae with median ampullae and dorsal and ventral vesicles, but its zooids differ in other respects, and its colony is naked and gelatinous.

Examination of the type specimen (AM G12216) of *A. ordinatum* Herdman and Riddell has shown that previous reports (see Kott 1963) of 8 folds in the stomach wall are incorrect. The zooids are contracted, and some of their details are obscured. Nevertheless, the relatively large stomach is seen to have the characteristic 5 shallow folds, the atrial aperture is on a short siphon just posterior to the muscular atrial lip, and each protuberant common cloacal aperture, in the centre of a circle of zooids, has sand embedded in it.

The name *Aplidium ordinatum* is a junior secondary homonym of *Psammaplidium ordinatum* Sluiter, 1906 (see also Van Name 1945) from the Antarctic and the name *Aplidium lunacratum* nom. nov. is accordingly proposed for this species.

Aplidium macrolobatum n.sp.
(Fig. 87)

Aplidium lobatum: Kott, 1963, p.97 (part, colonies from Heron I. and Sarina).

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I., north east, low tide on under surface or rubble, outer edge of reef, coll. P. Kott 2.11.86, holotype QM GH5169; 14.11.85, paratype QM GH5170).

FURTHER RECORDS: Queensland (Capricorn Group, AM Y1404, QM GH5166–8 GH5219 GH5276 GH5526 GH5544–9 GH5595–6 GH5606–7 GH5660 GH5663; Britomart Reef, QM GH380; Sarina — AM Y1445 Kott 1963; Lizard I., QM GH5550–1).

One colony from Heron I. (QM GH5663) was found on a small crab.

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are investing sheets up to 0.5cm thick, or irregular masses with the upper surface and margin extending into rounded or flattened lobes. Sand is embedded throughout the test, although often it is relatively sparse and the colonies are predominantly gelatinous. Sand is less crowded internally than just below the surface, and is absent from the smooth outer surface of the colony. Branchial apertures on the upper surface have each of the 6 large triangular branchial lobes outlined in fine sand grains. The cloacal apertures are large, sessile or protruding from the surface. They vary in size and shape, some being irregular openings but others regular and circular and often they are particularly extensive long or crescent-shaped openings exposing an extent of the cloacal cavity or canal directly to the exterior.

The systems are either circular, occasionally separated from one another by slight depressions in the surface test (holotype); but in other colonies crowded double rows of zooids converge to irregular and randomly scattered cloacal apertures. In several well developed colonies (QM GH380, AM Y1445) the common cloacal apertures are along the upper rim of flattened colony lobes and double rows of zooids extend down each side of the lobes, almost parallel to one another. The test usually is firm, gelatinous and occasionally glassy in preservative.

In life the colony is cloudy, owing to the embedded sand. When living, the thoracic body walls of the zooids are mauve, purple, raspberry, 'pink', 'hazel', 'rose-red', or 'ruby' (Ridgeway 1886) but other parts of the zooids are colourless. Colonies, with pink or red colour seen through the embedded sand, have been described as 'turkish delight', 'pink lozenge' or 'pomegranate'. Zooids are pale pink in preservative.

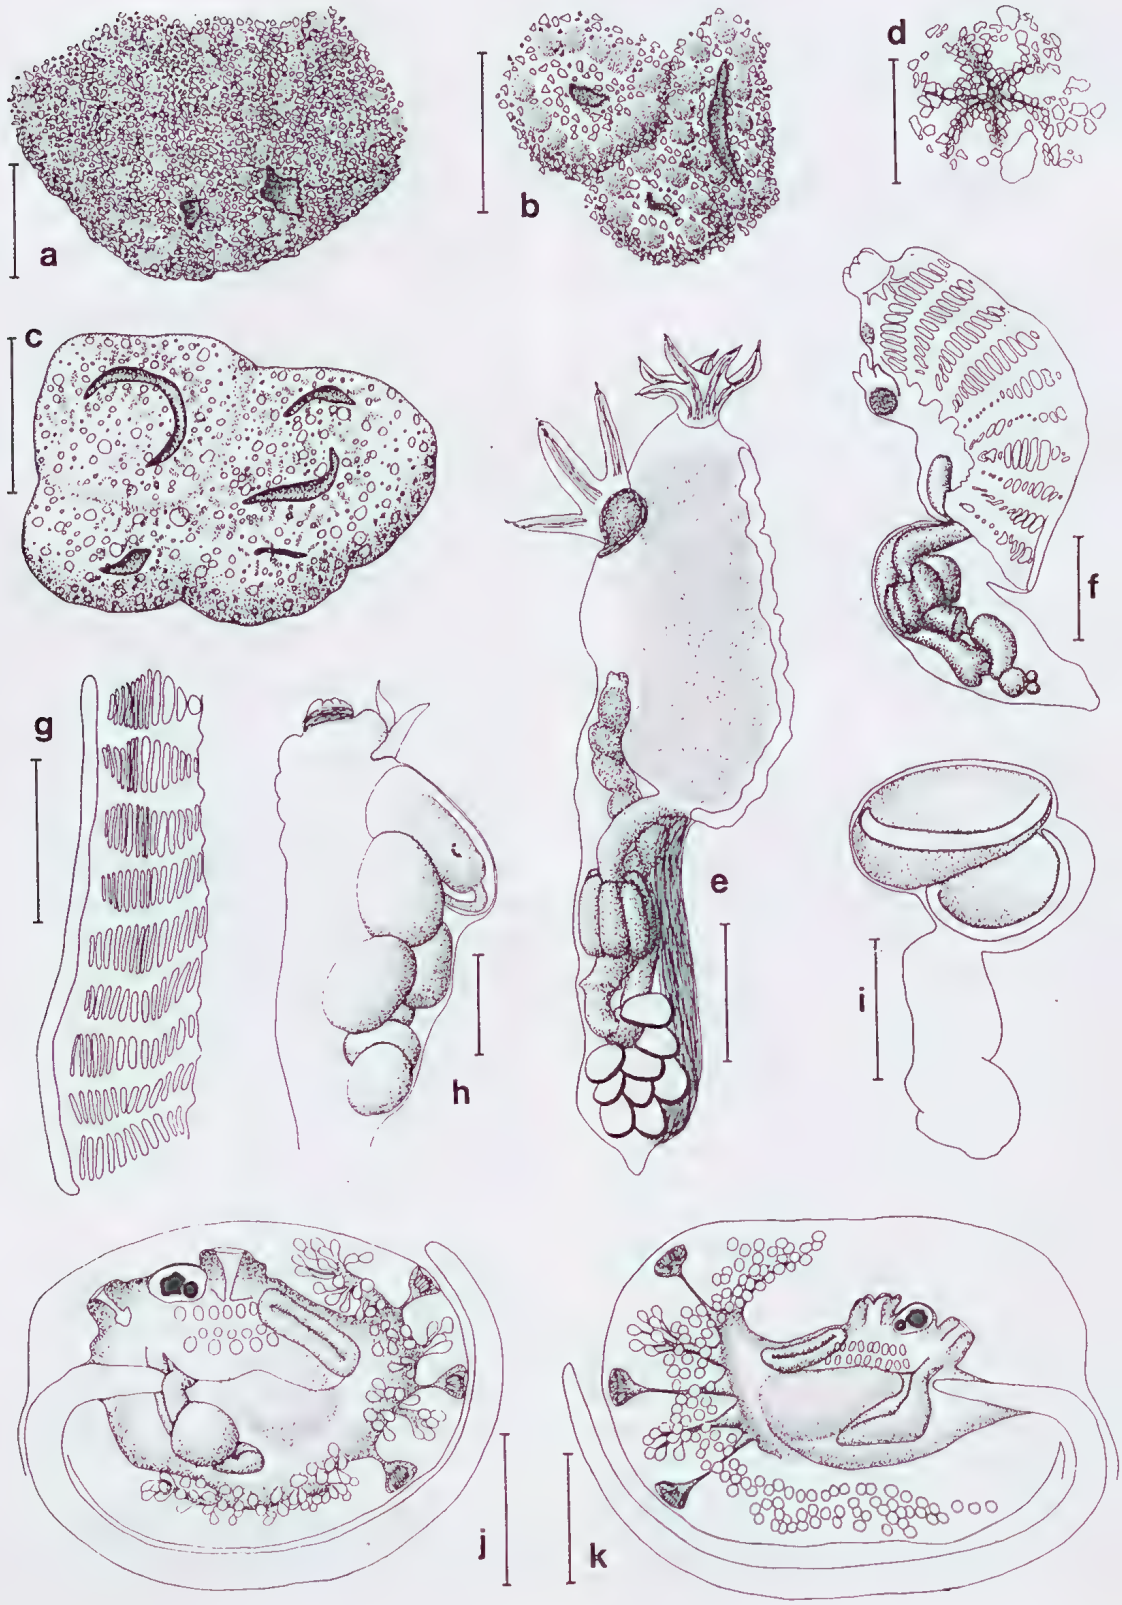
Prochloron is on the surface of some colonies and often large red and green spherical algal cells, 0.1 to 0.2mm in diameter are in the test between and around the zooids and in the floor of the cloacal cavities especially when these are exposed to the exterior (QM GH380 GH5606 GH5660 AM Y1445).

INTERNAL STRUCTURE: Zooids are small, 2mm long when contracted, the thorax and abdomen of about equal length and the posterior abdomen slightly shorter. Branchial lobes are large triangles with a narrow muscle band in the centre of each lobe, reaching to its pointed tip. The atrial lip from the upper rim of the opening is exceptionally large, and is divided into 3 to 5 long, pointed or straight-edged, leaf-like lobes with a narrow strap-like band of muscle fibres in the centre of each lobe. Both atrial and branchial lobes have a similar pointed tip into which the central muscle band is inserted. This tip sometimes appears as a pointed papilla projecting from the end of the lobe. When the muscles in it are contracted it is drawn back into the lobe, subdividing its terminal tip into 2.

Six to 10 strong longitudinal muscles are on the thorax of contracted specimens. These continue along the abdomen and posterior abdomen in 2 strong ventral bands. Nine or 10 rows of up to 15 stigmata per row are in the branchial sac. Stigmata are long and narrow, and are folded up when the delicate thorax is contracted.

The stomach wall has 5 deep folds. Sometimes the posterior abdomen is short, with up to 10 or more pear-shaped male follicles bunched in it. In other zooids, apparently in the female phase, a 3 to 10-egg ovary is about halfway down a long posterior abdomen, possibly after the testis follicles are spent (holotype). Male and female gonads are never present in the one zooid at the same time.

Up to 7 eggs and embryos are packed in the atrial cavity of the holotype and other colonies collected in August and November. The most advanced embryo is anterior. The larval trunk is



a
b
d
c
f
e
g
h
i
j
k

0.55 to 0.75mm long, the length increasing with maturity. A well developed ocellus and otolith are in the cerebral vesicle. Clusters of epidermal vesicles branch off the median ampullae that alternate with the 3 small, stalked adhesive organs. A band of small ectodermal vesicles is along each side of the adhesive organs. Further vesicles contrict off from posteriorly projecting stalks part of the way along the dorsal and ventral borders behind the adhesive organs on each side of the median line.

As the larvae mature, zooids degenerate and their remains persist as brood sacs in the test, each incubating one or 2 larvae.

REMARKS

The unusually large and lobed atrial lip, large branchial lobes, red body wall, and short posterior abdomen, with only male or female gonads present at a time, characterise this fleshy species which also contains variable amounts of embedded sand. A similar leaf-like atrial lip is known in the temperate species, *Aplidium elatum* Kott, 1972b. However, the latter species forms upright fan-shaped lamellae, has 8 rows of stigmata with only 8 per row and 15 stomach folds rather than the 5 of the present species. *Aplidium opacum* also has large lobes around the apertures, with muscle bands along the centre of each which sometimes subdivide the branchial lobes and crinkle the edges of the atrial ones. It is distinguished by its more numerous stomach folds and naked colonies without embedded sand.

Aplidium lobatum Savigny, 1816 from the Bay of Suez and Indonesia (see Michaelsen 1920) has a similar number of stigmata, stomach folds and a tripartite atrial tongue from the upper border of the opening. Like the present species, *A. lobatum* has a short posterior abdomen and only the male or female gonad present at one time. However, the colonies of *A. lobatum* have flat-topped oval areas separated by furrows into which the zooids open, and the species does not appear to be conspecific with the present one. *Aplidium tremulum*: Sluiter, 1909, proposed as a junior synonym of *A. lobatum*, has a short atrial lip. Thus, although Michaelsen (1920) may have been wrong in proposing the synonymy of *A. lobatum* and *A. tremulum* apparently neither are conspecific with the present species.

The degenerate zooids acting as brood pouches in the test, appear to be characteristic of the present species.

Aplidium magnilarvum n.sp.
(Fig. 88)

DISTRIBUTION

TYPE LOCALITY: Western Australia (115 nautical mls SW Eucla 38°17'S, 129°37'E, 180m, coll. W. Zeidler and K. Gowlett Holmes 16.1.89, holotype SAM E2582, paratype SAM E2583).

FURTHER RECORD: Western Australia (SSW Eucla, SAM E2590).

The species has been taken from the same general area at 180 to 190m depth.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are hard, upright, round-topped, about 4cm high and 2-3cm maximum diameter, narrowing toward the base where an aggregate of root-like projections of the test form a holdfast. Sand is not so crowded internally as it is on the surface around the sides and roots of the colony where it adheres to the test to form a thick layer. The sand layer is thinner toward the upper surface.

The surface sand obscures the systems, and their form was not determined. In between the sand particles, the test is firm and glassy, sometimes with some brown pigment cells.

INTERNAL STRUCTURE: The zooids in the availabile material are entering the vegetative phase with trophocytes accumulating in the abdomen, and the thoraces disintegrating. Only in the holotype are there adult organs persisting in the zooids. In some of these zooids a single large embryo is incubated in the atrial cavity, although none of these appears to have any larval organs developed.

In these zooids, the thorax (contracted) and abdomen together are up to 4mm. The thorax is muscular with about 15 longitudinal muscles running the length of the zooid, forming a wide band along the ventral border of the abdomen and posterior abdomen. The circular atrial aperture is

FIG. 87. *Aplidium macrolobatum* n.sp. — **a**, colony (QM GH5545); **b**, upper surface showing circular systems and large, irregular, sessile cloacal apertures (holotype QM GH5169); **c**, upper surface showing elongate systems with long, open cloacal apertures and embedded symbionts (QM GH5606); **d**, showing branchial lobes outlined in sand grains (QM GH5167); **e**, **f**, zooids showing short, contracted posterior abdomina with testis follicles and oocytes respectively (QM GH5167, holotype GH5169); **g**, portion of branchial sac (QM GH5314); **h**, thorax showing embryos being incubated (holotype QM GH5169); **i**, embryo being brooded in thorax of degenerating zooid (QM GH5526); **j**, **k**, larvae (QM GH5315). Scales: **a–c**, 5mm; **d–i**, 0.5mm; **j**, **k**, 0.2mm.

antero-dorsal, directed anteriorly, with a muscular atrial lip arising from the body wall just in front of it. The atrial lip either is undivided or it has 2 additional points on each side of the longer median one.

Stigmata are in 21 long rows. The thoraces are wide and robust, and appear to have at least 20 stigmata per row, although the exact number was not determined. The oesophagus is relatively long, and the long elliptical prestomach occupies most of its length. The stomach is short and has 5 deep folds. The post pyloric part of the gut has a posterior stomach, and proximal and distal parts of the mid-intestine. There are short rectal caeca. The gut is narrow in these specimens, however, and probably is not functional.

The large embryo completely filling the atrial cavity in some of the holotype zooids is up to 2mm long.

REMARKS

These small, upright bulbous colonies, with their basal holdfasts are unique, distinguished from *A. coniferum* by their hard, sandy consistency, the single large embryo in the atrial cavity, and more numerous stigmata in each row. This new species may be confined to locations at more than 100m depth on the southern continental shelf.

FURTHER RECORD: Victoria (Westernport — Kott 1976).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are soft, jelly-like flat-topped cushions to more extensive sheets lobed on the upper surface. They are found on stalks and fronds of weed. The holotype is from an experimental fouling panel. Zooids are in circular to elongate systems, and are clearly seen through the transparent but slightly brownish test. Their arrangement often is obscure in preserved

FIG. 88. *Aplidium magnilarvum* n.sp. — **a**, **b**, colonies (holotype SAM E2582, E2590); **c**, thorax and abdomen showing embryo being incubated in atrial cavity (SAM E2590). Scales: **a**, **b**, 1cm; **c**, 0.5mm.

material. Sand particles are embedded in the test, but are not crowded.

INTERNAL STRUCTURE: Zooids are small, to about 3mm, of which the thorax and abdomen are about half. The small, terminal branchial aperture has 6 pointed lobes, and the small atrial aperture has a single, short, pointed lip projecting out from the upper rim of the opening. Five rows of 10 to 12 stigmata are in the pharynx. The gut loop is short, with a small stomach with 10 deep folds in its wall. An oval posterior stomach is at the posterior end of the descending limb of the gut loop. A large rectal valve is present at the junction of the mid-intestine and rectum (at the base of the

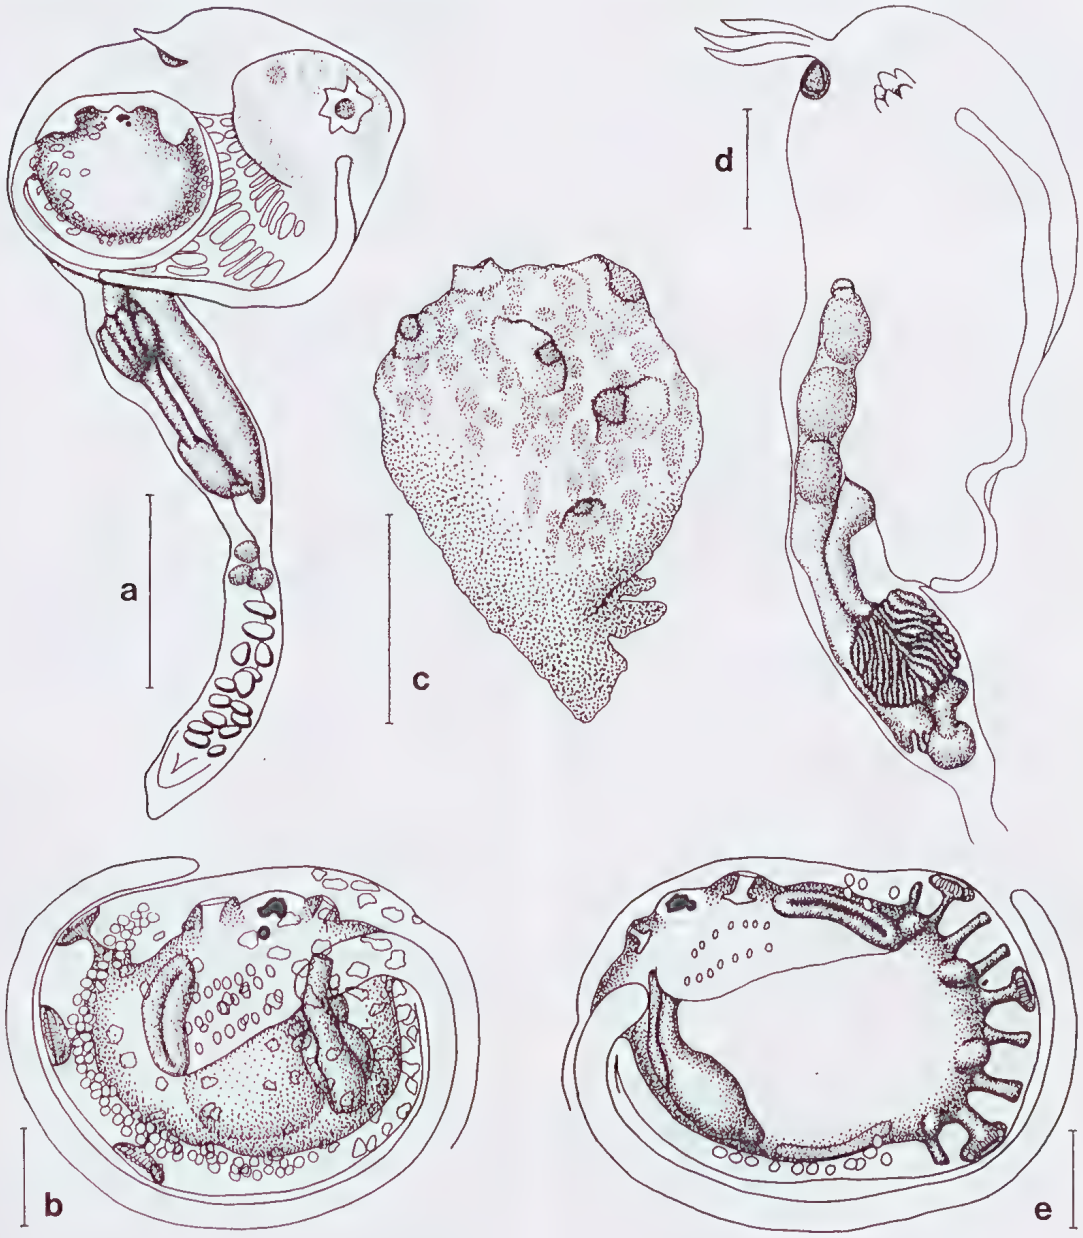

FIG. 89.*Aplidium minisculum* n.sp (holotype QM G11920)—**a**, zooid with embryo in atrial cavity; **b**, larva *Aplidium multilineatum* n.sp. — **c**, colony (holotype AM U3954); **d**, zooid (holotype AM U3954); **e**, larva (*A. flavolineatum*: Kott 1963 Cape Vlamingh, Rottnest I.). Scales: **a, d**, 0.5mm; **b**, 0.1mm; **c**, 5mm; **e**, 0.2mm.

ascending limb of the gut loop). The short posterior abdomen has a 2 or 3 egg ovary anterior to an irregular double row of male follicles.

In the holotype colony a single larva is in the atrial cavity, causing the short thorax to be almost spherical. These zooids also have mature male follicles, sperm in the vas deferens and some small oocytes in the ovary.

Larvae are almost spherical with a double row of ectodermal vesicles along each side of the median short-stalked adhesive organs, 3 rows of stigmata and large conspicuous test cells in the larval test. These test cells are absent from the anterior end of the larval trunk and become more crowded posteriorly. The larval trunk is about 0.4mm long.

REMARKS

Kott (1976) assigned the specimens from Westernport Bay to *A. depressum* on the basis of their similar colonies, small zooids, and similar numbers of rows of stigmata, numbers per row and numbers of stomach folds. Although there are similar test cells in the larval test, the larvae of *A. depressum* are smaller than those of the present species and have only a single row of 7 or 8 vesicles along each side of the adhesive organs. The zooids of *A. minisculum* also differ from those of *A. depressum* in the presence of an atrial lip.

Aplidium multilineatum n.sp.
(Fig. 89c–e)

Aplidium flavolineatum: Kott, 1963, p. 5 (part, AM U3954, ? AM U3955).

DISTRIBUTION

TYPE LOCALITY: Western Australia (Rottnest I., Salmon Bay, inner pool, low tide, coll. P. Kott 18.11.51, holotype AM U3954).

FURTHER RECORDS: Western Australia (? Cape Vlamingh, Rottnest I. — Kott 1963). ? Tasmania (Hunter I. — AM U3955 Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: The colony is a flat-topped cushion, 1cm in diameter, with a naked upper surface and a sandy base. Some sand is embedded in the test around the zooids but it is sparse, and is absent altogether from the surface test in the centre of the circular systems of zooids where large, plain-rimmed common cloacal openings protrude from the surface. The systems are numerous, about 8 being present in the small holotype. The test is soft and transparent in the preserved colony.

INTERNAL STRUCTURE: Zooids are delicate, with a large thorax twice the length of the abdomen and broader as well. The posterior abdomen is long and narrow. Fine longitudinal muscles are on the thorax. An atrial lip divided into 2 or 3 narrow, pointed branches, arises from the anterior rim of the antero-dorsal atrial aperture. Stigmata are in 10 rows of up to 16. The stomach is small with about 30 narrow, mostly oblique folds that are interrupted where they meet along lateral, mesial, dorsal, and ventral longitudinal lines which divide the stomach wall into 4 sections. The usual duodenum, mid-intestine and posterior stomach are in the descending limb of the gut loop. A rectal valve is at the proximal end of the rectum.

Embryos are not present in the holotype. Slide-mounted larvae are available from colonies from Cape Vlamingh (Rottnest I.) and Hunter I. (Tasmania). These were from colonies which, with the present colony, were assigned to *A. flavolineatum* by Kott (1963). The colony from Hunter I. (AM U3955) appears to have dried out at some time and neither the systems nor the structure of the zooids could be discerned. The specimen from Cape Vlamingh has not been located for reexamination. Thus the identity of these larvae cannot be confirmed, and they are only provisionally assigned to the present species — on the assumption that colonies from which they were taken were conspecific with the reexamined colony, viz. the holotype of the present species.

The larvae from both Hunter I. and Cape Vlamingh have a trunk 0.9mm long, with the tail wound about three-quarters of the way around it. There are median ampullae alternating with the adhesive organs, and those in the 2 interspaces are each divided into 2. Four lateral ampullae are present on each side of the median line, one near the base of each of the median ones. A trail of epidermal vesicles extends posteriorly from behind the dorsal and ventral median ampullae. A large ocellus and an otolith are in the cerebral vesicle.

REMARKS

The cushion-like colony with transparent test, and circular systems has some resemblance to *Aplidium uteute*, although the zooids and the systems appear larger, and the common cloacal apertures more protuberant. *Aplidium uteute* also has numerous stomach folds, but they are longitudinal rather than oblique, and it has a wide

thorax with more stigmata than the present species. Larvae of *A. uteute* with single series of epidermal vesicles around each side of the median line, and vesicles between the adhesive organs, are completely different from the larvae provisionally assigned to the present species.

Aplidium gastrolineatum has circular systems and oblique stomach folds but the stomach folds are fewer than in the present species, and the thorax is longer with about 16 rows of stigmata. The South African species *A. flavolineatum*, to which the holotype of the present species was assigned by Kott (1963), has a similar number of stomach folds, but they are not oblique.

The larvae provisionally assigned to the present species have median and lateral ampullae and dorsal and ventral vesicles like those of *A. robustum* and *A. ornatum*, but the median ones are subdivided and there are 4 lateral ones rather than only 2 (as in the latter 2 species). *Aplidium robustum* has a similar colony, but sessile cloacal apertures and fewer stomach folds.

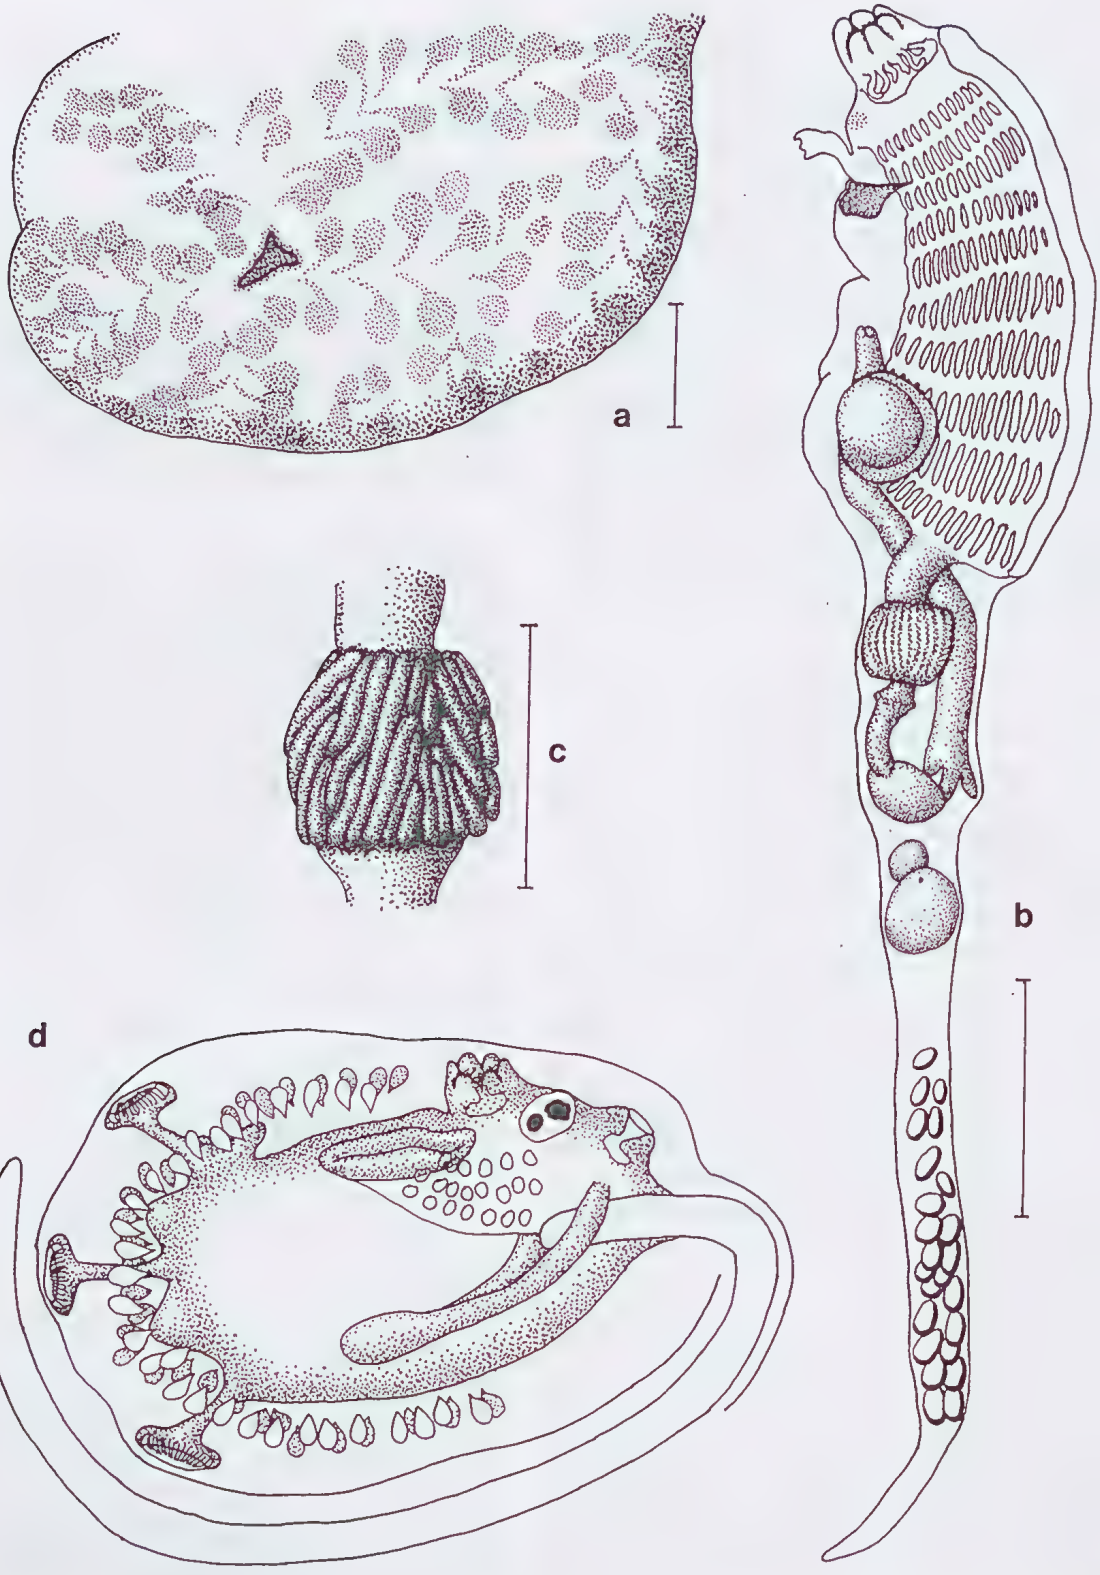
PREVIOUSLY RECORDED: Western Australia (South-western — AM Y1394 Kott 1963). New South Wales (Jervis Bay — AM Y1439; Port Hacking — AM Y815 Y823 Kott 1972c; Port Jackson — AM Y1423 U3931 U3956 Kott 1963). Kiribati and the Palau Is (Tokioka 1967); Phillipines (Van Name 1918); Truk and Ponape Is, Majuro Atoll (Nishikawa 1984a). Hong Kong (Kott and Goodbody 1982).

Despite confusion in the definition of this species which resulted in its being placed in synonymy with eastern Pacific and S. African species, the range appears to be Indo-West Pacific. It is especially common in tropical, usually reefal, habitats of the western Pacific. It extends into the temperate waters of south-western Australia, but not across the southern coast of the continent.

DESCRIPTION

EXTERNAL APPEARANCE: The species forms cushion- or plate-to spreading sheet-like colonies, to 7cm in maximum dimension and 1cm thick, with irregular borders. The upper surface is often even and horizontal. A colony from the Great Barrier Reef (QM GH5470) is a glassy dome, 6cm high, with the surface deeply divided into lobes of varying size and shape; and the specimen from Darwin Harbour (QM GH5361) has the upper surface raised into high, zooid-free round ridges between the double rows of zooids. In other parts of the colony, however, systems are more crowded. Zooids are crowded, along each side of canals that converge to a few large, sessile common cloacal apertures with irregular borders. The living specimens have translucent, slightly cloudy test coloured orange, pale apricot, 'poppy red', 'salmon' 'pinkish buff', 'yellow-buff', 'cream-buff' (Ridgeway, 1886). Zooids are crimson, 'scarlet vermilion', 'geranium red', 'scarlet', 'ruby', 'coral reef' (Ridgeway *loc. cit.*) brilliant or bright orange, or pink. When embryos are present they are a dark maroon colour. In preservative the test is translucent but cloudy, cream with pink zooids and mature eggs and embryos (but not tailed larvae) are a translucent brownish colour. Opaque white (possibly blood) cells are in the sheath of soft test around the zooids, and are crowded together to form a white band around the branchial siphon. The test is particularly soft, jelly-like, is easily torn, and the surface is smooth.

In some colonies green *Prochloron* cells and diatoms are in the common cloacal cavity, in the canals converging to them and on the outer surface of the colony. The species is one of the 5 or



a
b
c
d

6 *Aplidium* spp. which sometimes have *Prochloron* in the cloacal cavity (see Kott *et al.* 1984: *Aplidium* sp.3).

INTERNAL STRUCTURE: Zooids are small, the contracted thorax and abdomen together being about 2mm long. The posterior abdomen is short (about one-third of the total zooid length). The opaque white corpuscles that are such a feature of this species are in the body wall of the pharynx and atrial lip as well as around the base of the branchial siphon, and in the test around the zooid. The body wall is delicate with about 12 fine longitudinal muscle bands. Transverse muscle fibres are in the transverse vessels betwen the rows of stigmata.

The 6 branchial lobes are variable, but they usually are long, and are either pointed or rounded. The atrial lip, from the upper rim of the opening contains longitudinal muscles and is of various lengths. Its tip either is pointed and undivided, or is divided into 3 or 4 separate points. There are 9 to 11 rows of 14 to 20 stigmata. Twenty-two longitudinal folds are in the wall of the small stomach which is about halfway down the abdomen. The stomach folds are sometimes irregular, interrupted, and slightly oblique on the outside or ventral border of the stomach, but elsewhere they are longitudinal and parallel.

Bunched testis follicles occupy about three-quarters of the length, of the posterior abdomen, leaving the anterior quarter free of male follicles. In relaxed zooids the follicles are spread out into 2 irregular rows. A small ovary is behind the gut loop, anterior to the testis. Up to 2 embryos are in the atrial cavity of zooids collected in August from Darwin, May from the northern Great Barrier Reef, October from the Whitsunday Is, and January, April, May, August, October and November from the Capricorn Group. Some specimens from Port Hacking (AM Y815) have up to 7 embryos packed into the atrial cavity of specimens collected in June. When zooids are particularly contracted the embryos project out from the body wall in what could be mistaken for a brood pouch. The larval trunk is up to 0.9mm long, and the tail is wound about two-thirds of the distance around it. On each side of the 3 median adhesive organs, is a single arc of up to 30 large epidermal vesicles. Small conical median ampullae alternate with the adhesive organs in all except some of the smaller (0.6 to 0.7mm long trunk) and almost spherical larvae from the Capricorn Group, which also have fewer (14 to 20 rather than 20 to 30) epidermal vesicles in each lateral arc. The same opaque white corpuscles are in the larval test as those in the test sheath around the zooids, and in a band around the branchial siphon. These sometimes obscure the larval organs, especially those at the anterior end of the trunk.

REMARKS

The characteristic of this species are the opaque white corpuscles clustered around the branchial siphon and the zooid, and scattered in the cloudy, soft gelatinous test, as well as long, double row systems, numerous stomach folds, the moderately wide thoraces (with up to 16 stigmata per row), and larvae with lateral arcs of numerous (14 to 30) epidermal vesicles.

The discrepancy in larval size, and in the number of epidermal vesicles, between smaller almost spherical larvae from the Capricorn Group and the larger ones from the same as well as all other locations is puzzling. The only other difference observed is in the size (and probably the age) of the colonies. These Capricorn Group specimens, taken at low tide from rubble near the edge of the reef, are smaller than the colonies taken from other locations by SCUBA divers.

Sluiter's type specimens of *A. multiplicatum* are irregularly lobed plates 3cm in maximum diameter and 5 to 6mm thick, glassy and transparent, with the yellowish-white zooids showing through the test. Systems were not identified. Sluiter records delicate muscles, 7 rows of 10 stigmata, 18 longitudinal stomach folds and a short posterior abdomen with bunched male follicles.

Van Name (1918) reported larger specimens from the Philippines with more complex systems and 7 to 10 rows of up to 16 stigmata per row, with the same number of stomach folds (18–20) and double series of testis follicles. As in specimens of this and other species, the arrangement of the gonads and the length of the posterior abdomen changes with development of the zooid and with its state of contraction.

Aplidium multiplicatum: Kott, 1963 came from 2 locations in Queensland. Zooids from both locations are smaller than those of *A. multiplicatum* with only 6 or 7 rows of stigmata. Colonies from Sarina (AM Y1448) are specimens of *Aplidium fluorescum*. The colonies from Currumbin (AM U3994), with a layer of sand on the surface,

FIG. 90. *Aplidium multiplicatum* — **a**, part of small colony, indicating zooids along each side of the cloacal canals which converge to the common cloacal apertures (QM GH5113); **b**, zooid (QM GH5110); **c**, stomach, showing interrupted folds; **d**, larva (QM GH5361). Scales: **a**, 2mm; **b**, 1mm; **c**, 0.5mm; **d**, 0.2mm.

appear to be colonies of *A. ornatum* with circular systems and sand around the margin of the colony. *Aplidium multiplicatum*: Millar, 1963 is also wrongly assigned. The 3 specimens have circular systems, about 25 stigmata per row and 21 stomach folds. The larvae have lateral ampullae but no vesicles. It is possible that more than one species is involved. The number of rows of stigmata and number per row suggest *A. uteute* is one of the species, but the larvae and the number of stomach folds do not support that view.

Specimens assigned to *A. multiplicatum* by Tokioka (1967) also may include more than one species. In specimens only 2.0cm in maximum dimension, and not more than 1cm thick, there are some with circular, and others with more complex systems, a range of colours from 'pale brown', 'reddish brown', to 'purplish brown' (Tokioka 1967), 7 to 10 rows of stigmata, 10 stigmata per row (in zooids from Kiribati) up to 30 (larger zooids from Palau Is), and 20 to 35 stomach folds. The range in these characters is greater than could be regarded as intraspecific variation and greater than could be regarded as the effects of growth, especially when the range in colony size is relatively small. The larvae of the small colony from Kiribati, and the zooids figured from both Kiribati and the Palau Is (Tokioka 1967, Figs 8a–d, 9a,b) appear to be *A. multiplicatum*. Colonies with more numerous stigmata and stomach folds could be other species such as *A. uteute*, which resembles the present species in the colour of its zooids and embryos. However, *A. uteute* has median as well as lateral larval epidermal vesicles, more stigmata in each row and more stomach folds than *A. multiplicatum*.

Nishikawa and Tokioka (1976), Nishikawa (1990), Tokioka (1953) and Rho (1975) have assigned specimens from Japanese waters with 7 to 11 rows of stigmata, and 20 to 25 stomach folds to *A. multiplicatum*. The number of stigmata per row, and the arrangement of larval epidermal vesicles and ampullae do not fall within the ranges recorded for the present western Pacific species.

Tokioka (1953, 1967) proposed that the eastern Pacific *Aplidium californicum* (Ritter and Forsyth, 1917) is a synonym of the present species. However, the Californian species has sand embedded in the test, an atrial lip separate from the opening, fewer stigmata per row, and lacks the characteristics pigmentation of the present species (see Kott and Goodbody 1982, Nakauchi 1987, Millar 1988). *Aplidium californicum*: Monniot, 1987 from New Caledonia has the characteristic naked colony, pigmentation, stomach wall, branchial sac and larval form of *A. multiplicatum*.

In Australia *Aplidium opacum* is the species most closely related to the present one and specimens have been confused. It has similar colonies with crowded zooids in long branching double-row systems. Zooids are sheathed in a layer of soft test containing opaque white cells which are similar to those in *A. multiplicatum*, and are crowded around the branchial siphon in much the same way. The zooids also are similar, although the present species usually has more stigmata per row but fewer rows than *A. opacum*. *Aplidium opacum* has firmer test, and the larvae have long finger-like median ampullae that project between the adhesive organs, as well as a band of numerous lateral vesicles (rather than the single series arc that occurs in *A. multiplicatum*). Re-examination of some of the specimens from New South Wales and south-western Australia assigned to *A. opacum* by Kott (1963) has shown them to belong to the present species. Larvae of the south-western Australian specimen are characteristic of *A. multiplicatum* (see Kott 1963, p.110, Fig. 22). The ranges of *A. multiplicatum* and *A. opacum* overlap on the eastern and western coast, but the former is not recorded from southern Australia, and the latter species does not extend into the tropics (see *A. opacum*, below).

Kott (1963) wrongly assigned colonies of the present species and others (viz. *A. gastrolineatum*, *A. multilineatum* and *A. robustum* n.sp.) to the S. African *A. flavolineatum*.

DISTRIBUTION
NEW RECORDS: Western Australia (Rockingham, QM GH5461). South Australia (Great Australian Bight, SAM E2591; Port Bonython, QM GH4234–6, Perforated I., QM GH4194; Spencer Gulf, QM GH5440–1; Yorke Peninsula, SAM E2540 E2571 E2587; St. Vincent Gulf, SAM E2484 E2586 E2594). Tasmania (SE Fluted Cape, SAM E2589). New South Wales (Port Hacking, QM GH31).
PREVIOUSLY RECORDED: South Australia (Great Australian Bight — Kott 1975; St. Vincent Gulf — Kott

1972a). Victoria (Balnarring Beach — AM U3929 holotype Kott 1963; Westernport — Kott 1976).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are large and fleshy sometimes almost spherical or flattened upright masses to 8cm high and 6cm diameter. More often they are flat-topped, extensive cushions often with the surface partly divided. Crowded zooids are perpendicular to the surface, but posteriorly criss-cross one another in the test.

In preservative the test is soft, but firm, gelatinous and translucent white with minute opaque cells, possibly blood corpuscles, in a soft layer of test that sheaths each zooid. These opaque cells are especially crowded around each branchial aperture.

In photographs of well-developed living colonies zooids are seen to be in crowded, branching double rows, with large branching primary cloacal canals separating areas packed with zooids and secondary cloacal canals. Large, sessile common cloacal apertures are scattered over the surface at the junction of the primary canals. Zooids are cream (QM GH5441) or pink (QM GH5440). One colony (QM GH4194) is described as an 'orange morph'; and one is bright yellow (SAM E2586). At least 2 colour variants occur, both translucent, one pink or orange and one yellow or yellowish cream.

INTERNAL STRUCTURE: Zooids are relatively long and robust. The thorax and abdomen even when contracted are together up to 5mm long and the posterior abdomen is from twice to many times that length. About 15 strong longitudinal muscle bands extend from the thorax to the posterior end of the abdomen. The branchial siphon is short, often with well-developed bifid lobes. The atrial aperture, beside the third row of stigmata, has a fleshy muscular atrial lip, usually deeply divided into 3 equal, pointed lobes, from the upper border of the opening. Muscles are along the centre of each lobe, and when these are contracted the lobes are frilled and crinkled along the edges. The atrial lip is often (but not always) large and conspicuous.

Stigmata are in 12 rows with up to 12 in each row. The stomach is of moderate length with 20 narrow, sometimes interrupted folds. The thick duodenum, mid-intestine and oval posterior

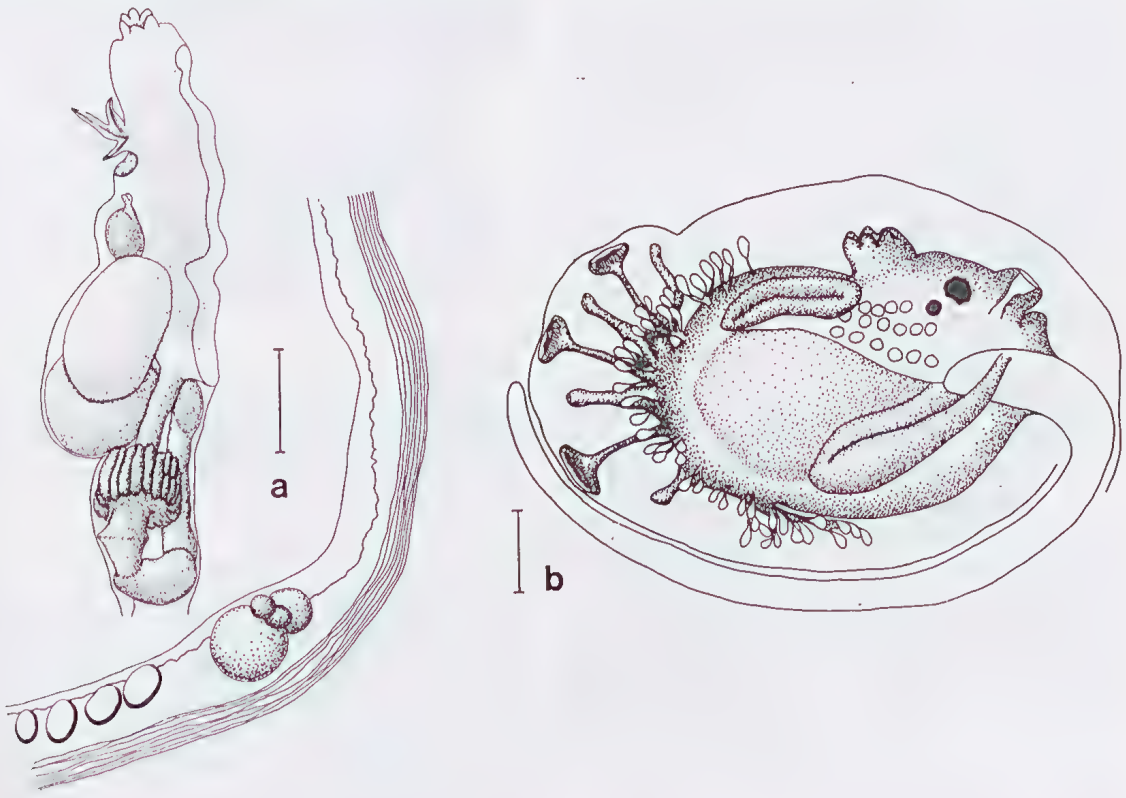

FIG. 91. *Aplidium opacum* — **a**, zooid, showing anterior part of posterior abdomen and embryos being incubated (QM GH5441); **b**, larva (QM GH4234). Scales: **a**, 0.5mm; **b**, 0.1mm.

stomach are characteristic of the genus, and there are 2 pronounced rectal caeca. Gonads are in the posterior part, or the whole of the narrow posterior abdomen, with the small ovary anterior to the long double series of male follicles.

One to 3 embryos are incubated in the top of the abdomen and in the atrial cavity, but only one at a time develops to a tailed larva. They are present in specimens from South Australia collected in February (QM GH5441 GH4234 SAM E2586), April (QM GH4236 GH4194), May (QM GH4235) and November (SAM E2571). Larvae have a trunk about 0.7mm long and a sturdy tail reaching to the anterior end of the trunk. Ectodermal vesicles (about 35) are crowded in an arc along each side of the adhesive organs. These vesicles are not in a single series, and clumps of them branch off a single stem from the larval ectoderm. Narrow, pointed, median ampullae alternate with the adhesive organs.

Remarks

Both the zooids and the large gelatinous colonies, with randomly scattered, sessile common cloacal apertures, and crowded branching systems of zooids in the present species are similar to *Aplidium multiplicatum*. These species also have in common the cloudy opaque cells in a sheath of soft test around each zooid, and about 20 stomach folds. The zooids of *A. opacum* are larger than those of *A. multiplicatum* however, and although they have the white opaque cells in a sheath around the zooids, they do not form as wide a band around the branchial aperture as in *A. multiplicatum*. The branchial sac of the present species is relatively narrower than that of *A. multiplicatum*, which has up to 20 stigmata per row but fewer than 12 rows. Larvae differ from those of *A. multiplicatum*, having long median ampullae and clumps of lateral vesicles in lateral bands (rather than a single arc of vesicles on each side).

Kott (1963) assigned several colonies to this species which have subsequently been found not conspecific with the holotype. A colony from Balnarring Beach (AM Y1401) made up of several lobes joined to a common base is probably a specimen of *A. inflorescens* (see above). The colonies from western Australia and Port Jackson (AM Y1423 Y1439) are specimens of *A. multiplicatum* as is the larva figured by Kott (1963, Fig. 22). Colonies from Tasmania with zooids in which the atrial aperture is separate from the atrial lip are also erroneously assigned to this species and appear to be colonies of a *Polyclinum* sp.

Kott (1963) assigned specimens of the present species from Cockburn Sound to *Aplidium plicif-erum* (Redikorzev, 1927). The latter species, known from coastal waters of Japan, including the Inland Sea (Tokioka 1953), has large colonies with branching double row cloacal systems as in the present species, and zooids and larvae which also appear to be similar to the Australian species. Only the stomachs are different, having from 25 to 32 fine pleats in the Japanese species, while the Australian one has 20 to 24. Thus the number of stomach folds appears to be the principal character separating these species, which are indigenous to temperate Australian and Japanese waters respectively. Despite their resemblance to one another, they apparently have different geographic ranges, and are separated from one another by the tropics.

Aplidium foliorum Kott, 1975 was thought to be distinguished by its large tripartite atrial lip. An identical lip now is known to be characteristic of the present species, although its length varies to some extent according to the position of the zooids relative to the cloacal apertures and according to their state of contraction. *Aplidium macrolobatum* has similar large lobes around the apertures, but it has sand embedded in the test, and only 5 stomach folds.

Aplidium ornatum n.sp.
(Fig. 92)

? *Aplidium multiplicatum*: Kott, 1963, p.103 (part, specimens from Currumbin).

Distribution

Type Locality: Queensland (Wistari Reef, NW corner, low tide under rubble near reef edge, coll. P. Kott 3.11.86 holotype QM GH5157).

Further Record: ? Queensland (Currumbin — AM Y3994 Kott 1963).

Description

External Appearance: The colony is small (5mm high), mushroom-shaped, with a flat top about 1cm in diameter. The diameter reduces toward the base. Sand is present around the outside of the colony but is absent from the upper surface and internally. Zooids are arranged in circular to elongate systems opening on the upper surface. The 3 or 4 common cloacal apertures are large and protruding, sometimes in the centre of a circle of zooids, but sometimes at one end of a

double row of zooids. In life the zooids are 'ruby' and the test 'isabella' coloured (Ridgeway 1886).

INTERNAL STRUCTURE: The zooids are vertical, with the long posterior abdomina extending into the base of the colony. Thorax and abdomen are together about 3mm long. The atrial tongue from the upper rim of the opening is undivided or divided into 3 pointed lobes. There are 12 rows of stigmata, and the maximum number per row is about 10, although the holotype is contracted and the exact number difficult to determine. The stomach wall is folded longitudinally into 25 folds.

Two large embryos are in the atrial cavity of the holotype. The larval trunk is 0.66mm long. In each interspace between the middle and the dorsal and ventral adhesive organs respectively, is a median ampulla with a bi-lobed lateral ampulla on each side. Dorsal and ventral clusters of numerous epidermal vesicles extend posteriorly from the anterior end of the larval trunk. The tail is relatively short, extending about two-thirds of the way around the trunk.

REMARKS

The distinctive characters of this species are its relatively narrow thorax, numerous stomach folds, and larvae with epidermal ampullae and numerous vesicles. *Aplidium incubatum* has a similar colony to the present species, but its circular systems are more regular and its larvae have median and lateral vesicles rather than the ampullae of the present species.

Aplidium multiplicatum, which it otherwise resembles in the colour of the zooids, and the bran-

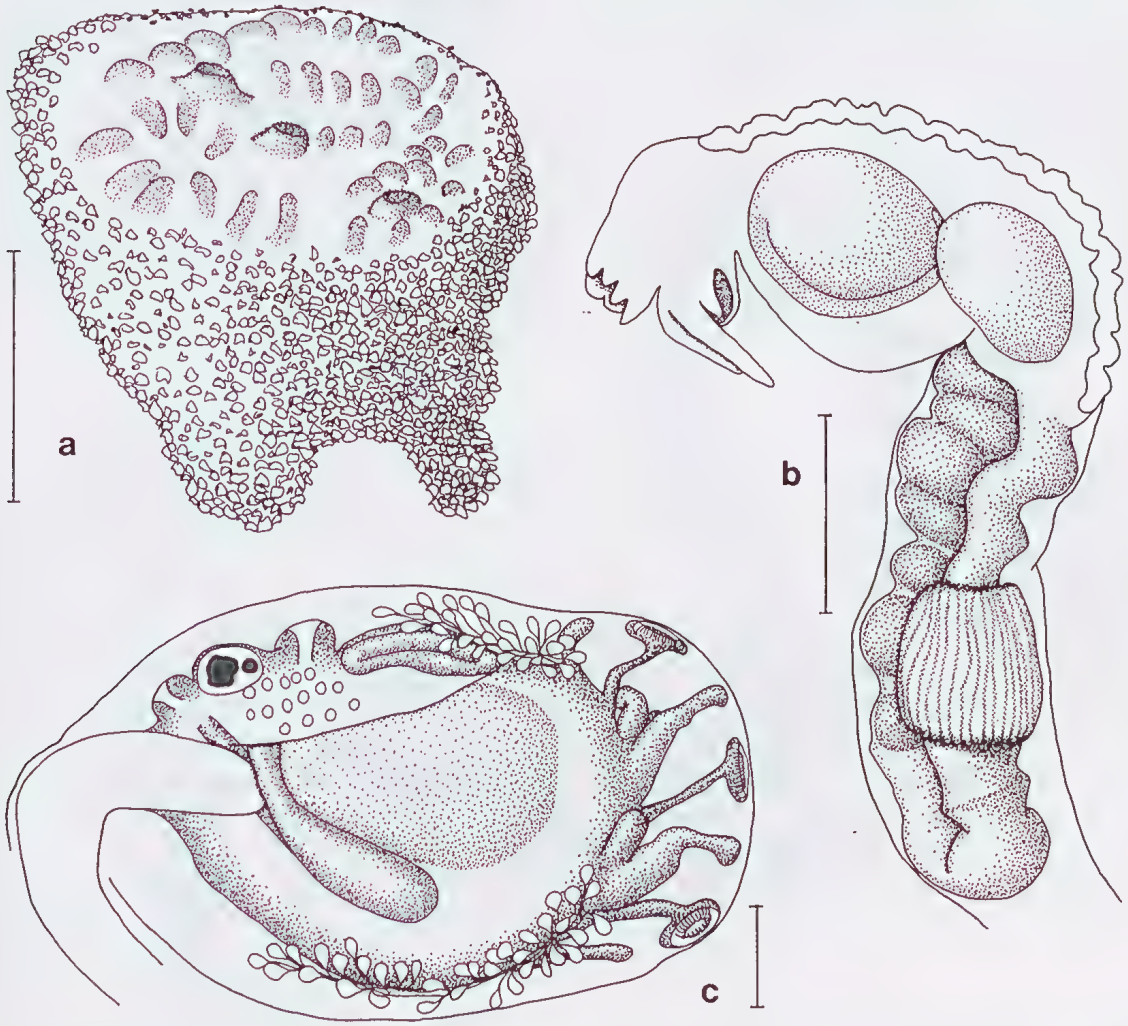

FIG. 92. *Aplidium ornatum* n.sp. (holotype QM GH5157) — **a**, colony; **b**, thorax and abdomen; **c**, larval trunk. Scales: **a**, 5mm; **b**, 0.5mm; **c**, 0.1mm.

chial sac and stomach folds, is distinguished by having single arcs of epidermal vesicles in the larval trunk, sand absent from around the border of the colony, a softer test, opaque white pigment particles around the branchial apertures and long branching double-row systems. The specimen from Currumbin assigned to *A. multiplicatum* by Kott (1963) has sand around the base and sides of the colony, but not in the upper suface or embedded. The zooids are small, contracted, and appear to be arranged in circular systems. The atrial lip is from the upper rim of the aperture, and there are 18 stomach folds. Other details of their morphology are obscured.

Aplidium uteute has numerous stomach folds, but is distinguished by its smaller circular systems, completely naked colonies, more numerous stigmata per row but fewer rows, single arcs of larval epidermal vesicles, and, usually, the absence of red pigment from the thorax. *Aplidium altarium* (Sluiter, 1909) has numerous stomach folds and colonies of similar dimensions to the present one, but the 9 or 10 rows of stigmata have about 25 per row, the posterior abdomen is short with bunched male follicles, and unlike the present species, the colony is transparent.

Aplidium paralineatum n.sp.
(Fig. 93)

DISTRIBUTION

TYPE LOCALITY: Tasmania (45 nautical mls NNE of Sister I., 39°00'S 148°25'E, 92m, sand bottom, epibenthic sled, CSIRO Statn 22, coll. W. Zeidler 14.10.84, holotype SAM E10648).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The specimen is a long (3cm), narrow cushion, broken at one end. It probably is a piece from a longer colony. A conical prominence about 1cm high with a terminal common aperture is at the other end. Zooids are in parallel double rows, a row along each side of the long, straight cloacal canals that run the length of the colony, converging to the large, sessile cloacal aperture. Long ridges separate the double rows of zooids from one another. The test is relatively soft, although sand is embedded throughout. Along the under surface the test is produced into fine root-like processes, which, with their adherent sand, create a felt-like mass holding the colony in the sandy substrate. The colony appears to have been organised in a single

FIG. 93. *Aplidium paralineatum* n.sp. (holotype SAM E10648) — **a**, colony; **b**, thorax and abdomen. Scales: **a**, 5mm; **b**, 0.5mm.

cloacal system, although there may have been a second cloacal aperture at the mutilated end.

INTERNAL STRUCTURE: The zooids are robust. However, the thorax and abdomen together are only about 3mm. The posterior abdomen is long and threadlike. The atrial tongue is relatively small, pointed, and produced from the anterior rim of the aperture. There are 15 rows of stigmata although these zooids are too contracted to determine the number in each row. The stomach is small with 5 deep folds in its wall. A single series of testis follicles are in the posterior end of the long posterior abdomen.

REMARKS

The species is distinguished by its long double row systems and sessile colonies. Similar long systems are in the stalked colonies of *A. australiense* which, however, has more numerous stomach folds than the present species.

Aplidium parastigmaticum n.sp.
(Fig. 94)

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I., reef slope 10m, coll. S. Cook 28.4.88, holotype QM GH5603).
FURTHER RECORD: Queensland (Heron I., QM GH5604)

DESCRIPTION

EXTERNAL APPEARANCE: The colonies are sessile spheres about 3cm in diameter. The test is firm and translucent, with some sand on the ridges between the systems. Living zooids are vermilion with buff coloured branchial apertures. In preservative both zooids and test are pinkish.

Zooids are arranged in circular to star-shaped systems, about 7mm in diameter. The cloacal cavity is large, with some peripheral extensions to reach the zooids in the outer periphery of each of the systems. The test is soft, and the zooids all lie parallel to one another. Sand is embedded in the basal test, but not elsewhere.

INTERNAL STRUCTURE: Zooids are large and robust, about 7mm in overall length even when contracted. In the contracted zooid the posterior abdomen is about half and the thorax is slightly more than one quarter of the total zooid length.

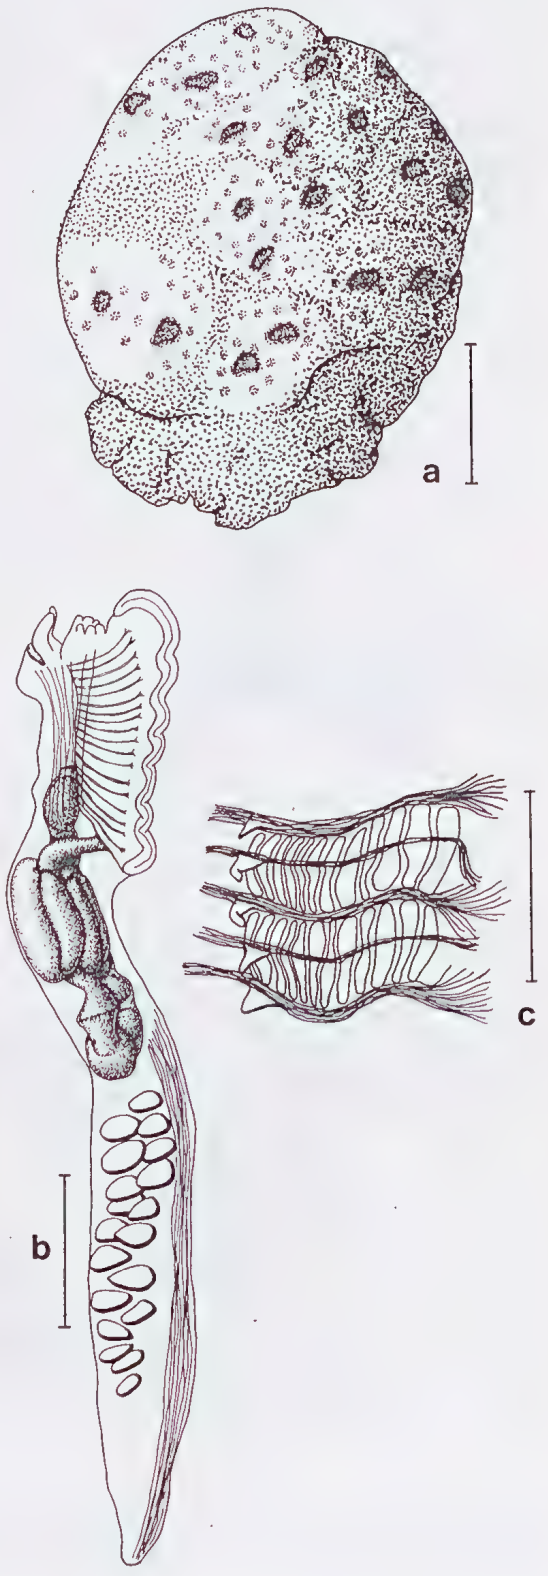

FIG. 94. *Aplidium parastigmaticum* n.sp. (holotype QM GH5603) — **a**, colony; **b**, zooid; **c**, portion of branchial sac showing muscle fibres in primary transverse and parastigmatic vessels. Scales: **a**, 1cm; **b**, 1mm; **c**, 0.5mm.

The longitudinal muscles tend to form a band in the dorsal half of each side of the thorax, and then continue in a wide band along the ventral part of the abdomen and posterior abdomen. Their contraction causes the thorax to curve around the shortened dorsum. Strong transverse muscle fibres are in the primary transverse and parastigmatic branchial vessels. They separate into short terminal branches on each side of the endostyle. The branchial aperture is 6-lobed, and the atrial aperture has a fleshy lip from the upper border of the opening. The tip of the atrial tongue is either undivided, or divided into 2 or 3 lobes. The forward pointing atrial aperture opens from a pouch

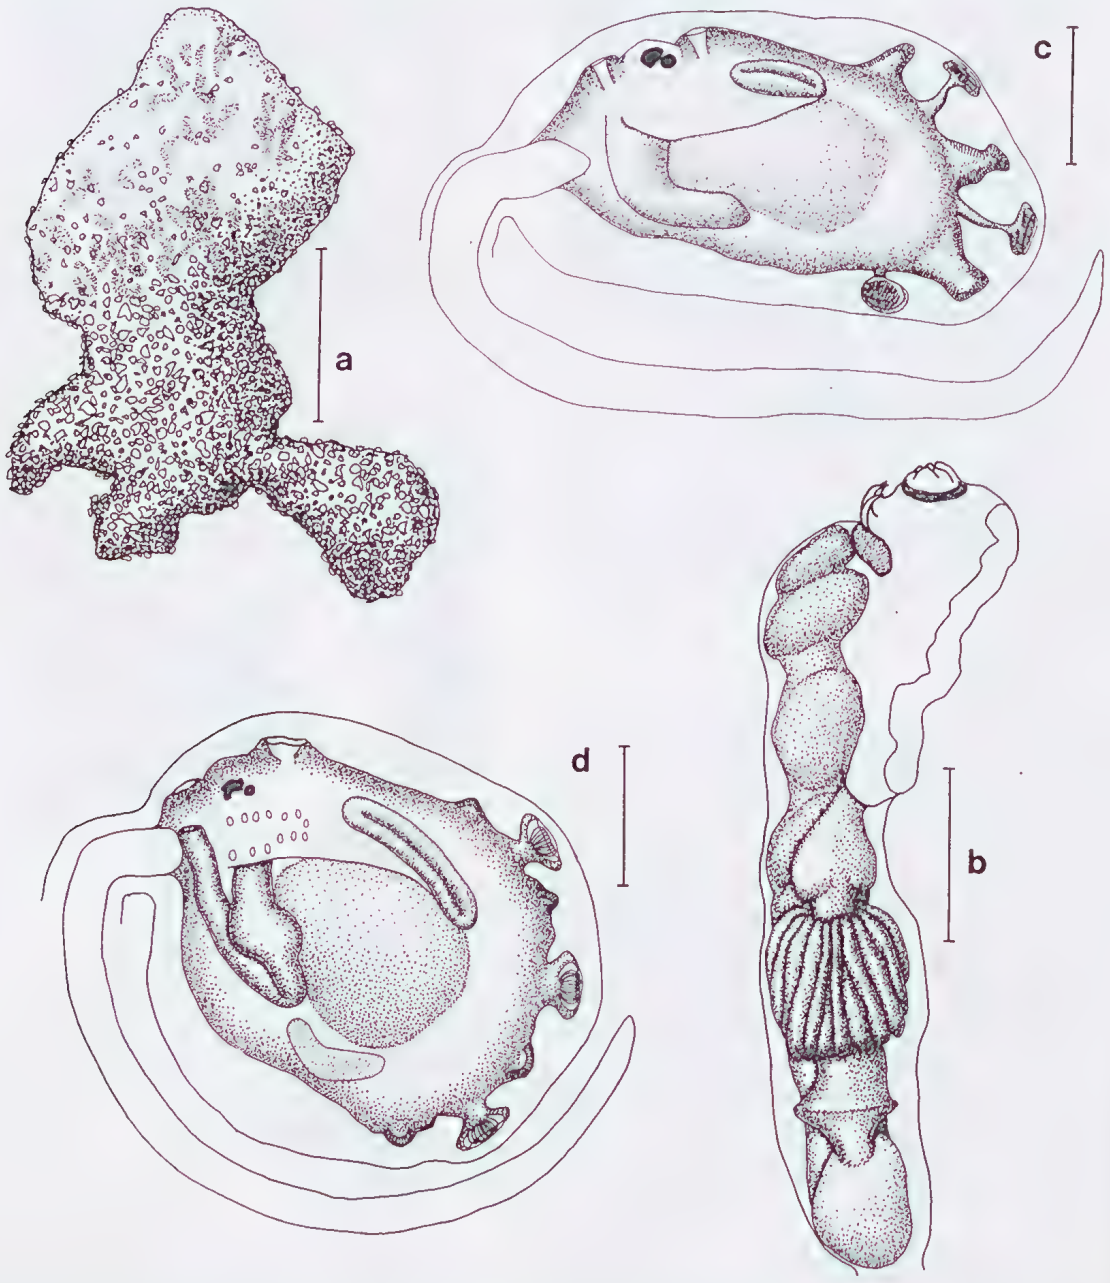

FIG. 95. *Aplidium parvum* — **a**, colony (AM Y1425); **b**, thorax and abdomen (AM Y1425); **c**, mature larva (AM Y1418); **d**, immature larva (AM Y1418). Scales: **a**, 5mm; **b**, 0.5mm; **c**, **d**, 0.2mm.

in the atrial cavity, which does not contract with the contraction of the dorsal part of the zooid. The stigmata are in 18 rows, with about 12 per row. Each row is crossed by a conspicuous parastigmatic vessel. A dorsal languet is on each parastigmatic, as well as on each primary transverse vessel.

The stomach at mid-abdominal level, has 5 distinct longitudinal folds. The male follicles are in two longitudinal series.

REMARKS

The red zooids in the translucent test resemble *A. uteute* which, however, has close circular systems (rather than the star-shaped ones of the present species) and more numerous stomach folds. The parastigmatic vessels, the atrial lip from the upper border of the opening, the pouch that forms beneath the atrial aperture when the zooid is contracted. The large stomach with 5 folds, and the parastigmatic vessels all occur in the temperate *Aplidium amorphatum* which is distinguished by its 8 branchial lobes, distinct circular systems, and poorly developed gastric folds. *Aplidium protectans*, which extends further north than *A. amorphatum* but has the same large zooid and atrial and branchial apertures, has distinct circular systems opening to depressions in the surface, and lacks parastigmatic vessels.

Some features of the present colony, such as the stellate systems, and surface sand between them, are reminiscent of *A. clivosum*. However, the atrial lip is separate from the aperture in *A. clivosum*, the zooids are larger than those of the present species and there are no parastigmatic vessels. It appears, therefore, that the colony is a member of a formerly undescribed species.

Aplidium parvum Kott, 1963
(Fig. 95)

Aplidium parvum Kott, 1963, p.112.

DISTRIBUTION

NEW RECORDS: None.

PREVIOUSLY RECORDED: Western Australia (Albany — AM Y1425 Kott 1963). Victoria (San Remo — AM Y1418 Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are small spherical transparent heads on short stalks to 1cm high overall. The zooids are arranged in longitudinal rows, converging to a common cloaca on the top of the head.

INTERNAL STRUCTURE: Zooids are small, the length overall extending to about 6mm. The posterior abdomen is up to twice the length of the remainder of the zooid. The short branchial siphon has 6 lobes around the aperture. The atrial aperture has a short, undivided lip from the anterior rim of the opening. Stigmata are in 12 rows of about 8. The short stomach has 18, mostly parallel, folds. The oesophagus has a pronounced prestomach enlargement at its distal end. Three embryos are incubated in a brood pouch that projects from the thorax in the syntypes (AM Y1418) collected in October.

The larval trunk is 0.8mm long. Anteriorly, single median ampullae are in the interspaces alternating with the adhesive organs. These median ampullae have columnar cells on them, and when well developed they become flat-ended rather than conical, the stalks of the adhesive organs become shallower and saucer-shaped, with long, slender stalks.

REMARKS

The small colonies, zooids and larvae are all distinctive. Although the systems resemble those of *A. altarium, A. geminatum, A. inflorescens* and *A. brevilarvacium*, the colonies are smaller, and stomach folds and stigmata are fewer. Like the present species the larva of *A. inflorescens* lacks epidermal vesicles. However, its trunk is about twice the length of that of the present species, and is further distinguished by the presence of lateral as well as median ampullae. *Aplidium geminatum, Aplidium altarium* and *Aplidium brevilarvacium* have different larval epidermal vesicles from the present species, and larger larval trunks (about 1mm long). Further, *Aplidium altarium* has appreciably more stigmata per row than the present species, *A. brevilarvacium* has fewer stomach folds (10), and in *A. geminatum* the stomach folds are more numerous.

Aplidium petrosum n.sp.
(Fig. 96. Plate 15d–f)

DISTRIBUTION

TYPE LOCALITY: South Australia (Cape Jaffa, Margaret Brock Lighthouse, coll. AIMS Bioactivity Group 18.2.89, holotype QM GH5454).

FURTHER RECORDS: South Australia (The Gap, QM GH4165–6; Hopkins I., QM GH4190).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are rigid, sandy, flat lamellae, about 1cm thick, which di-

vide and curve to form a large 3-dimensional maze. Zooids open on both sides of the lamellae. They are arranged along each side of cloacal canals that surround circular to elongate zooid-free areas. Common cloacal apertures are at the junctions of the cloacal canals. The test is slightly depressed over the cloacal canals in the preserved specimens. Sand is densely packed in the test and obscures the systems. Zooids, lying parallel to one another, are tightly enclosed in the test.

INTERNAL STRUCTURE: Zooids are small and slender, the thorax and abdomen together being about 2mm long. The branchial siphon is short and the aperture small with 6 short, rounded lobes. The small atrial lip is pointed or bipartite and projects from the anterior rim of the opening. Stigmata are in 9 rows with only 6 per row, in the narrow thorax. The stomach is long and narrow with 5 longitudinal folds. The posterior abdomen is about twice the length of the rest of the zooid, with male follicles in double rows; or when the zooid is contracted, drawn up into a bunch behind the gut loop.

Three embryos are being incubated in the atrial cavity of specimens collected in April (QM GH4165). The larval trunk is about 0.8mm long. Single large, conical, median ampullae alternate with the adhesive organs; which have slender stalks that expand into a cone at the base. A wide band of epidermal vesicles is along each side of the median line around the anterior half of the trunk.

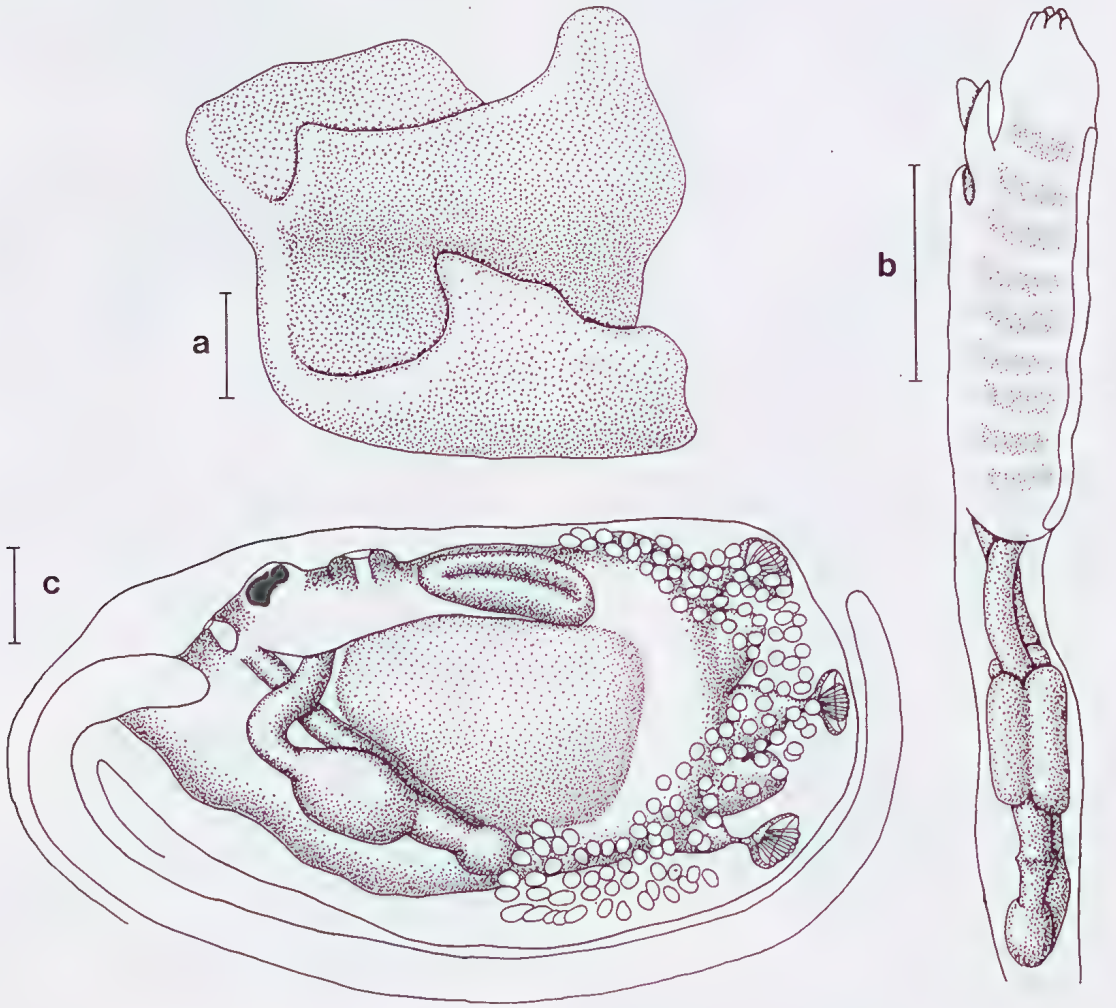

FIG. 96. *Aplidium petrosum* n.sp. — **a**, part of colony (QM GH5454); **b**, thorax and abdomen (QM GH5454); **c**, larval trunk (QM GH4166). Scales: **a**, 1cm; **b**, 0.5mm; **c**, 0.1mm.

REMARKS

Colonies forming stiff sandy lamellae are known also for *A. solidum* from the eastern and north-western coasts. They also have similar zooids, arranged in similar systems. The present species is distinguished by its more branched colony (*A. solidum* having upright lamellae rather than a 3-dimensional maze); and by the larvae which are larger than those of *A. solidum* (0.5 to 0.6mm long trunk) and have median ampullae (not present in *A. solidum*).

Aplidium ritteri have similar zooids with the atrial lip from the upper rim of the opening, but also have smaller larvae than those of the present species and long straight cloacal canals.

(Fig. 97. Plate 16a,b)

Amaroucum protectans Herdman, 1899, p.73.
Aplidium protectans: Kott, 1963, p.102.
Aplidium longithorax Monniot, 1987, p. 525.

DISTRIBUTION

NEW RECORDS: Queensland (Capricorn Group, QM GH5562 GH5574; central Great Barrier Reef, QM GH5362 GH5378; Lizard I., QM GH332 GH5553 GH5611–2; far nothern Great Barrier Reef, QM GH5336).

PREVIOUSLY RECORDED: New South Wales (Montague South — Kott 1963; Port Jackson — Herdman 1899). New Caledonia (Monniot 1987).

The species is recorded from 0 to 100m depth.

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are firm, gelatinous naked domes, spheres or cushions 2.5cm to 6cm in maximum dimension. The test is translucent both living and in preservative, and the zooids are pink, yellowish or orange. Circular systems, each of from 10 to 16 zooids are evenly distributed around the outer surface of the colony, and are slightly depressed into the surface in preserved colonies. The common cloacal apertures are in the central of each system. Systems are well spaced and never crowded. They appear as regular daisy-like patterns over the surface of the colony.

INTERNAL STRUCTURE: Zooids are large and robust, the thorax and abdomen even in contracted specimens together being more than 4mm long, and the posterior abdomen about the same length. The branchial siphon has 8 rounded lobes, the atrial siphon is produced out toward the central common cloacal aperture and an undivided, fleshy atrial lip arises from just above the sphincter muscle in the rim of the opening. In some zooids the atrial lip appears to be part of the rim of the siphon, but in others the atrial siphon is close to, but separate from its lip. The blunt tip of the atrial lip is divided into 3 to 6 characteristically regular, short, finger-like rounded lobes. The body wall is muscular with about 20 longitudinal bands on each side of the thorax, extending along the length of the zooid in a wide lateral band on each side. Stigmata are in 18 to 24 rows with about 20 per row. The oesophagus is relatively long, opening into a long barrel-shaped stomach with 5 shallow folds about one third of the way down the abdomen. When contracted the stomach wall tends to be drawn into horizontal folds. There is a short thick duodenum, but the remainder of the post-pyloric part of the descending limb of the gut loop is long, curving around in a corkscrew spiral, which may be a homologue of the posterior stomach, although it is longer than usual. A narrow, short section of mid-intestine intervenes between this thick distal end of the descending limb and the rectum. The rectal caeca are not well developed.

Two or 3 large eggs are present just behind the gut loop, separated from the pear-shaped male follicles which are in one or 2 longitudinal series in the remainder of the posterior abdomen or, if the longitudinal body muscles are sufficiently contracted, bunched. Up to 3 embryos, brown in preservative, are lined up in the posterior part of the atrial cavity of specimens collected in August (QM GH5362) and tailed larvae are present in colonies from Lizard I. collected in June (QM GH5553). The larval trunk is 0.8–0.9mm long. It has single median ampullae between and dorsal and ventral to the adhesive organs, and 4 clusters of epidermal vesicles, one on each side of the dorsal and ventral mid-lines behind the adhesive organs.

REMARKS

The large zooids in conspicuous circular systems, larvae with median ampullae and ventral and dorsal clusters of vesicles, and fleshy colonies are characteristic. Kott (1963) also noted the tendency for the stomach to collapse in horizontal folds in contracted zooids from a specimen from NSW waters - which was found on a crab.

Polycitor giganteum (also found on crabs) has similar large, firm, gelatinous colonies which may be a convenient consistency for the crab to hold in place and trim to an appropriate regular size and shape.

Colonies and zooids resemble *Aplidium amorphatum* in having 8 rather than 6 branchial lobes. The present species has firmer colonies a longer thorax and abdomen, and it lacks parastigmatic vessels. Larvae, although smaller, have median ampullae and dorsal and ventral vesicles like *A. lunacratum*.

Aplidium indicum (Renganathan and Monniot, 1984) from India has a similar fleshy colony to the present species and equally shallow stomach folds. However, the small, extended zooids of the Indian species were not seen to be arranged in circular systems, and have fewer rows of fewer stigmata than the present species.

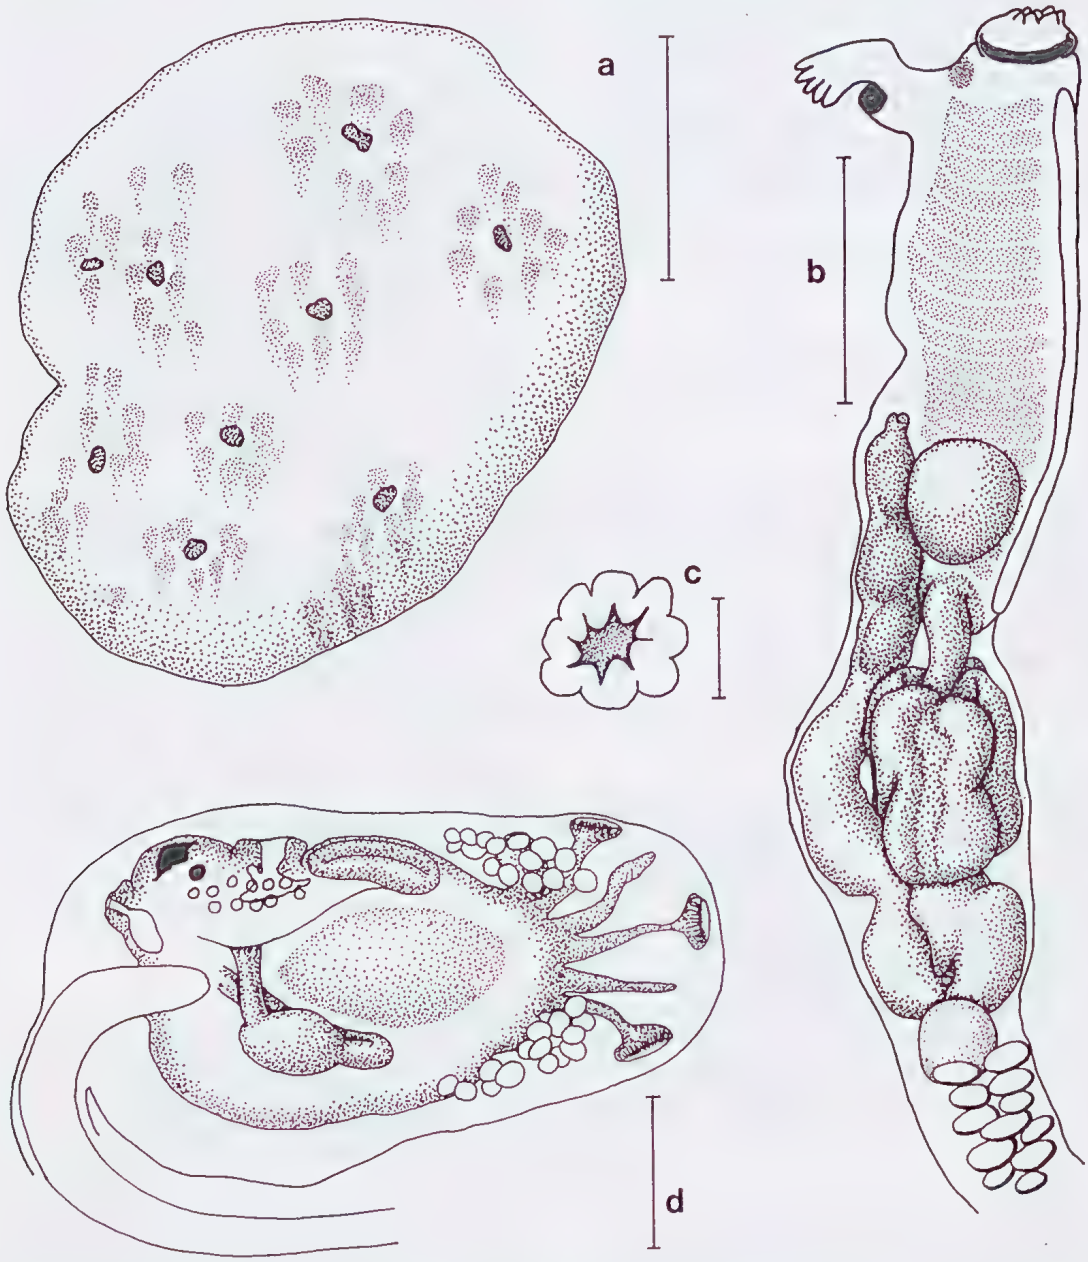

FIG. 97. *Aplidium protectans* — **a**, small colony (QM GH5329); **b**, thorax, abdomen and anterior part of posterior abdomen showing digitiform tip of atrial lip and large stomach (QM GH5553); **c**, branchial aperture from above

Aplidium lobatum: Tokioka, 1967, p.22. ? Nishikawa, 1984a, p.110. Monniot, 1987, p.525. Monniot and Monniot, 1987, p.73.

DISTRIBUTION
NEW RECORDS: Queensland (Capricorn Group, QM GH5649 GH5660 GH5685 GH5704 GH5779–81).
PREVIOUSLY RECORDED: Queensland (Torres Strait — Sluiter 1895). Western Pacific (Palau Is, New Caledonia — Tokioka, 1967, Monniot, 1987; Truk, Ponape — Nishikawa 1984a). French Polynesia — Monniot and Monniot 1987).

The species is a tropical one.

DESCRIPTION
EXTERNAL APPEARANCE: The colonies are investing sheets or lumpy and massive with a relatively even surface and sand embedded throughout. The ridges that separate the long double rows of zooids are relatively inconspicuous, and the zooid openings along each side of the cloacal canals between these long ridges often are obscured by the embedded sand. Common cloacal apertures are at the junctions of 2 or more canals. Living colonies, are described as 'sandy with pink', and 'solid, sandy'.

INTERNAL STRUCTURE: Relaxed zooids are about 3mm long. The thorax is about half the total length and the abdomen and posterior abdomen each half of the remainder. The 6 branchial lobes are well-formed and triangular. The atrial aperture is small and rounded with a short, pointed atrial lip from the anterior rim of the opening. A conspicuous bulging sphincter is behind the branchial lobes. The body muscles are strong and the short posterior abdomen is often drawn up into a short clump behind the abdomen.

Stigmata are in 11 or 12 rows of up to 8 in the narrow pharynx. The most ventral and dorsal in each row are short. The oesophagus is moderately long, and the stomach is divided into 5 by the deep folds in its wall. There is a long, narrow duodenum, narrow proximal part of the mid-intestine and an oval posterior stomach in the end of the descending limb of the gut loop.

The posterior end of the posterior abdomen is curiously flattened and straight edged. Up to 8 male follicles alternate with one another, or they are in a single series in the relaxed posterior abdomen; when the zooid is contracted they are bunched together. Male and female gonads are not present together in the one zooid. Embryos are incubated in the atrial cavity of specimens collected in November (QM GH5649) the tailed larva is small, the trunk 0.47 to 0.57mm long, with the tail wound three-quarters of the way around it. The adhesive organs are relatively deep

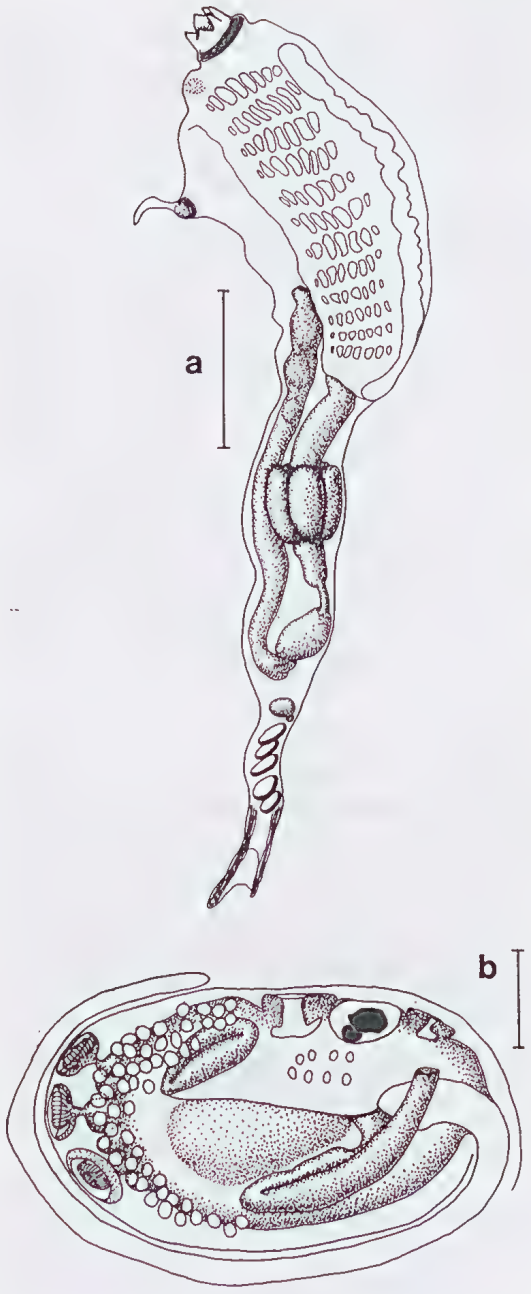

FIG. 98. *Aplidium ritteri* — **a**, zooid (QM GH5779); **b**, larva (QM GH5649). Scales: **a**, 0.5mm; **b**, 0.1mm.

axial cones in epidermal cups. The base of their stalks expand into wide cones. Short median ampullae alternate with them. The anterior end of the larval trunk is obscured by a long, wide lateral arcs of epidermal vesicles.

REMARKS

The specimens described above have all the characters of the type from Torres Strait, with the atrial lip from the upper rim of the opening, about 12 to 14 rows of 6 or 7 stigmata, 5 stomach folds, and furrows and ridges on the upper surface of the colony. The species has much in common with the Red Sea *Aplidium lobatum* Savigny, 1816 with which it often has been confused. The principal differences between these species are the larger branchial sac of *A. lobatum*, with up to 12 stigmata per row, and the division of the upper surface of the colony into more or less regular flat-topped, oval cushions, separated from one another by narrow furrows (see Michaelsen 1920). *Aplidium macrolobatum* n.sp. has a longer atrial lip, more stigmata per row, and median vesicles in the larva as well as lateral ones.

In Australian waters the temperate and east-coast species *Aplidium solidum* has much in common with the present one, having sandy colonies, the atrial lip from the upper rim of the aperture, 12 rows of up to 7 stigmata, 5 stomach folds and bunched male follicles in a short posterior abdomen with a flattened straight-edged tip. *A. ritteri* has straight rows of zooids in contrast with the curved ones surrounding circular zooid-free elevation of the test in *A. solidum*. Although this appears to be a minor difference, the larvae constitute more compelling evidence that the species are separate — the larvae of *A. solidum* lack median ampullae but their trunk length (0.4 to 0.5mm) overlaps the range in the present species.

Aplidium caelestis has similar sandy colonies, but more distinct long, double-row systems and zooids with the atrial tongue separate from the aperture.

Aplidium robustum n.sp.
(Fig. 99. Plate 16c)

Aplidium flavolineatum: Kott, 1975, p.5.

DISTRIBUTION

TYPE LOCALITY: Western Australia (King George Sound, Albany, small breaking reef, south of Mt Martin, 35°0.8'S 117°57.0'E, 2.0m, in small crevices in flat base rock, coll. AIMS Bioactivity Group 27.3.89, holotype QM GH5467; paratype QM GH5506).

FURTHER RECORDS: South Australia (Great Australian Bight — SAM E2595 Kott 1975). Tasmania (Dunnalley, TM D1866).

DESCRIPTION

EXTERNAL APPEARANCE: Colonies are sessile, spherical or conical to 8cm high and 6cm in greatest (basal) diameter. The test is soft and gelatinous, but turgid and opaque, cloudy beige in preservative. In life the colony is pink around the common cloacal apertures and white over the zooids. Zooids are in circular, oval or elongate systems around and converging to the common cloacal apertures, which are numerous, large, sessile, and scattered randomly over the surface. They are said to 'turn to slits' when the colony is touched. Sand is present on the basal surface of the South Australian specimen, which is smaller than the others.

The zooids are perpendicular to the surface but posteriorly criss-cross one another in the centre of the colony. A sheath of soft test containing opaque white corpuscles clings to the zooids.

INTERNAL STRUCTURE: Zooids are robust, the contracted thorax and abdomen together being about 3mm and about equal in length. When relaxed the thorax probably is longer than the abdomen. About 15 longitudinal muscles are on the thorax and extend the length of the zooid. The 6 branchial lobes are small and round. The atrial lip from the upper rim of the aperture has a fleshy lip divided into 2 or 3 pointed lobes, or undivided with or without smaller lobes on each side. Stigmata are in 14 to 16 rows of up to 12. The oesophagus is moderately long, and the relatively small stomach, in the middle third of the abdomen, has 20 longitudinal, parallel folds in its wall. The duodenum, mid-intestine and posterior stomach are in the posterior third of the descending limb of the gut loop. There are rectal caeca at the proximal end of the rectum.

Up to 3 embryos are in the atrial cavity of the type material, of which one may be a well-developed tailed larva. The larval trunk is long (1mm), and almost cigar-shaped. The tail reaches to its anterior end. A lateral ampulla is on each side of the conical or cylindrical median ampullae that is in each interspace between the adhesive organs. The median ampulla between the middle and ventral adhesive organs is divided into 2. A cluster of epidermal vesicles is along each side of the mid-dorsal and mid-ventral lines, but not around the anterior end of the trunk.

Up to 6 embryos are lined up in the atrial cavity of the South Australian specimen. The tailed lar-

vae are smaller (trunk 0.8mm long) and the lower median ampulla is not subdivided but otherwise they are similar to the larvae of the type specimens.

REMARKS

The species resembles *A. opacum* in having a sheath of soft test containing opaque white corpuscles clinging to the zooids, large fleshy colonies, and the same number of stomach folds. However zooids of the present species are more robust than those of *A. opacum*, with more rows of stigmata. They also have a larger larva with lateral ampullae and fewer vesicles than *A. opacum*.

The present species has larger opaque white cells around the zooids and firmer test than *A. multiplicatum*, and it lacks the characteristic single arc of lateral vesicles in the larval trunk.

In the distribution of epidermal vesicles this species resembles *A. ornatum* from tropical waters, although the latter species is smaller than the present one and is a different shape.

The smaller colony (*A. flavolineatum*: Kott, 1975) from South Australian waters with a layer of sand on its under surface and smaller larvae than the type may be found not to belong to the present species. However, at this stage it is possible that its differences represent no more than intraspecific variation. It was assigned to *A. flavolineatum* by Kott (1975) on the basis of its large number of stomach folds. However, the South African species has more numerous larval lateral ampullae and a brood pouch.

Aplidium gastrolineatum has many characters in common with the present species, but its common cloacal apertures are protuberant rather than sessile, and its larvae are different.

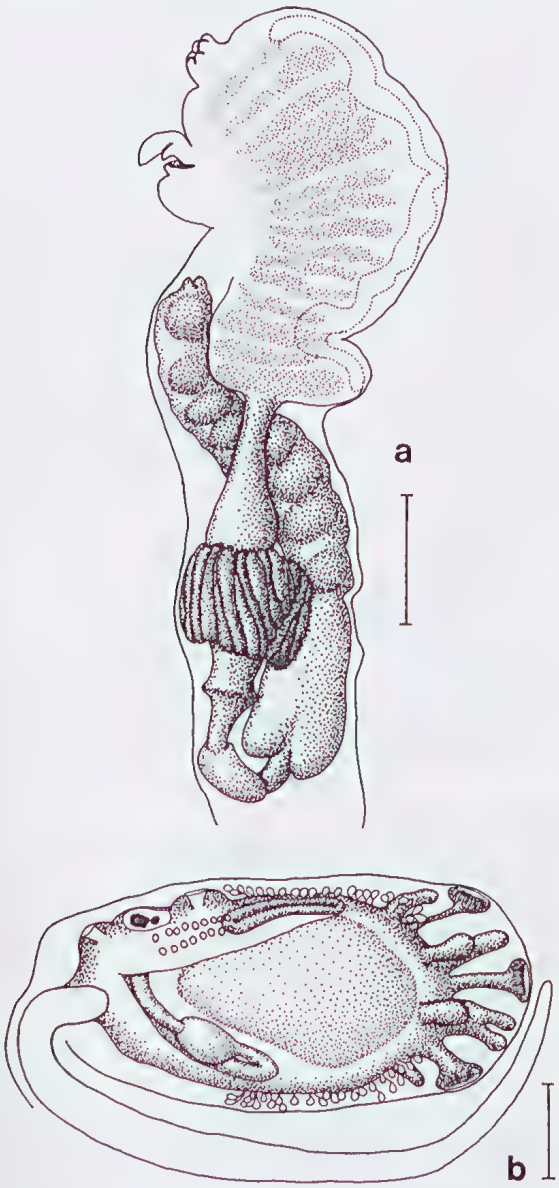

FIG. 99. *Aplidium robustum* n.sp. (holotype QM GH5467) — **a**, thorax and abdomen; **b**, larva. Scales: **a**, 0.5mm; **b**, 0.2mm.

Aplidium rosarium n.sp.
(Fig.100)

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I., Blue Pools, rubble fauna, low tide, coll. P. Kott 8.8.82, holotype QM GH 5224).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The firm, gelatinous colony is wedge-shaped, with a little sand embedded basally. When living the holotype was rose-purple, but in preservative it is white and cloudy, with beige-pink zooids. Zooids are along each side of long canals converging to the cloacal apertures.

INTERNAL STRUCTURE: The zooids are robust, with up to 4 embryos crowded in the atrial cavity. The longitudinal thoracic muscles are strong and the thorax and abdomen of contracted zooids are together only 2mm. The 6 branchial lobes are triangular and conspicuous. The atrial lip is fleshy and arises from the upper rim of the aperture. It has a central band of longitudinal muscles that

extend into the tip, which is pointed or divided into 3 small terminal lobes.

The stigmata are in 12 rows of about 12 per row. The short stomach wall has 20 folds. The posterior abdomen is about twice the length of the rest of the zooid.

Larvae are of moderate size, the trunk being 0.6mm long, with 2 rows of stigmata in the larval pharynx. A single arc of about 20 vesicles is along each side of the median line around the anterior end of the trunk. In immature larvae, a few median vesicles branch off the tip of the median ampulla which is in each interspace between the adhesive organs. The ampullae subsequently disappear and the stalk of each median vesicle appears to be independent, and attached directly to the larval ectoderm.

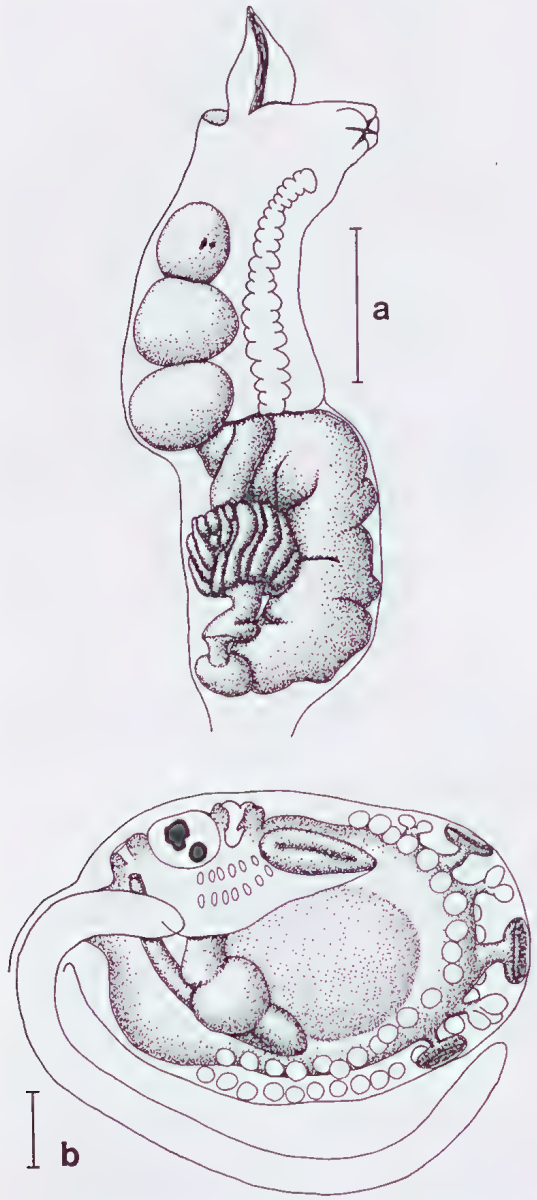

FIG. 100: *Aplidium rosarium* n.sp. (holotype QM GH5224) — **a**, zooid; **b**, larva. Scales: **a**, 0.5mm; **b**, 0.1mm.

REMARKS

Aplidium ornatum has a similar gelatinous colony, but its branchial sac is narrower and its large larvae have posterior vesicles and median and lateral ampullae, and lack the anterior arc of lateral vesicles that is present in *A. rosarium*. The larvae resemble those of *A. filiforme*, but colonies differ, and the zooids have more rows of stigmata.

The present species has some affinities with *A. altarium* but its larvae are smaller, the pharynx narrower and more muscular, and the stomach smaller with fewer folds. *Aplidium uteute* has circular systems, a brood pouch and more numerous stomach folds distinguishing it from the present species. Some aspects of the larvae suggest a relationship with *A. incubatum*, however the larval trunk of the latter species is larger, has more median vesicles and, the zooids have more stigmata and stomach folds, and are arranged in circular systems. Thus, despite the fact that only the holotype is available, the species is readily distinguished from other known species.

Aplidium rubricollum Kott, 1963
(Fig. 101. Plate 16d)

Aplidium rubricollum Kott, 1963, p. 103 (part, not specimens from Western Australia AM Y1403 < ? *A. solidum*); 1972a, p.15; 1972b, p.176.

DISTRIBUTION

NEW RECORDS: South Australia (Avoid Bay, QM GH4191; Port Noarlunga, QM G9304).

PREVIOUSLY RECORDED: South Australia (Reevesby I. — AM Y1417 holotype Kott 1963; Upper St. Vincent Gulf — SAM E2579 Kott 1972a; Pearson I. — Kott 1972b). Balnarring Beach — AM Y1415 Kott 1963).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies range from small cushions investing weed or rubble to regular oval cushions to 5cm in maximum extent but never more than 1cm thick. Sand is embedded in the internal test, becoming sparse in the upper layer around the thoraces. Sometimes it is completely absent from the upper surface of the colony, but in other colonies only the test above the

systems, including the protruding common cloacal apertures, is naked. Zooids are crowded along each side of relatively short canals that converge to the protruding cloacal apertures which are scattered over the surface, about 5mm apart. Red pigment cells are said to have been present in the surface layer of test in the living and freshly preserved specimens, and the colourless zooids are conspicuous, interrupting these. In the long-preserved specimens a brownish deposit in the surface test may be the remains of these red cells.

INTERNAL APPEARANCE: Zooids are small, with 10 fine longitudinal muscles. The atrial lip has an undivided tip which becomes bidentate through the contraction of a median band of muscles. The lip arises from the body wall close to, but separate from the opening, which is on a short protruding siphon, often flattened antero-posteri-

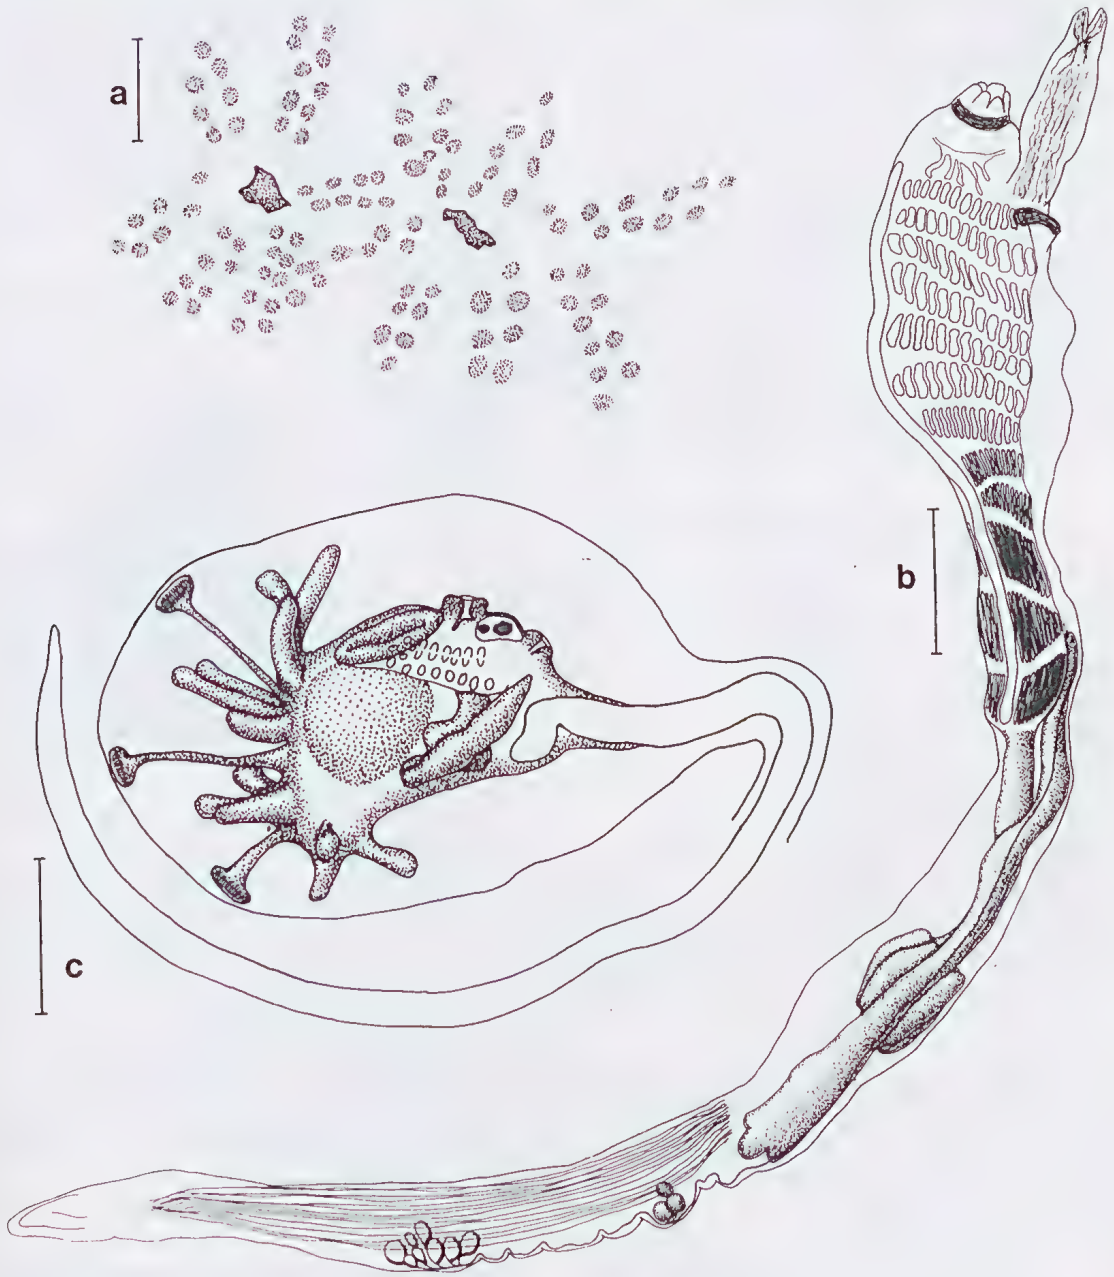

FIG. 101: *Aplidium rubricollum* — **a**, surface of colony showing 2 systems (QM GH4191); **b**, zooid (holotype AM Y1417); **c**, larva (holotype AM Y1417). Scales: **a**, 2mm; **b**, 0.5mm; **c**, 0.2mm.

orly. Stigmata are in 11 or 12 rows of up to 14. The stomach is short with 5 deep folds.

One specimen collected in February (QM G9304) and the holotype collected in December contain single, large embryos in the atrial cavity. The larval trunk is 0.7mm long. It has median and lateral ampullae, but no epidermal vesicles.

REMARKS

The systems and the colonies resemble those of *A. clivosum* except that the canals converging to the cloacal apertures are not so numerous, the zooids and systems are smaller, and the larvae lack the vesicles that obscure the anterior end of the trunk in *A. clivosum*. The zooids are small and, like those of *A. clivosum*, have the atrial aperture separate from the opening, but the present species has relatively shorter and wider thoraces with up to 12 rows of 14 stigmata while *A. clivosum* has up to 18 rows of about 12 stigmata. Colonies assigned to *Aplidium caelestis* (see above) often superficially resemble those of the present species. However, *A. caelestis* has a narrower thorax with fewer stigmata per row, the systems have longer double rows of zooids and the larvae contain epidermal vesicles.

DISTRIBUTION

NEW RECORDS: Western Australia (Dampier Archipelago, QM GH5411). New South Wales (Jervis Bay, QM GH5778; Batemans Bay, AM Y2278; Bass Point, QM GH5620; Arrawarra, QM GH5777). Queensland (Point Lookout, QM GH5782).

PREVIOUSLY RECORDED: New South Wales (Botany Bay — AM U3941 Herdman 1899; Millar 1963). Queensland (Bargara — holotype AM U3928, paratype QM G4937 *S. investum* Kott, 1963).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies form extensive rigid, sandy sheets, lobes and lamellae from about 3mm to 2cm thick. These branch and fuse with one another in a vertical plane. Along their upper border the lamellae terminate in rounded margins. The upright lobes and lamellae form when the sheet is folded, fuses back to back, and extends up in the vertical plane. Sand is embedded throughout.

Zooids appear to be fairly evenly placed and close to one another, along the sides of narrow, shallow canals. Circular or oval, raised zooid-free areas sometimes are between (or surrounded by) the double rows of zooids. Common cloacal openings are scattered over the surface of the colony at the junction of the canals. The colour of the colonies is dominated by the sand, although the zooids are pinkish in preservative.

INTERNAL STRUCTURE: The zooids are small, seldom more than 4mm even in relaxed condition. Thorax, abdomen and posterior abdomen are of about equal length. Fine longitudinal muscle bands extend the length of the zooid. A sphincter muscle is at the base of the 6 pointed branchial lobes. The small, circular atrial aperture has a small lip, undivided or divided into 2 or 3 pointed lobes, from the anterior rim of the opening.

Stigmata are in 9 to 12 rows of about 6. The long, narrow stomach has 5 folds. The posterior stomach is large, oval, at the distal end of the descending limb of the gut loop. The posterior abdomen is relatively short, with a single series of up to 7 male follicles in a single longitudinal series or sometimes bunched up behind the anterior ovary. However, even when it is not contracted, the extremity of the posterior abdomen has a truncated flat appearance. A small ovary is often present anterior to the testis follicles.

Two to 5 embryos are crowded into the atrial cavity of specimens from Botany Bay from Jervis Bay in February (QM GH5778) and from South Australia in April (QM GH4165). Larvae are small, the trunk 0.4 to 0.5mm long with the tail wound half to three- quarters of the way around it. A mass of epidermal vesicles surround the 3 median adhesive organs and obscure the anterior end of the trunk, but there are no median ampullae. The base of stalks of the adhesive organs expand into a cone.

REMARKS

Like the present species, *Aplidium acroporum* n.sp. has small zooids with the atrial lip from the rim of the opening. However it has 8 stomach

folds (rather than 5), and circular systems with zooids surrounding the cloacal cavity (rather than along each side of narrow canals).

The specimen from Rottnest I. appears to have been wrongly assigned to *A. rubricollum* by Kott (1963). Both colony and zooids resemble those of the present species except in the colour (pink with red zooids), which they have retained over a long time (40 years) in preservative. The colour of the living colony is not known. Although brown to orange living specimens of *A. solidum* are known the colour of the embedded sand dominates their

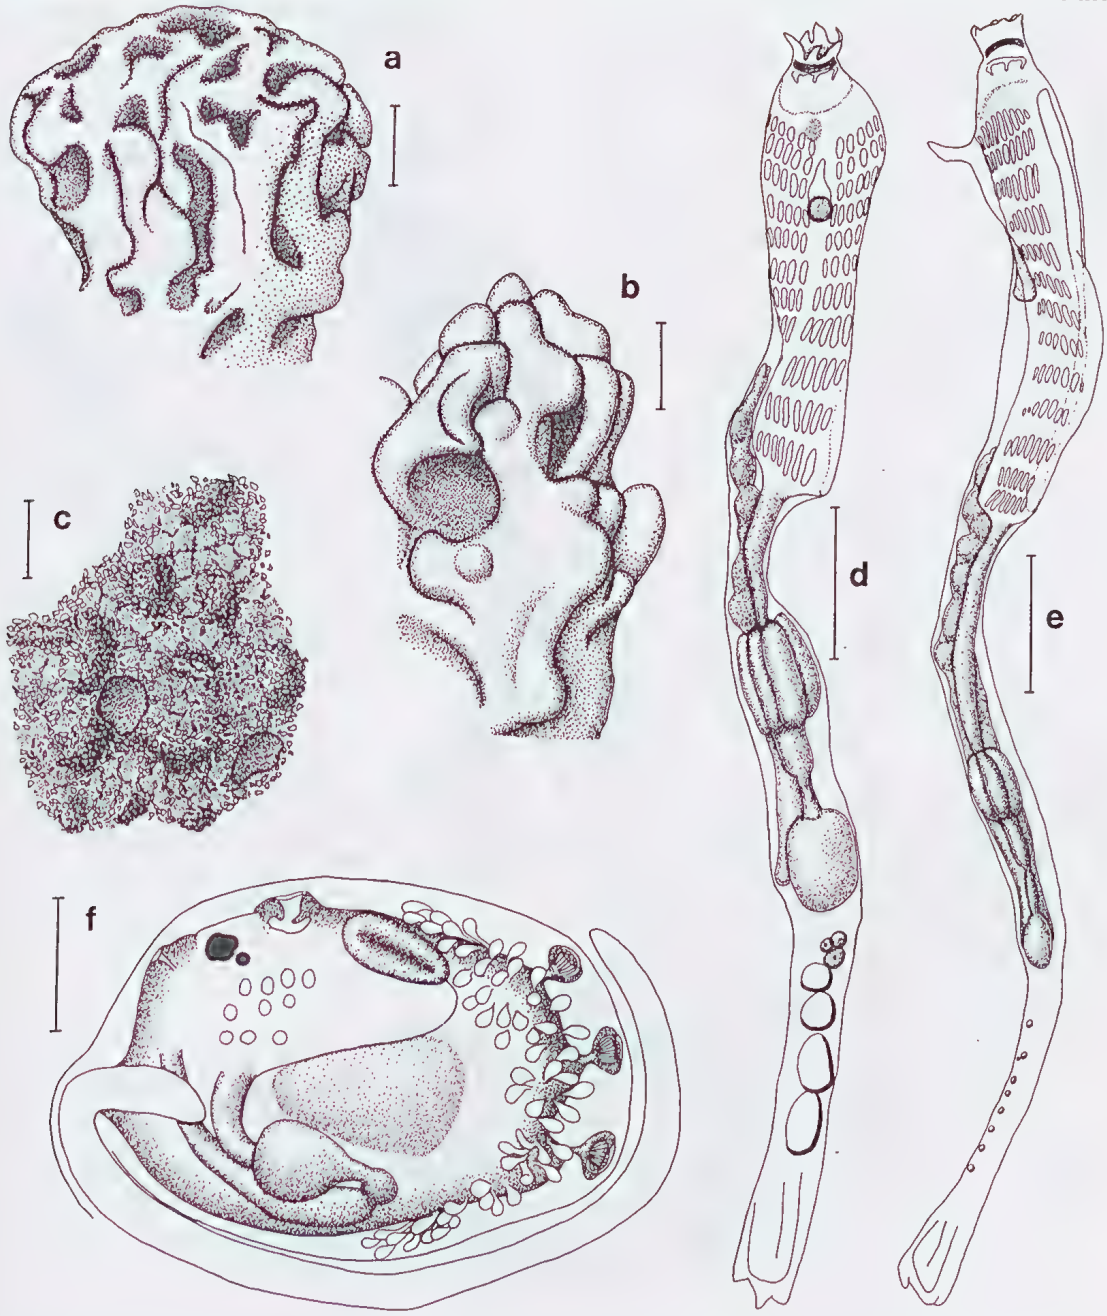

FIG. 102: *Aplidium solidum* — **a**, **b**, parts of colonies (QM G4937, AM U3941); **c**, surface of colony showing cloacal apertures at junction of the cloacal canals that surround the small zooid-free test areas (QM GH5782); **d**, **e**, zooids (QM GH5777 GH5782); **f**, larval trunk (QM G4937). e

colour in preservative. Therefore, the specimen from Western Australia is unusual and despite similarities in its morphology it may not be conspecific with *A. solidum*.

The sandy investing colonies resemble some of *Aplidium caelestis*, although cloacal canals of the present species surround circular areas rather than the long ridges of *A. caelestis*, which also has colonies that are thicker and do not fold back to form upright lamellae as they do in the present species. Further *A. caelestis*, has zooids with longer branchial siphons, the atrial lip separate from the opening, and testis follicles in a double series in a long (rather than short, truncated) posterior abdomen.

The species resembles *Aplidium ritteri* in its sand-filled colonies, small zooids with narrow thoraces, small atrial lip from the upper rim of the opening: and short, truncated and flattened tip of the posterior abdomen. The systems of *A. ritteri* are in long and relatively straight double rows, and the larvae have a trunk 0.5 to 0.6mm long, with median ampullae as well as lateral vesicles. *Aplidium petrosum* from South Australian waters has similar systems as well as similar zooids to the present species, but is distinguished by its more complex colonies and larger larvae with median ampullae.

Aplidium tabascum n.sp.
(Fig. 103. Plate 16e,f)

DISTRIBUTION

TYPE LOCALITY: Queensland (Heron I. reef, 15m, coll. N. Coleman 5.8.77, AMPI 207, holotype QM GH5208; Heron I, reef, 9m, coll. N. Coleman 16.7.73, AMPI 85, paratype QM G9726; coll. P. Fredrickson, paratype QM GH5542; Erskine I. 5–10m, coll. Roche (SLV 12) 21.3.76, paratype QM G9727).

FURTHER RECORDS: Queensland (Capricorn Group, QM G9725 GH5513 GH5543; Swain Reefs, MV).

DESCRIPTION

EXTERNAL APPEARANCE: The colonies form large fleshy mats or sheets to 7cm or more in maximum dimension. The surface has a 'marbled' appearance owing to irregularly shaped zooid-free areas of test, between and around which are slightly depressed areas where a relatively thin layer of surface test covers the cloacal canals. Sparse but evenly distributed sand grains are in the zooid-free solid parts of the test and sand grains are crowded into a line along the margins of these areas where zooids line the cloacal canals and the branchial apertures open to the exterior. Sand is also crowded around the margins and in the base of the colony, but is not present on the upper surface either over the common cloacal canals or the zooid-free areas they surround. Large common cloacal apertures are in the depressed areas over the common cloacal spaces and appear to be randomly distributed.

Sometimes the solid test areas are isolated from one another, forming islands surrounded by common cloacal cavities and zooids. In other specimens they are long and curved and meander through the colony between and around the cloacal spaces.

The colonies are a bright red-orange colour in life. Although a trace of the orange pigment at first persists in the preserved colony, subsequently they are white. In fresh material, the red pigment is in minute crowded spherical cells in the test and the zooids but these are not present in preserved specimens.

INTERNAL STRUCTURE: Zooids are small and narrow, 2 or 3mm long, although when contracted they are shorter with the posterior abdomen bunched and drawn up alongside the gut loop. The 6 branchial lobes around each branchial aperture have bands of muscles which sometimes are drawn in to subdivide the tip of each lobe. The atrial lip from the upper rim of the aperture is undivided or divided into 2 or 3 pointed lobes of varying size. Fine longitudinal muscle bands are on the thorax, and extend the length of the abdomen and posterior abdomen in a wide ventral band. The stigmata are in 15 rows with up to 8 per row. The stomach wall has 5 folds. The gut loop is relatively short. The posterior abdomen is club-shaped when the zooid is relaxed, with a long neck anteriorly and about 8 large male follicles in a single series in the expanded posterior part. When contracted, however, the testis follicles are bunched, and the posterior abdomen is drawn up alongside the gut loop. An ovary with 2 or 3 large oocytes is anterior to the testis follicles.

One or 2 embryos are in the atrial cavity of zooids collected in July and August (QM G9726 GH5208 GH5513) but none in March or December. The larval trunk is oval, about 0.6 to 0.8mm long, with the tail wound the whole way around it. On each side of the median line dorsal and ventral clusters of epidermal vesicles extend pos-

FIG. 103: *Aplidium tabascum* n.sp. — **a**, surface of colony showing almost continuous line of sand particles around each area of zooid-free test containing sparse embedded sand (QM GH5513); **b**, zooid (gut loop twisted to the left) (QM GH5208); **c**, sexually immature zooid (QM GH9725); **d**, thorax showing large bilobed atrial lip (QM GH5208); **e**, larva (QM GH5208). Scales: **a**, 1cm; **b–d**, 0.5mm; **e**, 0.2mm.

teriorly from opposite the base of the dorsal and ventral adhesive organs, respectively. These dorsal and ventral bands of vesicles are not continuous at the anterior end of the trunk. Neither vesicles nor ampullae are present in the median line between the adhesive organs. One larva found in the holotype had 5 adhesive organs instead of the usual 3.

REMARKS

The present species, based on a significant number of specimens, has a striking appearance with apparently stable characters showing little or no variability. It is distinguished by its double rows of zooids opening into depressions surrounding cushion-like elevations on its naked upper surface, the capacity to sort sand particles and arrange them around the margin of the zooid-free surface elevations, its red-orange colour, narrow thoraces, and the interruption of the band of lateral larval vesicles.

The same sort of cloacal systems, and the capacity to sort embedded sand particles and arrange them in the colony are properties of other *Aplidium* spp. (e.g. *A. caelestis*, *A. lenticulum* n.sp.). *Aplidium lobatum* Savigny, 1816 from Suez and *A. cellis* Monniot, 1987 from New Caledonia also have similar cloacal systems. *Aplidium caelestis* and *A. lenticulum* differ in having an atrial lip separate from the opening but the *Aplidium cellis* and *A. lobatum* have similar colonies, zooids and larvae to those of the present species, differing only in their embedded (and sometimes encrusting sand), smaller larval trunk (0.56mm long), and colour (white rather than red). Despite the description of *A. cellis*, the reported incrustation of sand on the upper surface (slightly less densely distributed over the cloacal canals) is not apparent in the published photograph (Monniot, 1987, Pl. 2B). Further, it is not clear whether the white colour recorded for the 2 New Caledonian specimens is their living colour, or their colour in preservative, or merely the colour of the sand encrusting them. Thus, in addition to the possibility that the New Caledonian species is a junior synonym of *A. lobatum*, *A. tabascum* could be as well.

Aplidium triggsense Kott, 1963
(Fig. 104)

Aplidium triggsensis Kott, 1963, p.104; 1976 (*A. triggiensis*) p. 61. Monniot, 1987, p.531.

DISTRIBUTION:

NEW RECORDS: Western Australia (Cockburn Sound WAM 23.84). South Australia (Pearson I., SAM E2574). Queensland (Heron I., QM GH5305).

PREVIOUSLY RECORDED: Western Australia (Triggs I. — AM U3923 holotype, Y1408 Kott 1963; Rottnest I. — AM Y1421 Y1428 Kott 1963; Nornalup — AM Y1405 Kott 1963). Victoria (Balnarring Beach — AM Y1427 Kott 1963; Westernport — Kott 1976). New Caledonia (Monniot 1987).

The Western Australian records are all from coastal habitats subjected to surf and turbulence, and the Westernport location is one where strong tidal currents prevail. A continuous temperate to tropical range is suggested by the record from Heron I.

DESCRIPTION

EXTERNAL APPEARANCE: One colony from Heron I. (QM GH5305) is an upright lobe, but usually the colonies are firm, gelatinous, investing sheets 0.5 to 0.6cm thick and 4 to 5cm in maximum extent. Varying quantities of sand are present in the basal half of the test but not in the transparent upper half. This strengthens the colony. The margins are irregular and reduced in thickness. Root-like projections from the base of the colony extend into and around particles of the substrate helping to anchor the colonies, which are found in rigorous, turbulent habitats. Zooids are crowded, conferring a reddish-pink colour on the preserved colonies. The living colony from Heron I. is reported to have been orange buff, with translucent test.

Circular cloacal apertures are randomly distributed over the surface. It is probable that the zooids are in double-row systems but this could not be confirmed in these crowded colonies. The posterior parts of the zooids criss-cross one another in the basal half of the colony.

INTERNAL STRUCTURE: Zooids are small, the contracted abdomen and thorax together being less than 3mm, although the thin posterior abdomen is up to twice that length. The branchial aperture is small, with a short siphon. The atrial aperture is a small, rounded, sessile opening with a small pointed or tridentate tongue from the upper border of the opening. The thorax has 12 wide longitudinal muscles and these extend the length of the abdomen. Stigmata are in 8 to 10 rows of up to 15. The stomach is short with 15 longitudinal folds. Testis follicles are in 2 longitudinal series, each of about 6 follicles.

One or 2 embryos are in the atrial cavity of specimens collected from Cockburn Sound in

January, Pearson I. in November, Heron I. in November, and Westernport (Kott 1976) and Western Australia in December. The larval trunk is 0.6mm long, and the tail is wound almost halfway around it. From each location larvae have from 7 to 14 small adhesive organs. These are on fine stalks expanding into cones at their base, and are in the mid-line around the anterior half of the trunk. Scattered epidermal vesicles arise in an arc from the lateral line on each side of the adhesive organs.

REMARKS

The species is distinguished by its firm colonies with sand in the basal half, its small zooids, 15

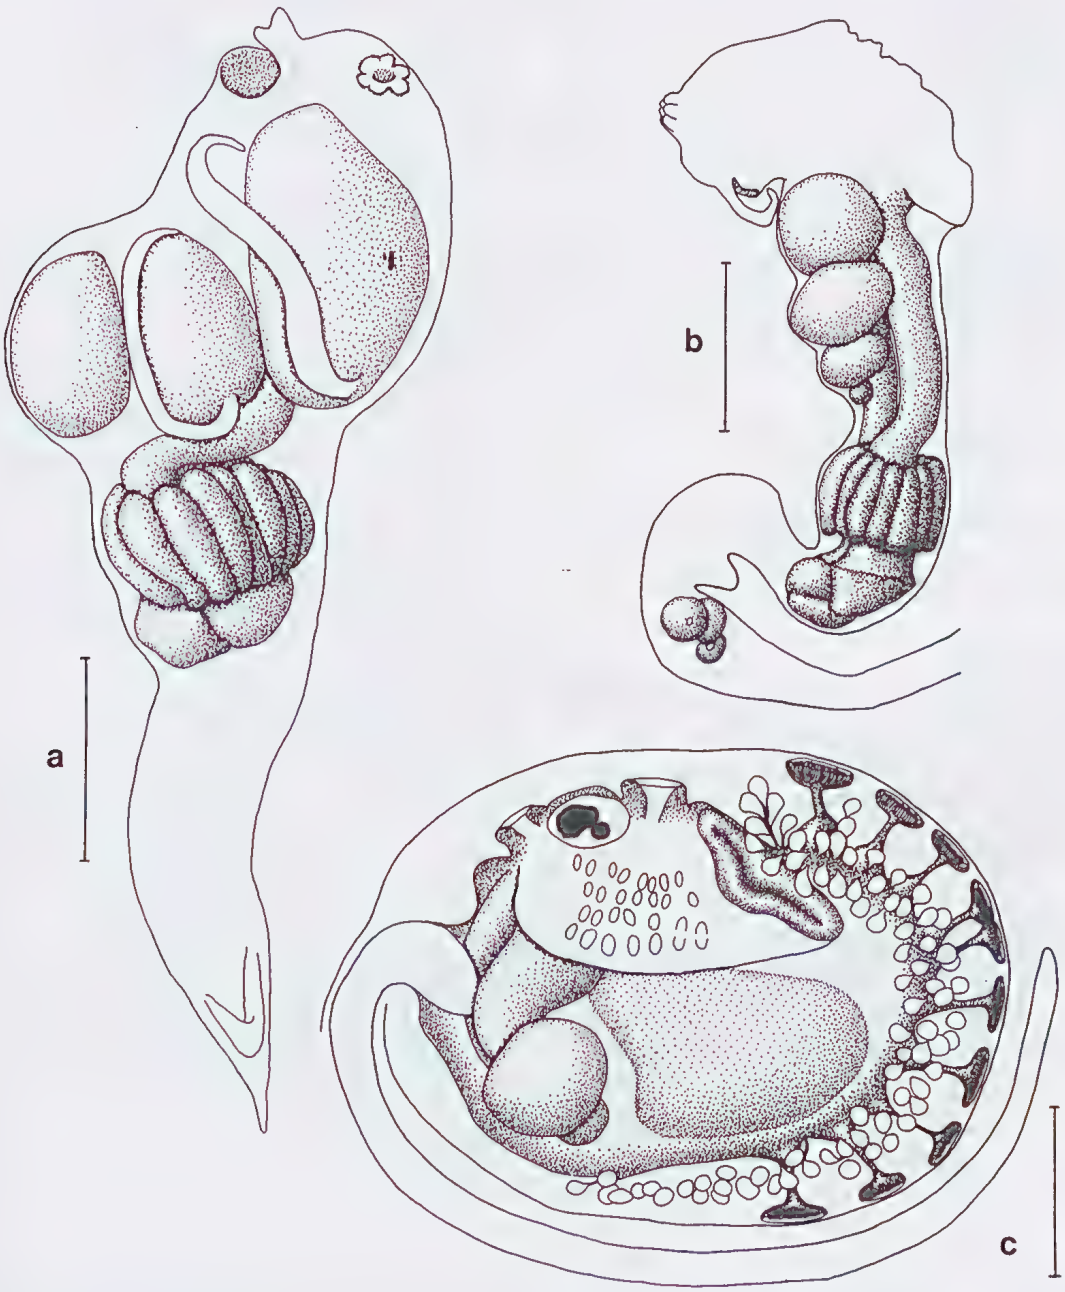

FIG. 104: *Aplidium triggsense* — **a**, **b**, zooids (WAM 23.84, QM GH5305); **c**, larva (AM Y1428). Scales: **a**, **b**, 0.5mm; **c**, 0.2mm.

stomach folds and remarkable larvae which, with 12 adhesive organs, seem adapted to make a firm adherence to the substrate in the stringent habitats from which it has been taken.

The colonies from 8cm in the lagoon, New Caledonia (Monniot 1987) are flattened lobes, joined basally, similar to the newly recorded upright lobe from Heron I.

This was previously regarded as a temperate species, but tropical records demonstrate a wider geographic range. The alternate possibility that different species are represented is not supported by the morphology of either colonies, zooids or larvae, which are all similar, with only small intrapopulation variations in size, number of stigmata, stomach folds, and adhesive organs.

Variation from the usual number (3) of adhesive organs occurs in *A. multipapillatum* Millar, 1975, from the China Sea, which has 7. It is probable that the large number in this apparently unrelated species is a convergent character, selected for in response to environmental pressures.

Aplidium uteute Monnniot and Monniot, 1987 (Fig. 105)

Aplidium uteute Monniot and Monniot, 1987, p.79.
Aplidium phortax: Kott, 1963, p. 109.
Aplidium latusexitus Monniot, 1987, p. 523.

Distribution

New Records: Queensland (Capricorn Group, QM GH1342 GH5132–48 GH5220–3 GH5313 GH5510 GH5524–5 GH5598–601 GH5610 GH5621–6).

Further Records: Queensland (Sarina — Kott 1963). Western Pacific (Solomon Is — Kott 1963; New Caledonia — Monniot 1987; French Polynesia — Monniot and Monniot (1987).

Description

External Appearance: The colonies form flat-topped cushions, to sheets fixed by a large part of the under surface, or they reduce in diameter toward the base to form flat-topped mushroom-like colonies about 1cm in maximum diameter and 0.5cm high, fixed by a small part of the under surface. The test is firm, clear and transparent in life, honey-coloured, 'rufous' (Ridgeway 1886), or colourless. It is only rarely cloudy, although it usually does become so in preservative. The living zooids, seen through the clear, transparent test, are red, 'chrome scarlet', 'buff-yellow', 'orpiment orange', 'salmon-coloured', cream with orange stomachs, or with 'orange chrome' thoraces and flesh-coloured branchial apertures, with 'geranium-coloured' or 'dragons-blood red' abdomina, and often a 'dragons-blood red' patch each side of the base of the atrial lip or between the apertures (Ridgeway 1886). Sometimes 4 lines of dark orange pigment radiate out from the branchial aperture, including one along each side of the endostyle. Embryos when these are present, are 'saturn red', 'burnt carmine' (Ridgeway loc. cit.) or maroon. In preservative the test is yellowish and translucent and the zooids white or cream. The zooids are arranged in conspicuous circular systems of 7 to 10 zooids. Sand is often present around the outer margin of the colony, but is never embedded internally.

Internal Structure: Zooids are up to 8mm long in semicontracted condition. They have large, rounded, sometimes subdivided branchial lobes and a large, fleshy, sometimes 2-lobed atrial lip from the upper border of the atrial aperture, which also has lobes around its posterior margin. Longitudinal muscles on the thorax are fine, and numerous (about 20), extending the whole length of the zooid in a wide ventral band. There are 9 to 11 rows of up to 25 stigmata in the wide thorax. The thorax is large probably exceeding the length of the posterior abdomen when it is not contracted. In preserved specimens there often is a crescent-shaped patch of greenish coagulated blood near the top of the abdomen, probably an artefact associated with the removal of the colony from the substrate.

The stomach is large and cylindrical with from 25 to 35 fine parallel longitudinal folds. The duodenal area and mid-intestine are continuous, and open into the oval posterior stomach at the base of the descending limb. A rectal valve is at the junction of the distal part of the mid-intestine and rectum at the end of the abdomen.

An ovary with up to 5 oocytes is about one-third of the distance down the posterior abdomen. The pear-shaped male follicles are posterior to the ovary, sometimes bunched but in other specimens spread out in an irregular longitudinal series. The posterior abdomen in this species is relatively short, often stumpy and only occasionally more than twice the length of the rest of the zooid.

Usually one or 2, but occasionally up to 5, embryos are in a brood pouch that projects out from, and is constricted off from, the posterodorsal corner of the thorax in zooids collected at Heron I. in May to August. The tailed larvae have a 0.65 to 0.8mm long trunk, and are deep sometimes almost spherical. The tail is wound two-thirds of the way around the trunk. Three or 4 fine,

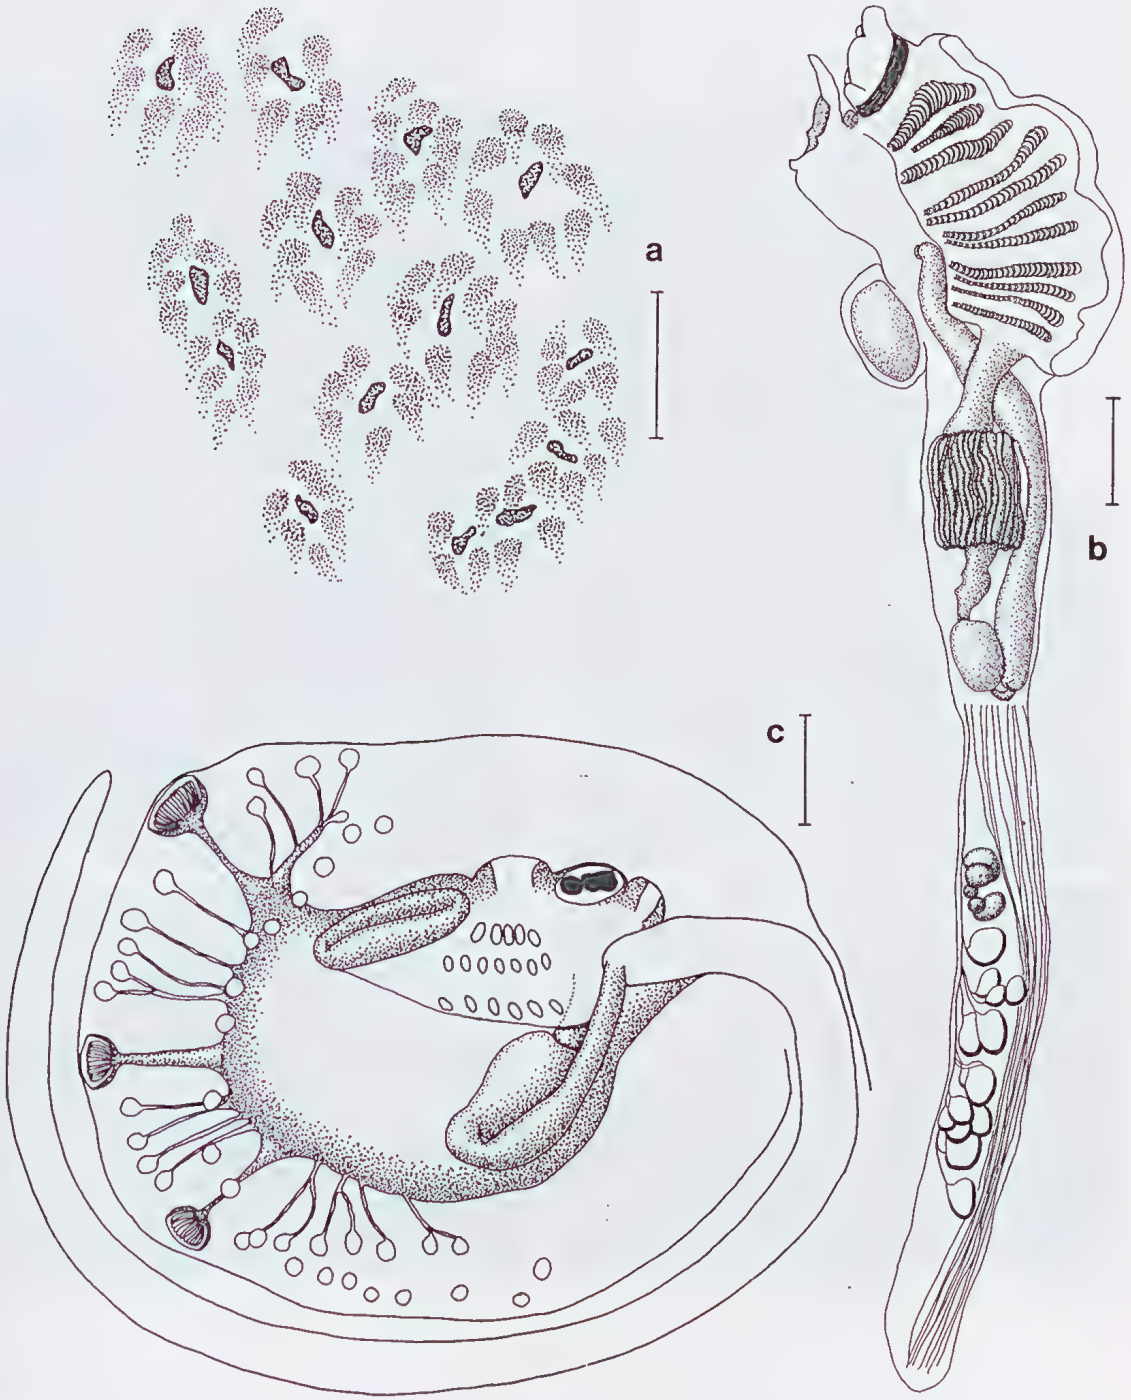

FIG. 105: *Aplidium uteute* — **a**, surface view of colony indicating systems (QM GH5134); **b**, zooid with embryos in brood pouch (QM GH5145); **c**, larva (QM GH5623). Scales: **a**, 5mm; **b**, 0.5mm; **c**, 0.1mm.

sometimes branched, stalks with terminal ectodermal vesicles extend out from the anterior mid-line in each interspace between the adhesive organs; and 20 vesicles develop in the same way from each lateral line around the anterior end of the larva. There are 3 rows of stigmata and a large ocellus and otolith in the cerebral vesicle.

REMARKS

The characteristics of this species are its transparent test, conspicuous circular systems, wide thorax, relatively long cylindrical stomach with numerous folds, postero-dorsal thoracic brood pouch, deep larval trunk with median epidermal vesicles alternating with the adhesive organs, and arc of about 20 vesicles along each lateral line. Stomachs are orange, some red pigment in the zooids, embryos and larvae are maroon-coloured.

The Australian material appears to be conspecific with *Aplidium uteute* Monniot and Monniot, 1987 from French Polynesia which has a similar stomach, large atrial aperture with the upper rim produced into a large lip, embryos incubated in a brood pouch constricted off from the thorax, red pigment each side of the neural complex, and apparently circular systems. The number of rows of stigmata are the same but unfortunately the number per row is not recorded for the Polynesian material. The number of stomach folds of the Polynesian type is said to be 50, but the number shown in Fig. 28 (Monniot and Monniot 1987) appears to be no more than 35. Monniot and Monniot (1987, Planche V-H) compared the species with a range of probably unrelated specimens assigned by various authors (Tokioka 1953, 1967a; Kott 1972, 1975; Nishikawa 1984a) to *A. pliciferum* Redikorzev, 1927 from the northwestern Pacific. *Aplidium uteute* is readily distinguished from these by many characters. However, there are others that appear to have closer affinities with which it was not compared.

Aplidium latusexitus Monniot, 1987 has circular systems, and, like *A. uteute*, red pigment patches each side of the neural gland, a large atrial aperture with a large lip, 10 rows of stigmata with up to 28 per row and lateral as well as median epidermal vesicles in the larva. Monniot (1987) has discussed its relationship with *A. multiplicatum* (*A. californicum*: Monniot 1987), but not with *A. uteute* with which it appears to be synonymous. *Aplidium uteute* is readily separated also from *A. multiplicatum* by its larvae, the form of the systems, the number of stigmata per row (i.e. the width of the thorax), and the consistency of the test.

Kott (1963) assigned specimens of the present species to *Aplidium phortax* (Michaelsen, 1924) from New Zealand. However, despite similarities in the colonies and brood pouches, *A. uteute* has a wider thorax than the New Zealand species which has only 9 or 10 stigmata per row. The larva of *A. phortax* is not known.

Aplidium flavolineatum (Sluiter, 1898) from South Africa (see also Millar 1962) has zooids arranged in conspicuous round to oval systems, and embryos incubated in a brood pouch slightly constricted off from the thorax. Michaelsen (1934) thought it was synonymous with *A. phortax*, however *A. flavolineatum* differs from both *A. phortax* and the present species by having embedded and encrusting sand, generally more stomach folds (although the numbers overlap, and the stomachs are a similar shape) and by usually being a red colour in life. Also, *A. flavolineatum* incubates up to 4 embryos in the brood pouch and has a larval trunk of 1mm with median ampullae and some large lateral vesicles or ampullae (Millar 1962); while *A. uteute* has a larval trunk less than 0.8mm long with more numerous epidermal vesicles.

Aplidium flavolineatum: Monniot, 1987, has circular systems, brood pouch, and stomach resembling those of the present species. However the larvae, found in the single colony that Monniot described, have fewer epidermal vesicles than *A. uteute*. These vesicles, like those of *A. altarium* remain attached to the trunk epidermis. *Aplidium altarium* also has a large number of stomach folds, but is distinguished by its converging double row systems.

Aplidium ornatum is another species with large numbers of stomach folds, but its larvae lack the long arcs of evenly spaced epidermal vesicles that characterise the larvae of the present species.

THE AUSTRALIAN ASCIDIACEA, SUPPLEMENT 2

PATRICIA KOTT

Kott, P. 1992 10 01: The Australian Ascidiacea, Supplement 2. *Memoirs of the Queensland Museum* 32(2): 621–655. Brisbane. ISSN 0079–8835.

Information from newly examined material and recently published reports supplements that in the continuing review of the Australian Ascidiacea (Kott 1985, 1990a, 1990b, 1992). Recorded ranges of *Sigillina fantasiana*, *Hypsistozoa distomoides*, *Polycitor obeliscus*, *Polycitorella coronaria*, *Exostoma ianthinum*, *Botryllus stewartensis*, and *Pyura rapaformis* are extended; the known depth range of *Pseudodiazona claviformis* increased; *Pycnoclavella aurantia*, *P. elongata*, *Distaplia prolifera* and *Eudistoma aureum* are now recorded from outside their type localities; new colour patterns and morphological variations are recorded for *Clavelina pseudobaudinensis*, *Pycnoclavella diminuta* and *P. elongata*; and larvae of *Pycnoclavella aurantia* and *Polycitor calamus*, described for the first time, are characteristic of their respective genera. A new species of the deep water genus *Protoholozoa* is from 7 to 15m off the southern Australian coast. A new species of *Cystodytes* has unusual spicules in a layer beneath the surface test, and one in *Polyandrocarpa*, indigenous to the central eastern Australian coast, forms colonies to a metre in maximum extent. A new *Cnemidocarpa* species has a large number of gonads, and another has only 3 branchial folds on each side.

Western Pacific species of *Ascidia* (1), *Ecteinascidia* (2), and *Pyura* (1), in the Australian fauna are found to have representatives in the component of the New Caledonian fauna previously supposed to be indigenous. The relationships and geographic range are discussed of a further 13 stolidobranch and phlebobranch species, including 4 believed to be pantropical, and abyssal *Asajirus indicus* and *Oligotrema psammites* of the Hexacrobylidae.

☐ *Ascidiacea, Aplousobranchia, Phlebobranchia, Stolidobranchia, Protoholozoa, Hexacrobylidae, Western Pacific.*

Patricia Kott, Queensland Museum, PO Box 3300, South Brisbane, Queensland, 4101, Australia; 13 May, 1992.

Australian ascidians in the suborders Phlebobranchia, Stolidobranchia and Aplousobranchia (excepting the family Didemnidae) have been reviewed by Kott (1985, 1990a and 1992). Morphological, taxonomic, phylogenetic and geographic information additional to that in the first part (Kott 1985) is presented in an initial supplement (Kott 1990b). This, the second supplement, complements parts 1 and 2 (1985 and 1990a). This information is presented only when it expands known geographical range, the known morphological parameters of the taxon, or where new phylogenetic insights are available from newly examined material or recently published accounts of the western Pacific fauna, as in Nishikawa (1984, 1986), Monniot and Monniot (1987, 1990, 1991), and Monniot, C. (1987a,b, 1988, 1989, 1991a,b).

A number of Australia's tropical species are discussed here, specifically in relation to their affinities with New Caledonian populations. The ascidian fauna of the western Pacific has been relatively well studied as evidenced by the works – cited below and in Kott (1985, 1990a, 1990b) – of Sluiter, Van Name, Tokioka, Nishikawa, Kott, Vasseur, Millar, and C. and F. Monniot. From these works it is clear that Fiji, the Tokhara Is in southern Japan, Indonesia, other western Pacific locations and tropical Australia share a common fauna which sometimes extends into the Indian Ocean (see Kott 1985, 1990a, 1992). In particular, the north eastern Australian coast and the Great Barrier Reef can be said to be part of the western Pacific region.

The reports of C. and F. Monniot (1987–91) on the ascidians taken in the French 'vaste programme d'exploration' (Monniot, C. 1987a, p. 3) around New Caledonia propose new species suggesting a larger indigenous fauna than has been found previously in this or any other western Pacific location. Comparison of a number of these species, however, with related ones in tropical Australia and other western Pacific locations has shown them not to be distinct. Differences reported between New Caledonian and other populations lie within the range of intraspecific variability that is a property of all biological material. This variability is associated with age

differences, intraspecific population differences, differences between genotypes, ecological differences in growth form or pigmentation, and differences due to artefacts associated with the collection and preservation of the material. The status of morphological differences has sometimes been difficult to determine where neither intraspecific variation nor the number of specimens examined is indicated. Thus, in some, but not all, cases intraspecific differences can be confused with the genetic differences indicating isolation and speciation.

A further problem in resolving some of these problems is the relationship between apparently conspecific populations in the tropical eastern Atlantic and western Pacific — where distance and other geographic barriers would appear to preclude gene flow (see *Ascidia archaia*, *Perophora multiclathrata*, *Polycarpa aurita*, and *Cnemidocarpa areolata*, below).

Museum registration numbers are given for all examined material. Abbreviations used are AM (Australian Museum), SAM (South Australian Museum), QM (Queensland Museum), MV (Museum of Victoria). For detailed data on distribution of each taxon the registers of relevant Australian Museums must be referred to.

The following taxa are discussed below:

DIAZONIDAE
Rhopalaea crassa (Herdman, 1880)
Pseudodiazona claviformis (Kott, 1963)

CLAVELINIDAE
Clavelina pseudobaudinensis (Kott, 1976)

PYCNOCLAVELLIDAE
Pycnoclavella aurantia Kott, 1990a
Pycnoclavella diminuta (Kott, 1957)
Pycnoclavella elongata Kott, 1990a

HOLOZOIDAE
Sigillina fantasiana (Kott, 1957)
Sigillina grandissima Kott, 1990a
Distaplia prolifera Kott, 1990a
Hypsistozoa distomoides (Herdman, 1899)
Protoholozoa Kott, 1969
Protoholozoa australiensis n.sp.

POLYCITORIDAE
Cystodytes ramosus n.sp.
Polycitorella coronaria F. Monniot, 1988
Polycitor calamus Kott, 1990a
Polycitor obeliscus Kott, 1957
Eudistoma aureum Kott, 1990a
Exostoma ianthinum (Sluiter, 1909)

ASCIDIIDAE
Ascidia archaia Sluiter, 1890
Ascidia liberata Sluiter, 1887

PEROPHORIDAE
Perophora multiclathrata (Sluiter, 1904)
Ecteinascidia diaphanis Sluiter, 1885
Ecteinscidia nexa Sluiter, 1904

STYELIDAE
Cnemidocarpa amphora n.sp.
Cnemidocarpa areolata (Heller, 1878)
Cnemidocarpa intestinata Kott, 1990
Cnemidocarpa tribranchiata, n.sp.
Asterocarpa humilis (Heller, 1878)
Polycarpa contecta (Sluiter, 1904)
Polycarpa aurita (Sluiter, 1890)
Polyandrocarpa colemani n.sp.
Botryllus stewartensis Brewin, 1958

PYURIDAE
Pyura albanyensis Michaelsen, 1927
Pyura curvigona Tokioka, 1950
Pyura rapaformis Kott, 1990b
Herdmania momus (Savigny, 1816)
Microcosmus tuberculatus Kott, 1985

HEXACROBYLIDAE
Asajirus Kott, 1989a
Asajirus indicus (Oka, 1913)
Oligotrema Bourne, 1903
Oliogtrema psammites Bourne, 1903

Suborder APLOUSOBRANCHIA Lahille, 1887

Family DIAZONIDAE Seeliger, 1906

The family is distinguished from Cionidae by its relatively small thorax, long, straight, vertical gut loop, and epicardial sacs isolated from the pharynx. Further, although only 2 species of *Rhopalaea* are known to form colonies of not more than 2 zooids, other genera of the Diazonidae are colonial, replicating as do some other aplousobranchs by horizontal strobilation of the abdomen across the epicardium.

Lahille (1887) proposed a common ancestor for taxa with complete internal longitudinal branchial vessels, and accordingly included Diazonidae and Cionidae in the suborder Phlebobranchia. Most authors accepted this phylogeny until Kott (1969, 1985, 1990a) drew attention to the rela-

tionships between Cionidae, Diazonidae and other aplousobranch families, based on the presence of entire epicardial sacs and their regenerative role in the process of replication. In Phlebobranchia (but not in Diazonidae or Cionidae) the epicardial sacs are divided into minute vesicles that serve an excretory rather than regenerative function. Further, in phlebobranch ascidians (including Diazonidae and Cionidae) the gut loop is folded up alongside the pharynx while the aplousobranch gut loop, although sometimes horizontal and twisted, is always behind the pharynx. As pointed out by Kott (1985), the loss of internal longitudinal vessels occurs in parallel in all sub-orders of the Ascidiacea as zooids reduce in size with the evolution of replication and a colonial habit (see Perophoridae and Polyzoinae). The morphological relationships between Diazonidae, Cionidae and other aplousobranch (rather than phlebobranch) families is confirmed by their chemistry (see Hawkins *et al.* 1983).

Genus **Rhopalaea** Philippi, 1843

C. Monniot (1991a) believes that *Diazona* and *Rhopalaea* are indistinguishable. However, these genera are readily separated by the relatively primitive characters of *Rhopalaea* including its particularly large branchial sac, and relatively short oesophagus. Although the epicardium is used to regenerate parts of zooids, apparently the process is not one of spontaneous replication, for only 2 species of *Rhopalaea* are known to form colonies (see Kott 1990a). On the other hand, *Diazona* species have smaller thoraces, a generally longer oesophagus, and a prolific replicative capacity resulting in large colonies of numerous zooids.

Rhopalaea crassa (Herdman, 1880)

Ecteinascidia crassa Herdman, 1880, p.723.
Rhopalaea crassa Kott, 1990a, p.26 and synonymy.
Nishikawa, 1991, p.25.
Rhopalaea respiciens Monniot, C. 1991a, p.494.

REMARKS

Monniot (1991a) has suggested that species of *Rhopalaea* can be separated by the colour of the living test, the musculature and relative size of the thorax and abdomen. The significance of the colour differences that occur in living specimens of this species is not resolved. However Kott and Goodbody (1982), Kott (1990a) and Nishikawa (1991) have reported on a wide range of specimens of *R. crassa* and its synonyms from a wide range of locations, including type locations and have demonstrated similar variations in the musculature associated with contraction, and variations in the relative size of thorax and abdomen, apparently the result of growth, and regeneration of the thorax which appears to occur from time to time.

Colour differences appear partly regional, blue being the usual colour recorded for living specimens in the Philippines, while specimens with colourless, transparent thoraces with yellow, white and black markings, becoming yellow and opaque when the test is thicker, are recorded from eastern Australia (Kott 1990), Hong Kong (Kott and Goodbody 1982), New Caledonia (Monniot 1991a) and Japan (Nishikawa (1991). The colour of all specimens is lost in preservative.

Rhopalaea respiciens Monniot, 1991a falls well within the range of variation recorded for even single populations of *R. crassa*, e.g. from Heron I. (see Kott 1990a).

Genus **Pseudodiazona** Millar, 1963

Pseudodiazona claviformis (Kott, 1963) (Fig. 1)

Protopolyclinum claviforme Kott, 1963, p.72.
Pseudodiazona claviformis: Kott, 1990a, p.31 and synonymy.

DISTRIBUTION

NEW RECORDS: Victoria (off Cape Everard, SAM E2460). South Australia (Spencer Gulf, SAM E2547).
RECORDED RANGE: The species is known from New South Wales and the eastern end of Bass Strait to the northern Great Australian Bight. The newly recorded specimen from Cape Everard increases the known depth range from 100 to 446m.

DESCRIPTION

The newly recorded specimens confirm the morphology of this seldom recorded species.

The specimen from Spencer Gulf retains a pattern of pale grey pigment in vertical petal shaped patches forming a ring around the base of each of the siphons.

In one specimen (SAM E2460) collected in October, the numerous male follicles are bunched in the posterior end of the zooid and eggs are lined up in a single series in the oviduct. In the other specimen gonads are not mature.

Family CLAVELINIDAE Forbes and Hanley, 1848
Genus **Clavelina** Savigny, 1816

Clavelina pseudobaudinensis (Kott, 1976)

Oxycorynia pseudobaudinensis Kott, 1976, p.54.
Clavelina pseudobaudinensis: Kott, 1990a, p.58, and synonymy.

DISTRIBUTION
NEW RECORDS: South Australia (Nuyts Archipelago, SAM E2434 E2471).
RECORDED RANGE: The known range is around the southern half of the Australian continent, from Houtman's Abrolhos to Jervis Bay (NSW).

DESCRIPTION
One of the newly recorded specimens from South Australia (SAM E2434) has a long (3cm) narrow (1.3cm diameter) stalk similar to that of *C. baudinensis* (see Kott 1990a). Otherwise the zooids are characteristic of *C. pseudobaudinensis*, with median pigment patches — one between the siphons and one at the anterior end of the endostyle. Larvae are large, with the trunk 0.9mm long (0.9cm *sic*, Kott 1990a).

Family PYCNOCLAVELLIDAE Kott, 1990
Genus **Pycnoclavella** Garstang, 1891

Pycnoclavella aurantia Kott, 1990
(Figs. 2,3)

Pycnoclavella aurantia Kott, 1990a, p.71.

DISTRIBUTION
NEW RECORD: South Australia (Thorny Passage, SW Hopkins I., SAM E2422).
RECORDED RANGE: The holotype from Franklin I. Nuyts Archipelago was the only previously recorded specimen (Kott 1990a).

DESCRIPTION
Unlike the type specimen, the vertical stalks of the newly recorded one form a sandy aggregated basal mass similar to that observed previously in *Pycnoclavella tabella* Kott, 1990a. Zooids are a gold colour in preservative.

The thoraces are turned at right angles to the long axis of the abdomen, and have a terminal atrial aperture and the branchial aperture on the side of the transparent head. Stigmata are in 6 instead of the 8 rows in the type specimens.

The newly recorded specimens, collected in October, have up to 12 embryos in the atrial cavity at the terminal end of the zooid. The larvae are large, with an almost spherical trunk about 0.9mm long with the tail wound almost once around it. There is an ocellus but no otolith, 4 rows of stigmata, and 3 characteristic deeply invaginated adhesive organs.

REMARKS
Pycnoclavella arenosa (Kott, 1972b) also has 6 rows of stigmata, but its thoraces are not turned at right angles to the long axis of the zooid, the abdomina are not free of the central common test, and the thorax is narrow (with only 20 rather than 50 stigmata per row). The tropical *Pycnoclavella detorta* (see Kott 1990a) resembles the present species in the orientation of the thorax, and in having 6 rows of stigmata. There is a difference in the number of stigmata, however, *P. detorta* having only about 24 per row.

The larva is also similar to that of *P. detorta*, having the characteristic 3 inverted tubular adhesive organs and lacking an otolith. No more than 4 embryos at a time have been found in the atrial cavity of *P. detorta*, while the newly recorded zooids have up to 12. Also the larvae of *P. detorta* have 1.7mm long trunks, longer than those of the present species (1.1mm).

The newly recorded specimens confirm the separate status of the related species *P. aurantia* and *P. detorta*.

Pycnoclavella diminuta (Kott, 1957)
(Figs. 4–7)

Clavelina diminuta, Kott, 1957, p.89.
Pycnoclavella diminuta: Kott, 1990a, p.73 and synonymy.

FIGS. 1–11: *Pseudodiazona claviformis* (SAM E2547) — 1, contracted zooid. *Pycnoclavella aurantia* (SAM E2422) — 2, zooid in test showing embryos in atrial cavity (1cm excised from oesophageal neck); 3, larva. *Pycnoclavella diminuta* — 4, section of colony stalk showing vesicles and hair-like test processes (SAM E2473); 5, part of colony (SAM E2473); 6, thorax showing pigment patches around apertures (SAM E2492); 7, detail of pigment patches around atrial (left) and branchial apertures. *Protoholozoa australiensis* n.sp. (holotype SAM E2423) — 8, head of colony showing zooid arrangement; 9, part of colony; 10, zooid from ventral surface; 11, zooid, dissected down endostyle showing transverse vessels in thorax. (Scales: 1,4,10,11 — 0.5mm; 2,5,8 — 2mm; 3 — 0.25mm; 6 — 1mm; 7 — 0.2mm; 9 — 5mm).

DISTRIBUTION
NEW RECORDS: South Australia (Nuyts Archipelago, SAM E2473; Lincoln National Park, SAM E2492).
RECORDED RANGE: The species is often encountered in benthic collections from all around the Australian coast and in the Western Pacific.

DESCRIPTION
The newly recorded colonies (SAM E2473), have their stalks aggregated together into a loose sandy mass that readily distintegrates. This mass is formed by hair-like test processes from along the stalks of adjacent zooids adhering to sand particles. The usual oily-looking spheres characteristic of this species are in the test of the stalks. It is probable that the basal sandy mass was buried in the substrate, and that only the thoraces projected above the surface.

The specimen lot SAM E2492 has unusual comma-shaped pigment patches around each smooth-rimmed aperture. In preservative these patches are a brown-orange colour. Around the atrial aperture 3 of these patches are arranged symmetrically in front of the aperture (between the siphons) and one is behind the aperture. Five patches, each with its point directed posteriorly, are in a row around the ventral border of the branchial aperture. These 5 separate patches sometimes are confluent.

Despite this unique pigment pattern, the zooids are characteristic of *P. diminuta*. Similar (but not identical) pigment patches are around the branchial apertures of specimens from Exmouth Gulf (QM GH4083: Kott 1990a, Plate 6d).

Pycnoclavella elongata Kott, 1990

Pycnoclavella elongata Kott, 1990a, p.76.

DISTRIBUTION
NEW RECORD: South Australia (St. Vincent Gulf; SAM E2418).
RECORDED RANGE: The species was previously known only from type localities amongst rocky outcrops around the Nuyts Archipelago. The newly recorded specimen is from a boat ramp at 3 to 5m.

DESCRIPTION
Thoraces are dark coloured in preservative, and naked. The stalks are aggregated together to form a basal mass of parallel, vertical sandy stalks. Zooids have 11 rows of stigmata, while the type material has 14 rows. Specimens otherwise conform with the previous descriptions of this species (Kott 1990a).

Family HOLOZOIDAE Berrill, 1950
Genus **Sigillina** Savigny, 1816

Sigillina fantasiana (Kott, 1957)

Eudistoma fantasiana Kott, 1957, p.76.
Sigillina fantasiana: Kott, 1990a, p.92.

DISTRIBUTION
NEW RECORDS: Tasmania (Break Sea I. Port Davey, QM GH5504). South Australia (Spencer Gulf, SAM E2505 E2518–9; Yorke Peninsular, SAM E2485 E2488; St. Vincent Gulf, SAM E2483 E2494; Pearson I., SAM E2537).
RECORDED RANGE: The species is known from Cockburn Sound (WA) and across the southern coast of the continent to Gabo I. off the south eastern coast. The newly recorded specimen from Port Davey, southwestern Tasmania, suggests a range around that island.

DESCRIPTION
Colonies from Tasmania are small cushions with evenly distributed blue zooids and a cloudy test. Larger sheet-like colonies from South Australia, growing along *Zostera* stalks, have almost glassy test and blue pigment around the apertures.

Zooids have a characteristically short abdomen up to 3 times the length of the thorax. A relatively long vascular stolon projects from the posterior end of the abdomen. Three embryos are lined up from the top of the abdomen to the postero-dorsal part of the thorax, where the most advanced projects from the body wall. Tailed larvae are present in February (SAM E2519), July (SAM E2494), September (SAM E2483), and November (SAM E2488 E2518)

Sigillina grandissima Kott, 1990

Sigillina grandissima Kott, 1990a, p.93.

DISTRIBUTION
NEW RECORDS: South Australia (W. Great Australian Bight, SAM E2452 E2457 E2479–81 E2545).
RECORDED RANGE: The species is known from Dampier Archipelago to the Great Australian Bight, although, so far there is a gap in the records between Cockburn Sound and Eucla (SA).

DESCRIPTION
The specimens are fleshy lobes with thick fleshy stalks about the same length as the oval head. They are a very soft, pale lemon in preservative with patches of dark pigment over the neural complex and at the anterior end of the endostyle.

There is no blue pigment in the epicardial sac as described for the type material.

Zooids and larvae are characteristically large, the larval trunk 3.8mm long with a short tail that reaches only part of the way along the ventral surface. A narrow waist is behind the 2 large adhesive organs. Three broad ampullae are on each side, at the base of the thick stalks of the adhesive organs. Larvae are present in January (SAM E2480).

Genus **Distaplia** Della Valle, 1881

Distaplia prolifera Kott, 1990

Distaplia prolifera Kott, 1990a, p.122.

DISTRIBUTION

NEW RECORDS: Western Australia, (Dampier Archipelago, QM GH5399 GH5409–10 GH5413).

RECORDED RANGE: Only the holotype colony from off Port Hedland was known previously.

DESCRIPTION

The colonies are all robust sheets with spongy test. Zooids are in circular systems, slightly depressed into the surface. They are pink in preservative. Parastigmatic vessels cross each row of moderately numerous stigmata. The vertical stomach has longitudinal striations internally but is smooth externally. The gonads are in a posterior abdominal sac.

Genus **Hypsistozoa** Brewin, 1956

Hypsistozoa distomoides (Herdman, 1899)

Amaroucium distomoides Herdman 1899, p.72.
Hypsistozoa distomoides: Kott, 1990a, p.134.

DISTRIBUTION

NEW RECORD: Tasmania (W. of Mutton Bird I., SAM E2451).

RECORDED RANGE: The species is known from the Great Australian Bight to Port Jackson New South Wales. The new record from Tasmania represents the southern limits of the known range.

Genus **Protoholozoa** Kott, 1969

Type species: *Protoholozoa pedunculata* Kott, 1969.

The genus has the long posterior abdominal stolon characteristic of the Holozoidae. Its short abdomen with the gonads and gastric vesicle in the gut loop, and its 2 to 4 transverse vessels suggest an affinity with *Sycozoa* and *Distaplia*. The arrangement of the zooids in the colony, opening separately rather than in double rows, is like another holozoid genus *Sigillina*. The colonies with long, soft, cylindrical stalks, also resemble those in other holozoid genera. The genus is separated from others in this family by its reduced branchial sac lacking stigmata.

As with all stalked, separately opening species, in this family (*Sigillina* spp.), as well as in other families (Pseudodistomidae and Clavelinidae: see Kott 1990a and 1992) the atrial apertures are directed toward the terminal free end of the colony while the branchial apertures face toward the base of the stalk. The advantages of this orientation of the apertures are discussed by Kott (1989b).

Six species are now described in the genus *Protoholozoa* (see Monniot and Monniot, 1991). *Protoholozoa pedunculata* Kott, 1969 from the Antarctic and *P. anthos* Monniot and Monniot, 1991 from off New Caledonia each have 2 transverse vessels, while *P. lilium* Monniot and Monniot, 1982 (see also Monniot and Monniot 1991) from the Antarctic and New Caledonia (sympatric with *P. pedunculata* and *P. anthos* respectively) has 3 transverse vessels as has *P. pigra* Monniot, 1974 from the Azores and *P. cantarella* Monniot and Monniot, 1985 off South Africa. Most of these species have internally ridged stomachs (except *P. anthos* and a specimen of *P. lilium*, both from New Caledonia). With the exception of *P. pigra*, the colonies are stalked, with translucent test and flat-topped heads. The long atrial lip of *P. anthos* also appears unique. However many of the other characters formerly used to distinguish species appear variable, and additional material (especially of sympatric species such as *P. lilium* and *P. pedunculata* from the Antarctic, and *P. anthos* and *P. lilium*: Monniot and Monniot, 1991 from New Caledonia) is needed to establish the range of intraspecific variation and the taxonomic significance of the number of transverse branchial vessels.

The absence of stigmata is a characteristic of most ascidian taxa from deep slope to abyssal waters from which previously recorded species of the present genus have been taken. The new species described below is the only one recorded from shallow waters.

The statement that *Protoholozoa* was the only genus of the family Holozoidae not known from Australian waters (Kott 1990a) is now known to

be incorrect, although the type location of the Australian species is off the most southerly part of the Australian continent.

The family Holozoidae is represented in Australian waters by all its known genera, including 2 indigenous ones (*Polydistoma* Kott, 1990a and *Neodistoma* Kott, 1990a). *Sigillina* Savigny, 1816, *Hypodistoma* Tokioka, 1967, *Hypsistozoa* Brewin, 1956, *Sycozoa* Lesson, 1830 and the present genus (with the exception of *P. pigra*) are known mainly from the southern hemisphere (see Kott 1990a). Only *Distaplia* is a cosmopolitan genus.

Protoholozoa australiensis n.sp.
(Figs. 8–11)

DISTRIBUTION

TYPE LOCALITY: South Australia (approximately 1km NE Margaret Brock Reef off Cape Jaffa, 7 to 15m dropoff, overhangs, caverns, coll. W. Zeidler, K. Gowlett Holmes 17.2.89, holotype SAM E2423, paratype SAM E2422).

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: The colony consists of almost spherical heads up to 5mm diameter, each at the end of the terminal branch of a branching stalk up to 1cm long. The combined length of primary, secondary and terminal branches of the stalk are about 2cm. However the available specimens are only part of a colony and the total length of the colonies could be greater. Stalks are narrow, cylindrical, about 1mm diameter, firm and translucent, with a stiff outer cuticle on the lower part.

Zooids are in a single circle, parallel with one another, around the perimeter of the head of the colony. The abdomina of the zooids are uppermost around the top of the head. The atrial apertures are at the posterior end of the thoraces opening to the exterior in a circle around the outer margin of the head just behind its terminal free end. The antero-dorsal branchial apertures are in a circle at the other end of the head, around the top of the stalk. Posterior abdominal vascular stolons extend parallel to one another along the length of the stalk, running back past the endostyle from the centre of the gut loop to enter the top of the stalk.

Vegetative zooids are in the stalk and sometimes in the head in a circle around the top of the stalk near the anterior ends of the adult zooids. However, there is no sign of more than a single circle of zooids in each head, and the vegetative zooids formed in the stalk may move up to increase the diameter of a head, and/or to form systems in developing terminal branches of the stalk.

INTERNAL STRUCTURE: Zooids are delicate and transparent, 2 to 3mm long with the gut bend slightly to the left against the posterior end of the thorax. The ventral border of the thorax is longer than the dorsum so that the short branchial siphon turns dorsally. It has fine crenellations around the rim but no lobes. Circular muscles are around the branchial and atrial apertures and short bands extend laterally from each end of the atrial aperture which is a transverse slit at the posterior end of the thorax. Twelve, short, stumpy branchial tentacles are in a circle at the base of the branchial siphon. The branchial wall consists of 4 transverse vessels attached to about the ventral one third of the parietal body wall, and free for the dorsal two-thirds of their length. They are attached to the dorsum where they cross the dorsal sinus as wide transverse membranes, but there are no dorsal languets. A few longitudinal connectives run between the transverse vessels each side of the mid-dorsal line.

The oesophagus is short, and turns to the right to open into an almost horizontal smooth walled, oval stomach. The post-pyloric part of the gut forms a smooth curve from the distal part of the stomach to the anus near the atrial aperture. As in other genera of the Holozoidae (see *Sycozoa*: Kott 1990a) a spherical gastric reservoir is in the gut loop, together with 4 or 5 immature ova. However, the gonads are not mature in the type material.

REMARKS

The type species of this genus, *P. pedunculata* Kott, 1969 (from the Scotia Sea, the South Pacific Basin and the Antarctic Peninsula at from 3000 to nearly 5000m) differs from the present species in having 2 rather than 4 transverse vessels, an internally ridged stomach, a larger head with a thick fleshy stalk and zooids in rows of about 3 down the length of the head.

Protoholozoa anthos Monniot and Monniot, 1991, and *P. lilium*: Monniot and Monniot, 1991 also have a smooth stomach, but 3 rather than 4 transverse vessels, and, in the former species, a long anterior atrial lip (an unusual feature in this genus). *Protoholozoa cantrella* Monniot and Monniot, 1985 differs in its internally ridged stomach and 3 transverse vessels.

Family POLYCITORIDAE Michaelsen, 1904
Genus **Cystodytes** Drasche, 1884

Cystodytes ramosus n.sp.
(Figs. 12–16)

DISTRIBUTION
TYPE LOCALITY: Queensland (Central section Great Barrier Reef, Haslewood I., in bay, 20m, coll. AIMS Bioactivity Group 17.10.87, holotype QM GH5374).

DESCRIPTION
EXTERNAL APPEARANCE: The colony is a knobbly mass, basically cylindrical with side branches. Each cylindrical branch is about one to 2cm diameter, to 2cm long. The colony is about 5cm in maximum extent overall.

Zooid systems open into furrows and depressions on the outer surface and circular to oval or irregular raised zooid-free elevations are scattered between the surface openings of the systems. Each system consists of a circle of up to 20 zooids, surrounding a depression (rudimentary common cloacal cavity) in the surface. This depression contains the circle of atrial apertures. The circle of branchial apertures is slightly less than 1cm in diameter.

In life, photographs show the specimens to have a smooth, translucent colourless surface layer covering brownish-pink test. The surface 2mm of test is a translucent, firm and gelatinous layer of bladder cells. It covers a layer of calcareous plate-like spicules, lying parallel to the surface of the colony. The layer is only 1 spicule thick, but the spicules overlap one another slightly around their thickened, scalloped edges. These spicules are relatively pliable, consisting of deposits of granular calcareous material, rather than the hard rigid spicules of *Cystodytes dellachiajei*. Minute brown pigment cells are scattered through the test, especially in the surface layer. In the holotype the zooids are withdrawn from the surface into the central layer of test through the layer of spicules.

INTERNAL STRUCTURE:Contracted zooids are one to 2mm long. Both the branchial and atrial apertures are 6-lobed, on cylindrical siphons, the atrial siphon larger than the branchial siphon. Strong longitudinal muscles are in the body wall. Stigmata are long, arranged in 4 rows of about 12. The gut loop is vertical, with a large, smooth-walled stomach. About 5 pear-shaped male follicles are in the gut loop.

REMARKS
The species is distinguished from *Cystodytes dellachiajei* by the layer of spicules beneath the surface bladder cells, and the absence of a capsule of spicules enclosing the abdomen of each zooid.

Genus **Polycitorella** Michaelsen, 1924

Polycitorella coronaria F. Monniot, 1988
(Figs. 17–22, 43)

Polycitorella coronaria F. Monniot, 1988, p.228. Kott, 1990a, p.184 and synonymy.

DISTRIBUTION
NEW RECORD: Queensland (Heron I. QM GH5616).
RECORDED RANGE: The species is recorded from 3 to 190m from Northwest Cape to Port Phillip Bay. The new record extends this range to the southern tip of the Great Barrier Reef.

DESCRIPTION
EXTERNAL APPEARANCE: The colony is a small thick cushion, about 1.5cm diameter and 1cm deep. Zooids are arranged in 7 circular systems of about 6 per system. Spicules are crowded in the lower half of the colony, at abdominal level. In the upper half, at thoracic level, they are present only in the centre of each circle of zooids, forming a pillar of spicules that reaches to the upper surface. The branchial apertures open around the outside of the upper margin of this white pillar, and the atrial apertures project through the upper edge and open just inside its upper margin. The external surface of the colony, both around the sides and on the flat upper surface is covered with a thick layer of bladder cells, free of spicules and pigment cells.

Pigment cells are black in the living specimen, but brown in preservative. They are crowded in the test lining the zooid compartments, and are evenly distributed elsewhere except where they are excluded by either colourless bladder cells or white spicules. Spicules are 0.025 to 0.07mm. The smaller ones are most plentiful at abdominal level around the zooids. Moderately sized ones are most frequently encountered, and the largest ones are rare. They have about 30 short pointed rays in optical section, although the smaller ones often have rounded rays. The living colony was black and white, the white circular upper surface of the pillars of spicules in the centre of each system contrasting with the rest of the upper surface where spicules are not present to dilute the black pigment cells.

21
22

INTERNAL STRUCTURE: Zooids are contained narrow vertical canals in the test, and in the present colony seem always severed somewhere along the long, narrow oesophageal neck. The rounded, slightly expanded posterior ends of the abdomina appear to have remained in place in their test compartment in the base of the colony and are not very much contracted. The anterior part of the zooids also has remained in place at the surface.

However, both the thorax and the most of the oesophageal neck is very much contracted, and it is this that appears to have caused the zooids to break apart, the abdomina remaining in the base of the colony and the apertures at the surface. The rim of the branchial aperture is divided into 6 small lobes. The atrial aperture is on a moderately long siphon. The upper rim of the opening is produced into a tongue-like lip, its tip divided into 3 round lobes. The posterior rim of the aperture also is divided into 3 lobes.

The thoracic musculature consists of about 16 narrow longitudinal bands, with very fine transverse muscles overlying them to form square meshes. Around the anterior part of the abdomen the longitudinal muscles reorganise themselves into about 8 wider bands on each side. Further posteriorly 4 wide longitudinal muscle bands encase the abdomen, but break up into separate fibres anterior to the gonads and stomach. Fine circular muscles are in one or 2 bands around the anterior part of the abdomen. These appear to be a continuation of the layer of transverse thoracic muscles onto the abdomen. Their arrangement in several bands may be due to the contraction of the longitudinal muscles. These transverse bands do not appear to have become embedded in the test, and there is not a constriction of the test between the thoracic and abdominal compartments, as there is in the large colonies of this species from southern and western Australia (see Kott 1990a).

The branchial sac is long with 13 rows of about 16 stigmata. The stomach is smooth, and located in the posterior end of the abdomen. It is obscured by the large testis consisting of numerous crowded pyriform follicles covering the dorsal side of the pole of the gut loop, and partly covered by a single large ovum.

REMARKS

Although it has been taken from Northwest Cape (Western Australia) this species has not previously been recorded from the eastern tropical coast of Australia or from any other location in the Western Pacific. The species appears to flourish in temperate Australian waters, where large colonies often are taken. This small specimen from the southern tip of the Great Barrier Reef may represent a population at the northern limits of its range. The single specimen does not appear juvenile, despite its small size, having large, mature male follicles and a large ovum. The gonads, branchial sac, circular systems, spicules, pigment cells and other features of the zooid and colony are characteristic of the species. The only significant difference appears to be the absence of a test constriction with a bundle of transverse muscle bands embedded in it between the thoracic and abdominal zooid compartments. However the transverse muscles are present outside the longitudinal ones, behind the thorax, and the fact that they have not become embedded in the test may be associated with the small size of the colony.

Genus **Polycitor** Renier, 1804

Polycitor calamus Kott, 1990
(Figs. 23–25)

Polycitor calamus Kott, 1990a, p.167.

DISTRIBUTION

NEW RECORD: South Australia (Spencer Gulf, SAM E2530).

RECORDED RANGE: The species is recorded from the Great Australian Bight and Spencer Gulf, South Australia, and from the Kurnell Peninsula (Botany Bay) New South Wales.

DESCRIPTION

The newly recorded colony is characteristic, with its long cylindrical stalk, divided into basal holdfasts that are spread out over sea grass leaves (*Posidonia*). A few epibionts are on the stalk. The expanded head has scattered spots in the surface of the preserved specimen.

FIGS. 12–22: *Cystodytes ramosus* n.sp. (holotype QM GH5374) — 12, colony; 13, section through upper part of colony showing contracted zooids beneath a layer of disc shaped spicules; 14, systems; 15, disc shaped spicules; 16, zooid. *Polycitorella coronaria* (QM GH5616) — 17, colony; 18, system from above; 19, thorax and anterior part of abdomen; 20, thorax showing atrial lip; 21, zooid showing muscle bands on abdomen; 22, gut loop and gonads. (Scales: 12 — 2cm; 13, 17 — 2mm; 14 — 5mm; 15, 16, 20–22 — 0.5mm; 18, 19 — 1mm).

The zooids have the usual long thorax and abdomen. In this colony (collected at the end of September). There are up to 9 embryos in a developmental series in the top of the abdomen. In some zooids the 2 best developed have moved up into the posterior end of the atrial cavity.

The larval trunk is up to 0.9mm long, with the tail wound about three-quarters of the distance around it. Half of the length of the trunk is taken up with a large frontal lobe which, at its anterior end, supports 3 triradially arranged, large adhesive organs. Each consists of a small everting cone in a depression at the end of a thick cylindrical stalk. The cerebral vesicle contains a large ocellus and otolith. There are 3 rows of stigmata in the larval pharynx.

REMARKS

Larvae of this species previously were unknown. Kott (1990a) suggested that since larvae were not present in the known specimens (collected in January and April) the breeding season could be restricted. The newly recorded specimens contain large numbers of relatively large embryos which appear to have been fertilised at the base of the long abdomen, and to have been developing as they move up the long stalk of the colony. This could be a lengthy process, and it suggests that sexual reproduction in this species could be an event that occurs once only during the year. The larvae, with their triradial adhesive organs and long frontal lobe, resemble the larvae of *Polycitor giganteus*, the tropical *P. annulus*, and *P. circes* (see Kott 1990a).

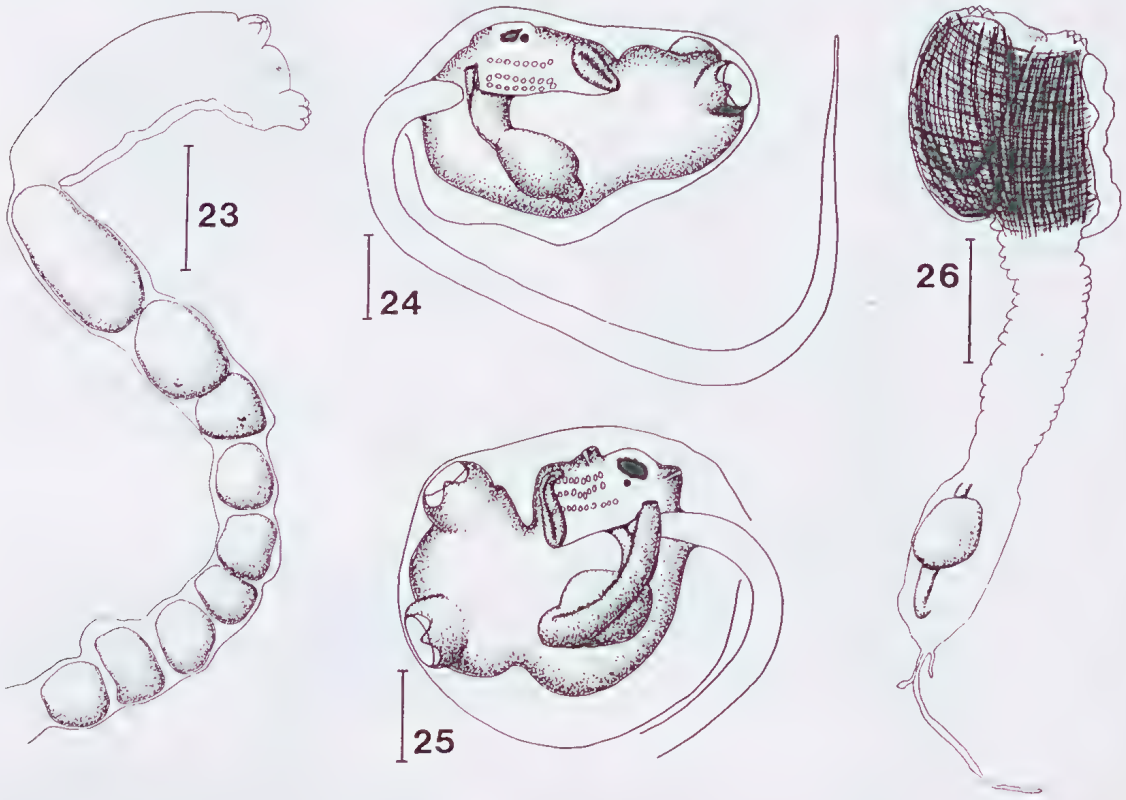
Polycitor obeliscus Kott, 1972

Polycitor obeliscus Kott, 1972b, p.171; 1990a, p.175.

DISTRIBUTION

NEW RECORDS: South Australia (Nuyts Archipelago, SAM E2543–4). Victoria (Bass Strait, MV H454).

RECORDED RANGE: The species previously was known only from its holotype from Investigator Strait. Its range is apparently restricted to the southern coast of



FIGS. 23–26: *Polycitor calamus* (SAM E2530) — 23, zooid showing embryos in abdomen; 24, 25, larvae. *Eudistoma aureum* (SAM E2538) — 26, zooid with two embryos in atrial cavity. (Scales: 23, 26 — 1mm; 24, 25 — 0.2mm).

Australia from the Great Australian Bight to Bass Strait.

DESCRIPTION

EXTERNAL APPEARANCE: The newly recorded colonies are of various shapes. The specimen from Bass Strait (at 70m) is upright, egg-shaped and fixed by its narrow base. The other colonies are fixed by a broad base (to 3cm diameter). One is a wide cone on the upper surface, but the other has a vertical margin and is flat-topped. Sand is present internally. It is absent from the surface of much of the upper part of the colony although occasionally, especially around the margins, or toward the base, some sand is present on the surface around the zooid openings. Atrial and branchial apertures open separately to the surface.

In one colony the zooids seem arranged in pairs, but there are no systems. The test is white and the zooids are reddish-orange to flesh-coloured in preservative.

INTERNAL STRUCTURE: Zooids are large and robust, with almost continuous coat of external longitudinal and internal circular muscles. The longitudinal muscles continue in 2 bands along each side of the abdomen. Stigmata are in 6 or 7 rows of about 20. The stomach, in the expanded posterior end of the abdomen, is smooth-walled. The testis follicles are clustered in a large mass on the dorsal side of the gut loop.

REMARKS

The present species is distinguished mainly by the number of rows of stigmata and the smooth-walled stomach.

Genus **Eudistoma** Caullery, 1909

Eudistoma aureum Kott, 1990
(Fig. 26)

Eudistoma aureum Kott, 1990a, p.199 and synonymy.

DISTRIBUTION

NEW RECORD: South Australia (off Eucla, 170 to 190m, SAM E2538–9).

RECORDED RANGE: The species was known only from its type locality in *Posidonia* beds in St. Vincent Gulf.

DESCRIPTION

EXTERNAL APPEARANCE: The largest colony (SAM E2538) consists of upright lobes, possibly spherical in life, but slightly laterally flattened in preservative, about 4cm diameter. It is fixed to the substrate by a narrow basal part. Internally the colony contains grey sand throughout. Sand also is present in the surface test on the lower half, which may be buried in the substrate. In preserved colonies, the surface test on the upper part of the colony, which is free of sand, is translucent and greenish black with black zooids showing through it. The arrangement of the zooids is obscure in these colonies.

INTERNAL STRUCTURE: The zooids are robust, with conspicuous muscles, about 50 internal transverse bands and 30 external longitudinal ones. Apertures are both 6-lobed. Stigmata are in 3 rows of 25 (middle row) to 30 (anterior) in each row. The dorsal end of the anterior row extends forwards along each side of the neural complex.

In the large colony taken from off Eucla, up to 2 large embryos (trunk 1.25m long) are being incubated in the atrial cavity. They have 4 lateral ampullae along each side of the median adhesive organs. However, these are crowded, the larvae are opaque and other details could not be determined. The tail is wound two-thirds of the way around the larval trunk.

REMARKS

The pigmentation in the large colony is more intense than in previously recorded specimens, which were said to have red-brown zooids in grey colonies (Kott 1990a). Possibly the colour fades in long-term preservation, for other features of both zooids and colony such as the muscular zooids, and the large number of stigmata per row, with the anterior row inclined along the mid-dorsal line, are identical.

Previously recorded colonies were said to have been yellow in life. Unfortunately the colour of the newly recorded ones is not known.

Exostoma ianthinum (Sluiter, 1909)

Polycitor ianthinus Sluiter, 1909, p.20.
Exostoma ianthinum: Kott, 1990a, p.234 and synonymy.

DISTRIBUTION

NEW RECORD: Queensland (Far northern Great Barrier Reef — Great Detached Reef, QM GH5726).

RECORDED RANGE: The southern limit of the recorded range of this species was previously thought to be Motupore I. New Guinea. It is known also from Palau Is, Philippines, and Bunda (Indonesia).

Suborder PHLEBOBRANCHIA Lahille, 1887

Family ASCIDIIDAE Adams & Adams, 1858
Genus **Ascidia** Linnaeus, 1767

Ascidia archaia Sluiter, 1890

Ascidia archaia Sluiter, 1890, p.346. Kott, 1985, p.26 and synonymy. Monniot and Monniot, 1987, p.92 and synonymy. Monniot, C. 1987a, p.18.

DISTRIBUTION

RECORDED RANGE: The species is known from Norfolk Is, from north of Moreton Bay and northwards up the Great Barrier Reef to New Caledonia, the Philippines, Indonesia, French Polynesia, Fiji, the Marshall Is, and the southern islands of Japan; and from the northwest coast of Australia and south to Shark Bay. The tropical Atlantic species *Ascidia corelloides* (Van Name, 1924) appears to be inseparable from it (see Van Name 1945, Tokioka 1953). Nevertheless, the Western Pacific and Atlantic populations apparently are isolated from one another, neither having a range into temperate waters.

REMARKS

Monniot and Monniot (1987) do not accept the view (Kott 1985) that *A. aperta* Sluiter, 1904 is a synonym of the present species on the grounds that it is large, up to 5cm long, with an open gut loop and with muscles on the right better developed than in the smaller specimens they have assigned to *A. archaia*. None of the characters invoked by Monniot and Monniot are outside the range of variation observed in *A. archaia*, which is one of the most common species on the Heron I. reef flat, under rubble. It is known to reach a size of 5cm in less than 6 months (see Kott 1985).

Ascidia liberata Sluiter, 1887

Ascidia liberata Sluiter, 1887, p.251. Kott, 1985, p.43 and synonymy.
Ascidia solomonensis Nishikawa, 1986, p.61.
Ascidia dorsalis C. Monniot, 1987a, p.9.
Not *Ascidia liberata*: Sluiter, 1904, p.32. C. Monniot, 1987a, p.8.

DISTRIBUTION

RECORDED RANGE: The species is recorded from Norfolk I. and the Great Barrier Reef, Indonesia (Sluiter 1887; Bay of Batavia, ZMA TU244), New Caledonia and Solomon Is.

DESCRIPTION

The species is characterised by the naked, transparent test, pointed papillae on the siphons, the fringe of minute tentacular projections along the edge of the lobes surrounding the apertures, and tranverse muscles across the dorsal surface of the generally laterally flattened, short, often triangular body, extending about half to two-thirds of the way across the right side but only about one-third of the way down the left. Short longitudinal muscles extend from along each siphon, those from the branchial siphon crossing the transverse muscles.

The red colour at the anterior end of the body in the living specimens has been referred to by Kott (1985), Nishikawa (1986) and Sluiter (1887).

REMARKS

Monniot (1987a) refers to the poor condition of the type specimen (ZMA TU244). Nevertheless it was this type specimen that Kott (1985) examined before assigning this common species to it. At the time she examined it, the characteristic papillae on the siphons, the tentacular fringe around the apertures, and the transverse muscles on the dorsal part of the right side of the body were all clearly visible. The general shape of this individual, which was figured by Sluiter (1887), closely resembles many of the more recently examined specimens.

Monniot, C. (1987a) examined and figured a specimen from the Siboga collection assigned to *A. liberata* by Sluiter (1904). Although Kott (1985) did not include it in the synonymy of *A. liberata*, Monniot believed the *Siboga* specimen to be identical with the type of *A. liberata*, and since it has characters inconsistent with *A. liberata*: Kott, 1985 he assigned the latter to a new species, *A. dorsalis* Monniot, 1987a. However, the Siboga specimen Monniot examined is not conspecific with *A. liberata* Sluiter, 1887. Its muscles, both on the right and left sides, as well as the swollen gut, the remnants of a fringe around the apertures and the foreign particles attached to the test, suggest that the Siboga specimen Monniot examined is *A. sydneiensis*.

Kott's specimens, for which *A. dorsalis* was erected, being conspecific with *A. liberata* Sluiter, 1887, *A. dorsalis* becomes a junior synonym of *A. liberata*. Similarly *Ascidia solomonensis* Nishikawa, 1986 has the characteristic features of *A. liberata* Sluiter, 1887.

Family PEROPHORIDAE Giard, 1872
Genus **Perophora** Wiegman, 1835

Perophora multiclathrata (Sluiter, 1904)

Ecteinascidia multiclathrata Sluiter, 1904, p.12.
Perophora multiclathrata: Kott, 1985, p.106 and synonymy (part, **not** *P. bermudiensis*: *pers. comm.* I. Goodbody). Nishikawa, 1986, p.30 and synonymy; 1991, p.38. C. Monniot, 1987a, p.88.

DISTRIBUTION
RECORDED RANGE: The species has a wide range in the Western Pacific from the Japan Sea (Sado), in both Micronesia and Melanesia as well as the northeastern coast of Australia, the Great Barrier Reef and Norfolk Island. *Perophora multiclathrata* also occurs on the western coast of Africa (> *Perophora africana* Millar, 1953; *fide* Nishikawa, 1986) and in the West Indies (although it is not a synonym of *P. bermudiensis*). The record from the Japan Sea is the only one outside tropical locations.

REMARKS
It is of interest that a possible junior synonym of *P. bermudiensis* (*P. fascia* C. Monniot, 1991a) occurs in New Caledonia. Although Monniot has discussed the differences of *P. fascia* from the temperate *P. hutchisoni* and tropical *P. namei*, both with jointed stolons (see Kott 1985), he has not compared the morphology of his new species with either *P. multiclathrata* or *P. bermudiensis*, species with which it has more in common. If *P. fascia* is a synonym of *P. bermudiensis*, both *P. multiclathrata* and *P. bermudiensis* are sympatric in the Western Pacific and the Atlantic.

Genus **Ecteinascidia** Herdman, 1880

Ecteinascidia diaphanis Sluiter, 1885

Ecteinascidia diaphanis Sluiter, 1885, p.168. Kott, 1985, p.90.
Ecteinascidia koumaci C. Monniot, 1987a, p.3.
Ecteinascidia ndouae C. Monniot, 1991a, p.505.

DISTRIBUTION
RECORDED RANGE: The species is known from northern New South Wales, Great Barrier Reef, Northern Australia, Palau Is, Indonesia, and New Caledonia.

REMARKS
Monniot has compared the New Caledonian material with *E. hedwigiae* Michaelsen, 1918 from the coast of Natal, and with the Western Pacific *E. diaphanis*. The latter, on geographical grounds is a more likely taxon to occur in New Caledonia. Differences between *E. diaphanis* and the 2 species from New Caledonia, viz. *E. koumaci* and *E. ndouae*, appear to be either the result of intraspecific variation, or artefacts such as muscle contraction. They include variations in the red or pink-orange pigmentation at the anterior end of the zooids, which forms rings around the siphons, and sometimes spots as well (see Kott 1985). In *E. ndouae* C. Monniot, 1991a, the colour is described as yellow-gold.

Ecteinascidia koumaci Monniot, 1987a is distinguished from *E. diaphanis* by the interval between the band of transverse muscles behind the atrial siphon and the siphonal muscles. This is affected by contraction of the longitudinal muscles along the length of the siphon. The membrane between the dorsal languets, also said to distinguish the species, is not always present (Monniot, C. 1987a). There seems no valid justification for the assignation of *E. koumaci* and *E. ndouae* to species distinct from *E. diaphanis*.

Ecteinascidia nexa Sluiter, 1904

Exteinascidia nexa Sluiter, 1904, p.11. Kott 1985, p.94 and synonymy. Nishikawa, 1986, p.42.
Ecteinascidia aequale C. Monniot, 1987a. p.5.
Ecteinascidia imperfecta: Nishikawa 1984, p.42.

DISTRIBUTION
RECORDED RANGE: The species is recorded from Lord Howe I., the northeastern Australian coast and the Great Barrier Reef, Solomon Is, Indonesia, Philipines, Fiji, Tokhara Is, the Indian Ocean (Sri Lanka), and now from New Caledonia.

REMARKS
C. Monniot (1987a), comparing *E. aequale* with *E. nexa*, was unable to reconcile the descriptions of Kott (1985) and Nishikawa (1986). However, there are not significant differences in these accounts. The species is readily characterised by its muscles, cloudy body wall in preservative, smooth stomach, duodenal and posterior stomach enlargements in the gut loop, hemispherical mass of male follicles and usually yellow colour in life. All of these characters are referred to by both Nishikawa (1986) and Kott (1985).

Ecteinascidia nexa has a range of orientations of the sessile to stalked zooids and a variety of primary and accessory stolons attaching them to the basal stolons or to one another. Apertures are, respectively, terminal and halfway along the

body, sometimes sessile, but usually on conical siphons when living. Kott (1985) describes the preserved zooids as flaccid and distorted, cloudy in preservative, with numerous blood cells. Nishikawa (1986) refers to the 'lustreless' free surface with pale yellowish spherules densely distributed in the body wall. Similar body muscles are described (in some detail) by Kott (1985) and Nishikawa (1986). Stigmata are in 19 (Kott 1985) or 20 (Nishikawa 1986) rows, and there are from 14 to 24 longitudinal vessels on one side of the body.

Both authors, independently, examined the types of *P. hornelli* Herdman, 1906, and proposed its synonymy. Nishikawa (1986) also examined the type of *E. nexa*.

The branchial processes on the prepharyngeal band figured by Kott (1985, fig. 39b) only occur in the most robust zooids and are not characteristic of the species, nor was it suggested that they are.

Ecteinascidia aequale C. Monniot 1987a from New Caledonia appears to fall within the range of variation reported for *E. nexa*.

Suborder STOLIDOBRANCHIA Lahille, 1887

Family STYELIDAE Sluiter, 1895
Subfamily STYELINAE Herdman, 1881
Genus **Cnemidocarpa** Huntsman, 1912

Cnemidocarpa amphora n.sp.
(Figs. 27–31)

DISTRIBUTION

TYPE LOCALITY: South Australia (Sir Joseph Banks Group, North Point, Marum I., 200m offshore in sand, rubble, *Posidonia*, 7m, coll. W. Zeidler 13.1.84, holotype SAM E2531; Sir Joseph Banks Group, W. Partney I., Partney Shoal Reef, rubble, sand, *Posidonia*, 5–15m, coll. W. Zeidler and K. Gowlett Holmes 21.8.86, paratypes SAM E2536.

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: Individuals are club-shaped, with an expanded body, rounded anteriorly and posteriorly continuous with a thick, cylindrical stalk about the same length as the body. The branchial and atrial apertures are directed away from one another in opposite sides of the anterior end of the body, the branchial siphon almost terminal, and the atrial one on the dorsal side.

The available specimens are contracted, and behind the large, naked lobes of each aperture is a collar or band of wrinkled test. When the animal is relaxed it is probable that these disappear, and that the siphons are long, projecting out like horns from the anterior end of the body.

Sand adheres to the anterior part of the body around the base of the siphons, and to the fine hairs around the base of the stalk. The hairs aggregate together to form a sandy holdfast. The test is transversely wrinkled over most of the surface. It is particularly thin on the base of the stalk where it is surrounded by the sandy holdfast.

INTERNAL STRUCTURE: The body wall is red, shiny and muscular. Posteriorly it is extended into an inflated stolon which projects down into the stalk. Anteriorly the two siphons are relatively long, the branchial siphon directed obliquely away from the substrate, the atrial one curved over to the side toward the substrate. Attenuated body muscles are confined to the anterior part of the stolon, which is thin-walled and hollow in its distal part. The hollow may be part of the haemocoele, as it does not appear continuous with the atrial cavity, being separated from it by a thin membrane.

Longitudinal stripes line the siphons, and numerous fine branchial tentacles surround the base of the branchial siphon. The dorsal tubercle is a particularly large cushion with a double spiral slit, both horns rolled in, and directed either to the left or anteriorly. A large dorsal ganglion occupies the space between the base of the 2 siphons in these contracted specimens.

The branchial sac has 4 low folds on each side of the body, with crowded internal longitudinal vessels arranged according to the formula DL0(18)2(10)3(12)3(10)2E. About 4 stigmata are in meshes in the interspaces, and more are between the endostyle and the first longitudinal vessel on each side.

The gut loop is simple, and vertical, its pole compressed into the V of the posterior end of the body where, in these contracted specimens, it projects slightly into the top of the stalk. The oesophageal opening is halfway down the dorsal side of the pharynx. The oesophagus is short, the stomach long with parallel internal longitudinal folds. The stomach and post pyloric part of the intestine (proximal to the pole of the gut loop) are of about equal length. The rim of the anal opening (at the base of the atrial aperture) is deeply divided into 16 rounded lobes. On each side, up to 10, crowded, parallel gonads lie horizontally (at right angles to the long axis of the body). They

consist of a double rows, each row of about 10 large testis follicles, beneath a long ovarian sac.

A very short oviduct is at the dorsal end of each ovary. The short vas deferens opens on top of the female duct. Irregular, upright endocarps are crowded along the dorsal one third of each side of the atrial cavity (between the dorsal ends of the gonads, and dorsal to them).

REMARKS

Both *Cnemidocarpa floccosa* (Sluiter, 1904) and *C. completa* Kott, 1985 have a similar number of cnemidocarp gonads on each side of the body as the present species. The former tropical species is rounded posteriorly, while the present one narrows to its stalk; the gonads lie vertically, parallel to the long axis of the body in *C. floccosa*, rather than at right angles to it as in *C. amphora*; and the gut loop in the present species lies vertically, extending back from the oesophageal opening, while that of *C. floccosa* curves anteriorly around the ventral margin of the body. *Cnemidocarpa completa* Kott, 1985 is known from temperate waters, although not from South Australia. It also is distinguished from the present species by the curve of the gut loop around its posterior ventral border, the absence of a dorsal band of endocarps, the long stomach, and the loose attachment of gonads to the body wall.

Cnemidocarpa areolata (Heller, 1878)

Styela areolata Heller, 1878, p.26.

Cnemidocarpa areolata: Kott, 1985, p.122 and synonymy. **Not** Monniot, 1983, p.451 (< *C. legali* Gravier, 1955).

Cnemidocarpa valborg Monniot, 1988, p.193; 1991b, p.27 (part, ? not specimen from Dumbéa). **Not** Monniot and Monniot, 1984a, p.577 (< *C. legali* Gravier, 1955); ? 1991, p.400.

Cnemidocarpa irene: Nishikawa, 1991, p.96 and synonymy.

DISTRIBUTION

RECORDED RANGE: The species is known from all around the Australian coast, from Sri Lanka, and the western Pacific to the Marianas, Fiji, Japan and Hong Kong (see Kott 1985). The newly recorded specimens from New Caledonia (Monniot 1991b) are consistent with other records from the western Pacific.

REMARKS

Monniot and Monniot (1984a, p.577), having examined the type specimen of *C. areolata* (from Sri Lanka) found that its vas deferens was divided and that it opened by 'unbouquet de papilles'. Comparing its gut loop with Herdman's figure of *C. areolata*: Herdman, 1906 (Pl. 4, Fig. 24), Monniot and Monniot assume that Herdman's specimens, also from Sri Lanka, are conspecific with the holotype of *C. areolata*, and separate from the (principally western Pacific) specimens assigned to *C. areolata* Heller, 1878 by various authors (see Nishikawa 1991). Monniot and Monniot (1984a, p.577) contend that 'La synonymie certaine de cette espèce est restreinte au type de l'espèce et à l'échantillon de Herdman'. The specimen recorded by Nishikawa (1991) as 'C. Monniot's collected from India' apparently is part of the type of *C. areolata* Heller, 1878 'mounted on a glass slide' (see Nishikawa 1991, p.97). Neither Monniot and Monniot (1984a) nor Monniot (1988, 1991b) refer to the examination of Herdman's specimens, and there is no record that these have the remarkable, and possibly abnormal, replicated openings of the male ducts which they found in the type. Apparently the synonymy of Herdman's specimens with the type is based entirely on the curvature of the gut loop reported by Herdman (1906, pl.4, fig. 24). The curve of the gut loop is variable in the large sample of examined specimens from Australia (Kott 1985), Japan (Nishikawa 1991) and New Caledonia (Monniot 1988). Further, its curvature varies according to the curvature of the body, influenced party by its state of contractions, and by the size and shape of the adhering surface. The curvature of the gut loop is not on its own a reliable enough character to determine the relationships of the Sri Lankan specimens to one another and to others from the Indo-West Pacific. These relationships will be resolved only when the status of the unusual opening of the vas deferens (known in the one, albeit type, specimen) is established.

Cnemidocarpa valborg: Monniot and Monniot 1991 from 300 to 500m off New Caledonia has different gut loop, branchial sac and endocarps from the present species, and does not appear conspecific. Similarly, the specimen from Dumbéa (Monniot 1991b) with ducts turned ventrally does not appear to belong to this species.

The specimens from the Atlantic (Monniot 1983; Monniot and Monniot 1984a) lack the characteristic yellow and red stripes lining the siphons of living specimens, which turn to black in preservative; the gut loop is narrow, the limbs parallel to one another with endocarps in an irregular row (rather than being bunched together in the open pole of the loop (as they are in *C. areolata*);

the stomach lacks the numerous, regular parallel folds of *C. areolata*; and the posterior gonad on the left is much more branched, or it does not curve over the anterior pole of the gut loop, as in *C. areolata*. Although there are certain similarities in the morphology of these two species, they do not seem sufficiently close to justify their synonymy, especially where there is no reasonable geographic basis for gene flow between them.

Cnemidocarpa intestinata Kott, 1985

Cnemidocarpa intestinata Kott, 1985, p.128.
Not *Cnemidocarpa* aff. *intestinata*: Monniot and Monniot, 1991, p.401.

REMARKS

This species, recorded from northern and north-eastern Australia, is well characterised by its hollow conical overlapping spines (Kott 1985 Fig. 50d), large numbers of stigmata (15) in the meshes between the folds, a narrow gut loop, a gonad directed posteriorly in the second gut loop, and clumps of male follicles constricting the ovarian tubes at regular intervals along each side. Endocarps are not present.

The specimen from 700m depth off New Caledonia (Monniot and Monniot 1991), believed to have affinities with *C. intestinata*, shares only one of these characters — viz. the lack of endocarps. It does not appear to be related in any way.

Cnemidocarpa tribranchiata n.sp.
(Fig. 32–35)

DISTRIBUTION

EXTERNAL APPEARANCE: South Australia (Encounter Bay, Seal Rocks, with bryozoan *Hornera foliacea*, 15m coll. N. Holmes 24.8.88, holotype SAM E2533; Willunga Reef, low tide, coll. I.C. Kowanka 23.11.76, paratype SAM E2534.

FURTHER RECORDS: None.

DESCRIPTION

EXTERNAL APPEARANCE: Individuals are upright and oval, about 2cm long, with fleshy, 4-lobed, sessile apertures, the branchial terminal and the atrial about halfway down the dorsal surface. Irregular extensions of the basal test fix the animal to the substrate. The test is white, translucent and moderately thick and firm. The surface is slightly rough, and has patches of epibionts and shell and sand particles attached here and there.

INTERNAL STRUCTURE: The body wall has strong longitudinal muscle bands radiating from each siphon and crossing one another over the sides of the body. About 15 are from the atrial siphon and 12 from the branchial siphon. They branch into fine bands forming a delicate inconspicuous network on the postero-ventral part of the body. Circular muscles are around each siphon. A long neural ganglion is between the siphons.

The simple branchial tentacles (about 40) are of various sizes and alternate with rudimentary ones. The dorsal lamina is wide and plain-edged. A long neural ganglion is between the siphons. The dorsal tubercle is a circular slit with a large C-shaped opening, the open interval directed anteriorly.

Three broad, but not overlapping folds are present on each side of the pharynx. Internal longitudinal vessels are thick and project into the pharynx. They are arranged according to the formula E3(13)3(12)2(13)ODL. They are not crowded, either on the folds or in the interspaces, there being 8 stigmata per mesh between the folds and 6 per mesh on the folds.

The gut loop is long and narrow, curving at least halfway around the postero-ventral curve of the body. It is open at the pole where it encloses a flat-topped endocarp which is lobed around its margin. The stomach occupies about three-quarters of the ascending limb of the gut loop. It has 11 parallel, slightly oblique folds. These flatten out at its pyloric end, which tapers gradually to the intestine. The oesophagus is short and narrow. The anus is visible through the open atrial aperture. Its margin is divided into 5 shallow lobes.

Two gonads are on each side of the body, converging toward the atrial aperture. The ovarian tubes are sinuous, the curves giving an impression of irregular lobes along each side, an impression that is emphasised by the presence of an endocarp on each outer curve. Crowded testis follicles are in 2 rows beneath each ovary. On the left side of the body the posterior gonad is curved into the secondary gut loop, and the anterior one

FIGS. 27–35. *Cnemidocarpa amphora* n.sp. (27, paratype SAM E2536; 28–31, holotype SAM E2531) — 27, 28, external appearance; 29, body removed from test showing extension into stalk; 30, internal organs; 31, lateral view of gonad. *Cnemidocarpa tribranchiata* n.sp. (holotype SAM E2533) — 32, external appearance; 33, body removed from test; 34, dorsal tubercle and anterior part of dorsal lamina; 35, internal organs on left side. (Scales: 27–29, 31, 32 — 5mm; 30, 34, 35 — 1mm; 33 — 2mm).

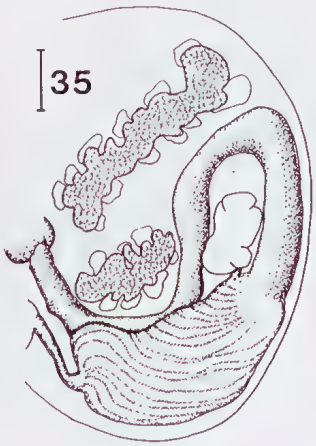
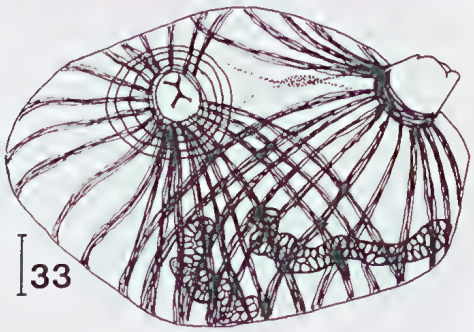
34



35



33

extends across the body wall anterior to the pole of the gut loop. Endocarps are scattered on the body wall between the gonads.

REMARKS

Cnemidocarpa tripartita Kott, 1985 from Bass Strait has, like the present species, a rounded body, white (but thin) translucent test, 3 branchial folds on each side of the body, a long stomach with longitudinal folds, an endocarp enclosed in the pole of the gut loop, and 2 gonads on the left and 3 on the right. Its significant differences from the present species are its low branchial folds with only 2 or 3 internal longitudinal vessels (while those of the present species are broad and flat with 12 or 13 longitudinal vessels), its light attachment of the gonads to the body wall by fine ligaments (while in the present species gonads are embedded) and the absence of endocarps on the body wall between the gonads.

Genus **Asterocarpa** Brewin, 1946

Asterocarpa humilis (Heller, 1878)

Styela humilis Heller, 1878, p.26.
Asterocarpa humilis: Kott, 1985, p.141 and synonymy.
Not *Cnemidocarpa* aff. *humilis*: Monniot, 1991b, p.25.

DISTRIBUTION

RECORDED RANGE: This species is known from temperate waters from Albany, across the southern coast of Australia to Tasmania and Victoria, New Zealand, and from South Africa and the eastern Pacific (see Kott 1985).

REMARKS

The specimen from tropical New Caledonian waters which Monniot (1991b) believed to have affinities with this species has 2 long, branched gonads across each side of the body, between the ventral and dorsal mid-line, converging to the atrial aperture. The short, cnemidocarp-type gonoducts are at the dorsal (distal) end of each gonad. This contrasts with the genus *Asterocarpa* which has irregularly branched gonads, with ventrally directed gonoducal openings, around the ventral margin of the right side of the body, and one in a similar (ventral) position anterior to the gut loop on the left. The New Caledonian specimen also has more longitudinal branchial vessels than the temperate species *Asterocarpa humilis*.

Cnemidocarpa lobata Kott, 1985 has undulating branched gonads, like the New Caledonian specimen, but it has a particularly long gut loop and also is temperate. The New Caledonian specimen appears either a small (1cm diameter) specimen of *Cnemidocarpa stolonifera*, or the related *C. pedata* which has a short stomach like Monniot's specimen.

Genus **Polycarpa** Heller, 1877

Polycarpa aurita (Sluiter, 1890)

Styela aurita Sluiter, 1890, p.338.
Polycarpa aurita: Kott, 1985, p.152 and synonymy. Monniot, 1987b, p.294. Nishikawa, 1991, p.92.
Polycarpa insulsa: Monniot 1987b, p.294 and synonymy.

DISTRIBUTION

RECORDED RANGE: The species apparently is pantropical, being recorded from the Caribbean, as well as from the Japan Sea, Indonesia, New Caledonia and the Philippines, north-western and north-eastern Australia, and south to Cockburn Sound and Port Jackson respectively.

REMARKS

Van der Sloot (1969) believed there to be 2 species, a Caribbean one, consisting of *P. insulsa* (Sluiter, 1898) and its synonyms, and a western Pacific one, *P. circumarata* (Sluiter, 1904) which Kott (1985) and Monniot (1987b) believe to be a junior synonym of *P. aurita* (Sluiter, 1890). The distinctions between the Atlantic and Pacific species which were established by Van der Sloot are differences between the type specimen of *P. circumarata* (lacking gonads in the posterior end of the body) and the Caribbean populations. This distinction can be sustained only if specimens from the Western Pacific never have gonads on the posterior part of the body wall. In fact, specimens from Australian waters show a great range in the distribution of gonads. Other distinctions such as the tough lining of the atrial cavity, which is said to occur in *P. insulsa*, occur also in *P. aurita*.

A problem with the separation of the Pacific and Atlantic species, is that specimens of the former have a range in characters, such as the number of internal longitudinal vessels, the consistency of the test and surface projections from it, that transcends any of the currently recognised differences between the species. Thus, although it is always difficult to justify genetic continuity

for pan-tropical species, the present evidence supports such a range for this species.

The occurrence of the specimen from New Caledonia assigned to *P. insulsa*: Monniot, 1987b, which is said to be identical with specimens from the Caribbean, adds support to the view that there is no distinction between these species.

Polycarpa contecta (Sluiter, 1904)

Styela contecta Sluiter, 1904, p.66. Kott, 1985, p.162.
?C. Monniot, 1987b, p.291.

DISTRIBUTION
RECORDED RANGE: The species is recorded from Indonesia, and Townsville, and possibly from New Caledonia.

REMARKS
Monniot (1987b) remarks that his (single) specimen from New Caledonia corresponds well with Kott's (1985) description (based on the Siboga type material and specimens from Townsville). However, it does differ in 3 important respects. The opening of the neural gland is not the deep S-shaped slit — which Kott (1985) believes to be characteristic of *P. contecta*, its gonads are embedded in thick endocarp while those Kott examined are attached by a membrane along the proximal half of each, and the stomach of *P. contecta* is characteristically long, occupying most of the proximal limb of the primary gut loop while that of the New Caledonian specimen is shorter. Thus, there is some doubt about the assignation of the New Caledonian specimen.

Genus **Polyandrocarpa** Michaelsen, 1904

Polyandrocarpa colemani n.sp.
(Figs. 36–41, 44)

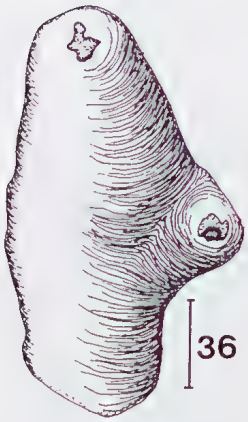
DISTRIBUTION
TYPE LOCALITY: New South Wales, off Queensland border (Cook I., 9m, north side of I. rocky bottom, coll. N. Coleman January 1987, holotype QM GH5724; Arrawarra, 12m, south face of North Rock, coll. AIMS Bioactivity Group 19.2.88, paratype, QM GH5392).
FURTHER RECORDS: New South Wales (Coffs Harbour, photographed specimens; Cook I., QM GH5725).
The species grows along the top of of ridges where it is subjected to maximum current flow.

DESCRIPTION
EXTERNAL APPEARANCE: Colonies are firm, massive, to 1m long and about 0.3m wide, opaque and grey, with white rings around the apertures. The apertures protrude from the otherwise smooth surface of the colony on short cylindrical siphons. Branchial apertures are bent over to lie on the surface while the atrial apertures are directed upwards. The apertures appear to have smooth rims, the usual 4 lobes usually characteristic of styelid ascidians not being evident. In preservative the external test is dark grey, but internally the test is whitish, translucent and gelatinous, without embedded nor encrusting sand. The dark zooids are completely embedded in the tough test, and are evenly spaced. They protrude only slightly from the surface of the colony. They lie on their ventral surface with the dorsal surface uppermost, near the outer surface of the colony. Blood vessels anastomose through the thick gelatinous internal test.

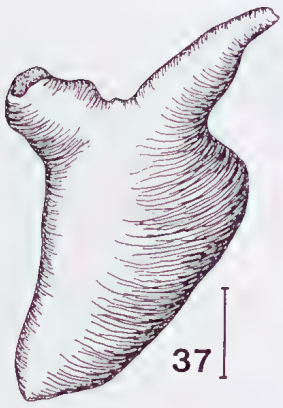
INTERNAL STRUCTURE: Zooids are muscular, and much contracted in the available colonies. From the base of the branchial siphon to the posterior end of the contracted body is about 1cm. The siphons are sometimes long and thin, but in other specimens they are withdrawn and the apertures appear sessile. Externally circular muscles form an almost complete layer. The internal longitudinal muscles are less crowded. Branchial tentacles are long and pointed, and number about 50. The peritubercular area is a shallow V. The opening of the neural duct is a long, sessile slit, oriented transversely, longitudinally, or obliquely, and affected by the body's contraction — the transverse slit sometimes being bent into a U- or V shape. The slit often is obscured by the closely papillated and wrinkled lining of the prebranchial area, although this also may be caused by contraction of body wall muscles.

The branchial sac is robust, with conspicuous longitudinal vessels arranged according to the following formula: DL0(4)1(6)1(8)1(5)1E. Stigmata are 6 per mesh in the middle of the branchial sac, and 8 per mesh between the first fold and the plain-edged, long, dorsal lamina. The oesophagus is also long, curving up posteriorly toward the oesophageal opening.

The oesophagus is short. The long stomach, occupying about three-quarters of the ascending limb of the gut loop, is narrow at the cardiac end, gradually increasing in width to its junction with the wide intestine. There are 18 internal longitudinal stomach folds. A small, straight caecum is at the distal end of the stomach, in the inside curve

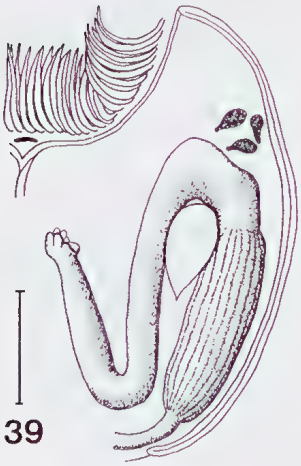


36



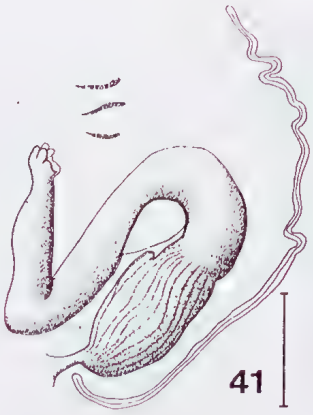
37

38

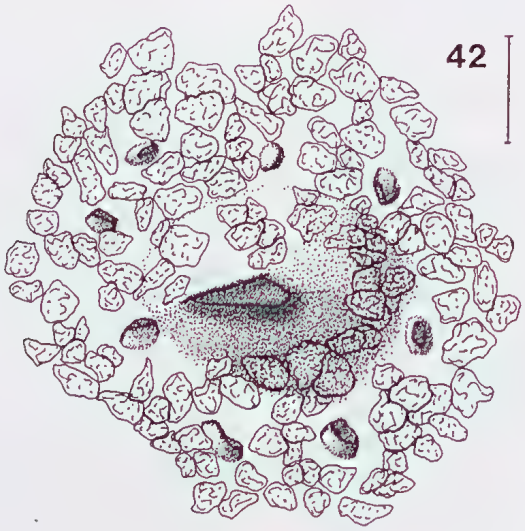


39

40



41



42

of the loop, crowded between the stomach and the short, comma-shaped, flat-topped endocarp which is enclosed in the pole of the gut loop. The descending limb of the narrow primary gut loop is parallel to the ascending limb, although this could be an artefact resulting from contraction. The rectum is long. Although there is some variation in its length relative to the descending limb of the primary loop, this variation may also be the result of contraction. The anal border has 4 to 6, sometimes subdivided, deep lobes on its dorsal rim. The opposite side is undivided.

Gonads are present only in the holotype colony. They are long, narrow polycarps lying on, rather than embedded in, the body wall. Immature ova fill the ovarian tube, but male follicles are not developed in any of the zooids examined. On the left are up to 4 gonads in a row in the middle of the body wall, sometimes with an additional one dorsal to them in what may represent an incomplete second row. In one zooid a rather irregular clump of 3 polycarps is near the pole of the gut loop, just to the left of the endostyle. On the right, gonads are seldom present, being observed in only 2 of approximately 10 zooids examined. They are in one or 2 incomplete rows on the dorsal half of the body wall, and are directed toward the atrial aperture. The lining of the parietal wall of the atrial cavity is foamy with crowded vesicles about 0.05mm in diameter.

Remarks

There are several known species of *Polyandrocarpa* with embedded zooids. Of these, *P. abjornseni* Hartmeyer and Michaelsen, 1928 and *P. simulans* Kott, 1972a (respectively from Western Australia and South Australia) have a simlar flat-topped endocarp in the gut loop, and similar numbers of branchial vessels to the present species. However, they both lack the great mass of zooid-free test that is characteristic of the present species. *Polyandrocarpa robusta* Sluiter, 1915 (which Kott, 1985, thought may be similar to *P. colligata* Sluiter, 1913) has one to 3 internal longitudinal vessels in the interspaces while the present species never has more than one; and it has a curved stomach caecum, only 14 stomach folds, a smooth anal border, and gonads in a row each side of the endostyle. *Polyandrocarpa maxima*: Van Name, 1918, 1945 from the Philippines and western (*sic*, eastern, Kott 1985) Atlantic has scattered gonads (which may be in a similar position to the gonads in the present species), and a vestigial gastric caecum. Zooids in Van Name's material, however, are crowded with only thin layers of test between them, longitudinal vessels are more numerous both on the folds and in the interspaces, and although the stomach has a similar number of folds to the present species, it is markedly shorter, and the gonads are only loosely attached to the body wall (possibly tending to be upright: see Kott 1985).

Polyandrocarpa colligata Sluiter, 1913 from the Aru Is has a bulky colony, with protuberant apertures, and it closely resembles that of the present species. Also the zooids are similar with similar slit-like openings of the neural duct, a small stomach caecum, a long stomach with apparently a similar number of folds (see Sluiter 1913, pl.VI, Fig. 14) and long, narrow polycarps. Sluiter's species is distinguished from the present one by the course of the gut, and its position across the posterior end of the zooid (features which Sluiter has emphasised do not necessarily constitute a distinction from *P. robusta* since they are readily affected by contraction). *Polyandrocarpa colligata* is also distinguished by its more numerous longitudinal branchial vessels, both in the interspaces and on the folds, its gonads in a row each side of the endostyle (as in *P. robusta*) and the endocarps on the body wall. Other characters conspicuous in the present species and not observed (but possibly overlooked) in *P. colligata* are the foamy layer of vesicles lining the parietal wall of the atrial cavity, and the lobed anal border.

Nevertheless, *P. colemani* has a limited distribution at the boundary of tropical and temperate zones of the eastern Australian coast. It is well isolated from the tropical *P. colligata*.

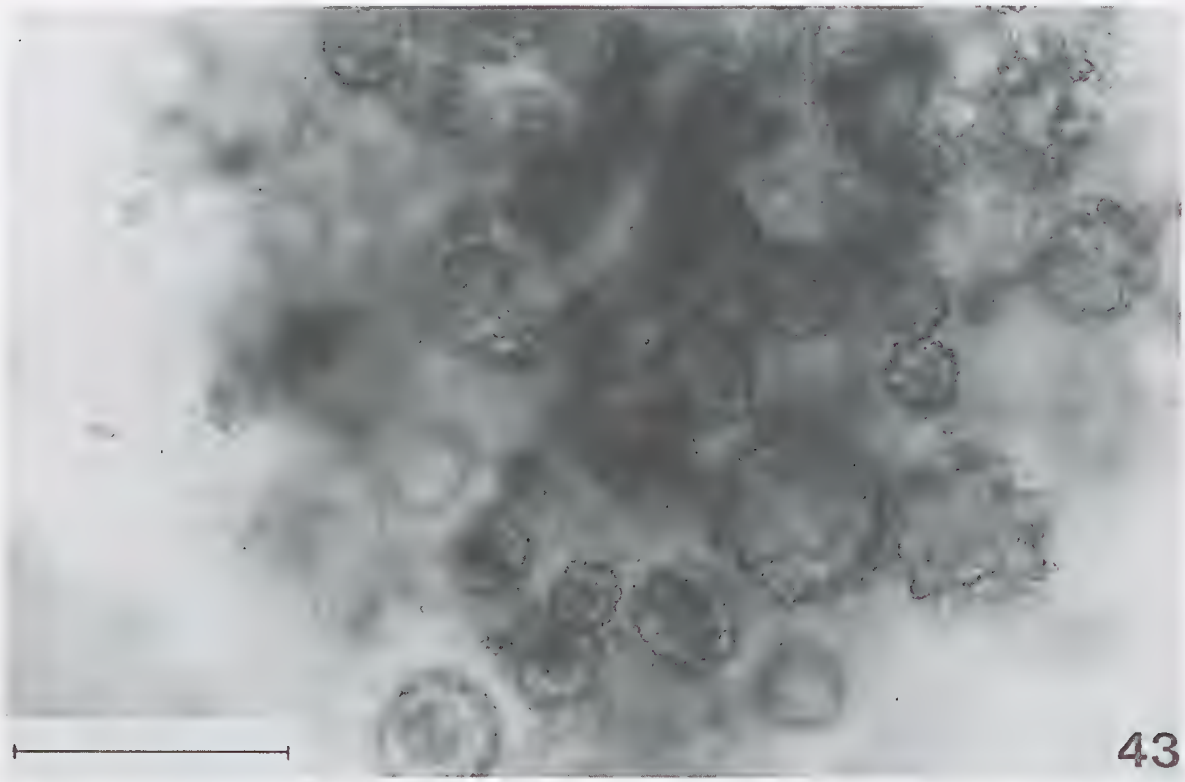
Subfamily BOTRYLLINAE Adams and Adams, 1858

Genus **Botryllus** Gaertner, 1774

Botryllus stewartensis Brewin, 1958 (Fig. 42)

Botryllus stewartensis Brewin, 1958, p.444. Kott, 1985, p.269 and synonymy; 1990b, p.286.

FIGS. 36–42: *Polyandrocarpa colemani* n.sp. (holotype QM GH5724) — 36, 37, bodies removed from test; 38, section across colony showing blood vessels and position of zooids; 39–41, internal organs on left. *Botryllus stewartensis* (QM GH5294) — 42, system showing branchial and common cloacal apertures from above. (Scales: 36, 37, 39–41 — 2mm; 38 — 1cm; 42 — 0.5mm).



FIGS. 43, 44: *Polycitorella coronaria* (QM GH5616) — 43, spicules. 44, *Polyandrocarpa colemani* n.sp. — view of colony (photo, N. Coleman). (Scale: 43, 0.1mm).

DISTRIBUTION

NEW RECORD: Queensland (Point Lookout, QM GH5294).

RECORDED RANGE: The species is known from Albany (WA) across the southern coast of Australian to Port Kembla and Port Stephens (NSW) and Moreton Bay (Qld), as well as Stewart I. and South I. (New Zealand).

Previous records from Moreton Bay are from inside the Bay. The new records are from the ocean side of North Stradbroke I. indicating that Moreton Bay is part of the continuous range of this widespread species, rather than being a refuge at the northern limit of its range.

DESCRIPTION

The colonies are irregular sandy slabs to 5cm or more in maximum dimension, and 1cm thick. They are subdivided into lobes on the surface. About 5 zooids are in each circular system of about 2.0m diameter. Two or 3 systems are crowded into each lobe. Sand particles are embedded in the basal test, and adhere all over the surface. However there is little sand in the tough white internal test, around the zooids.

REMARKS

The present colonies do not have quite such long, narrow stalks as have been previously described. They are otherwise characteristic of this species.

Family PYURIDAE Hartmeyer, 1908
Genus **Pyura** Molina, 1782

Pyura albanyensis Michaelsen, 1927

Pyura albanysensis Michaelsen, 1927, p.193.
Pyura obesa: Kott, 1985, p.315 and synonymy.
Not *Pyura albanyensis*: Monniot, 1989, p.492. Monniot and Monniot, 1991, p.411.

DISTRIBUTION

RECORDED RANGE: The species is known from tropical and temperate waters around the Australian coast, the Arafura Sea, and the Palau Is.

REMARKS

Monniot (1989) distinguishes *Pyura albanyensis* from *P. curvigona* (> *P. vittata*: Monniot, 1989, 1991) only by the presence of the swollen rectum in the latter species. He remarks that 'tous les autres caractères sont peu importants et les différences observées entre les espèces pourraient correspondre à une variabilité'. However, there are significant differences in a number of conspicuous and stable characters between these two species. The principal difference is the form of the siphonal spines (Kott 1985). In *P. curvigona* these have a flat scale halfway along them, which is not present in *P. albanyensis*. In *P. albanyensis* the needle-like spines are of two sizes. Further differences are the short dorsal lamina, the long, deeply curved U-shaped gut loop and the distinct longitudinal stripes down the outside of the siphons in *P. albanyensis*. The species are similar only in the crowded endocarps on gut loop and gonads, in the almost pinnate form of the ovarian tube, each short branch with a cap of male follicles, and in the distribution of the siphonal spines, which continue over the outer surface from inside the siphon.

Monniot (1989) assigned 2 specimens from New Caledonia, one 5cm and one 1.2cm long, to *P. albanyensis*. In neither were the small spines between the larger ones reported, nor can they be detected in Monniot's scanning electron micrographs. It is possible that these have been obscured by the larger spines, although this does not seem to be the case. The smaller spines, like the larger ones, are on the surface of the test both inside and outside the siphons, and should be apparent if they are present.

Further, although the gut loop and gonads have crowded endocarps on them, and the long ovarian tubes have pinnate branches, each with a cap of terminal testis follicles, the New Caledonian specimens differ from *P. albanyensis* in having a long dorsal lamina and a narrow but gently curved gut loop.

The form of the siphonal armature needs to be established by light microscope examination of cleared preparations in order to accurately assign the New Caledonian specimens.

Monniot(1989) drew attention to the fact that the name Hartmeyer applied to the holotype of this species is preoccupied by the Antartic *Pyura obesa* Sluiter, 1912.

Pyura curvigona Tokioka, 1950

Pyura curvigona Tokioka, 1950, p.147. Kott 1985, p.296 and synonymy.
?*Pyura vittata*: Monniot, 1989, p.490.
?*Pyura uatio* Monniot, 1991b, p.33.

DISTRIBUTION

RECORDED RANGE: The species is known from Shark Bay (Western Australia), Heron and Lizard I. (Queensland), the Palau Is, Indonesia (see Kott 1985), and possibly from New Caledonia.

REMARKS

Monniot (1989) has synonymised this species with the Atlantic Ocean *Pyura vittata*. He appears to have overlooked the opalescent scale which is such a feature of the siphonal armature of the present species (see Kott 1985, Figs 5k, 145a,b). Since the New Caledonian specimens assigned to *P. vittata* have the enlarged rectum, pinnate gonads, and endocarps of the present species it is possible that they are conspecific. Examination of cleared preparations of siphonal armature by light, rather than by scanning electron, microscopy, would, if they are present, display the scales of the siphonal spines which are just under the surface of the test.

The green liver and pink body wall of this species is found also in *P. uatio* from New Caledonia which, however, lacks an expanded rectum, and may be a different species.

Pyura rapaformis Kott, 1990
(Figs 45, 46)

Pyura rapaformis Kott, 1990b, p.287.

DISTRIBUTION

NEW RECORD: South Australia (Beachport Jetty piles, SAM E2510).

RECORDED RANGE: The species, previously recorded from the upper surface of a reef at Cottesloe, probably has a continuous range between Cockburn Sound and St Vincent Gulf.

DESCRIPTION

The present specimens are as previously described, with both apertures on the upper, more or less flattened, surface of a turnip-shaped body. The surface test has irregular extensions and papillae to which sand adheres, and sand also is embedded in the test. The body has a posterior stolon projecting down into the test. The siphonal spines are about 0.08mm long, with a long narrow opening and 4 rounded knobs at the posterior end of the shaft. Branchial tentacles are feathery, with long primary branches. The branchial sac has 6 wide, overlapping folds on each side with 7 to 18 internal longitudinal vessels on the folds and up to 3 between. Leafy, irregular endocarps are on the gut and gonads.

REMARKS

Externally the species resembles individuals of *Pyura isobella* Kott, 1985 from Ulladulla (NSW) and internally it has similar endocarps and gut loop and gonads. The siphonal spines lack the posterior expansion, and the small opening of spines of *P. isobella*, and more closely resemble the spines of *P. tasmanensis* Kott, 1985 (as observed by Kott 1990b).

Genus **Herdmania** Lahille, 1888

Herdmania momus (Savigny, 1816)

Cynthia momus Savigny, 1816, p.143.
Herdmania momus: Kott, 1985, p.338.
Pyura momus: Monniot, 1989, p.498.

DISTRIBUTION

RECORDED RANGE: The species is pantropical, extending into temperate waters of southern Africa and southern Australia.

REMARKS

Monniot (1989) believes the genus *Herdmania* to be a junior synonym of *Pyura*. In addition to the characteristic long barbed spines, *Herdmania* has a continuous ovarian tube surrounded by male follicles, rather than being broken up into separate gonad blocks as in *Pyura*; and the liver lobules are embedded in the body wall, rather than lying free in the atrial cavity as in *Pyura* (see Kott 1985).

Genus **Microcosmus** Heller, 1877

Microcosmus tuberculatus Kott, 1985

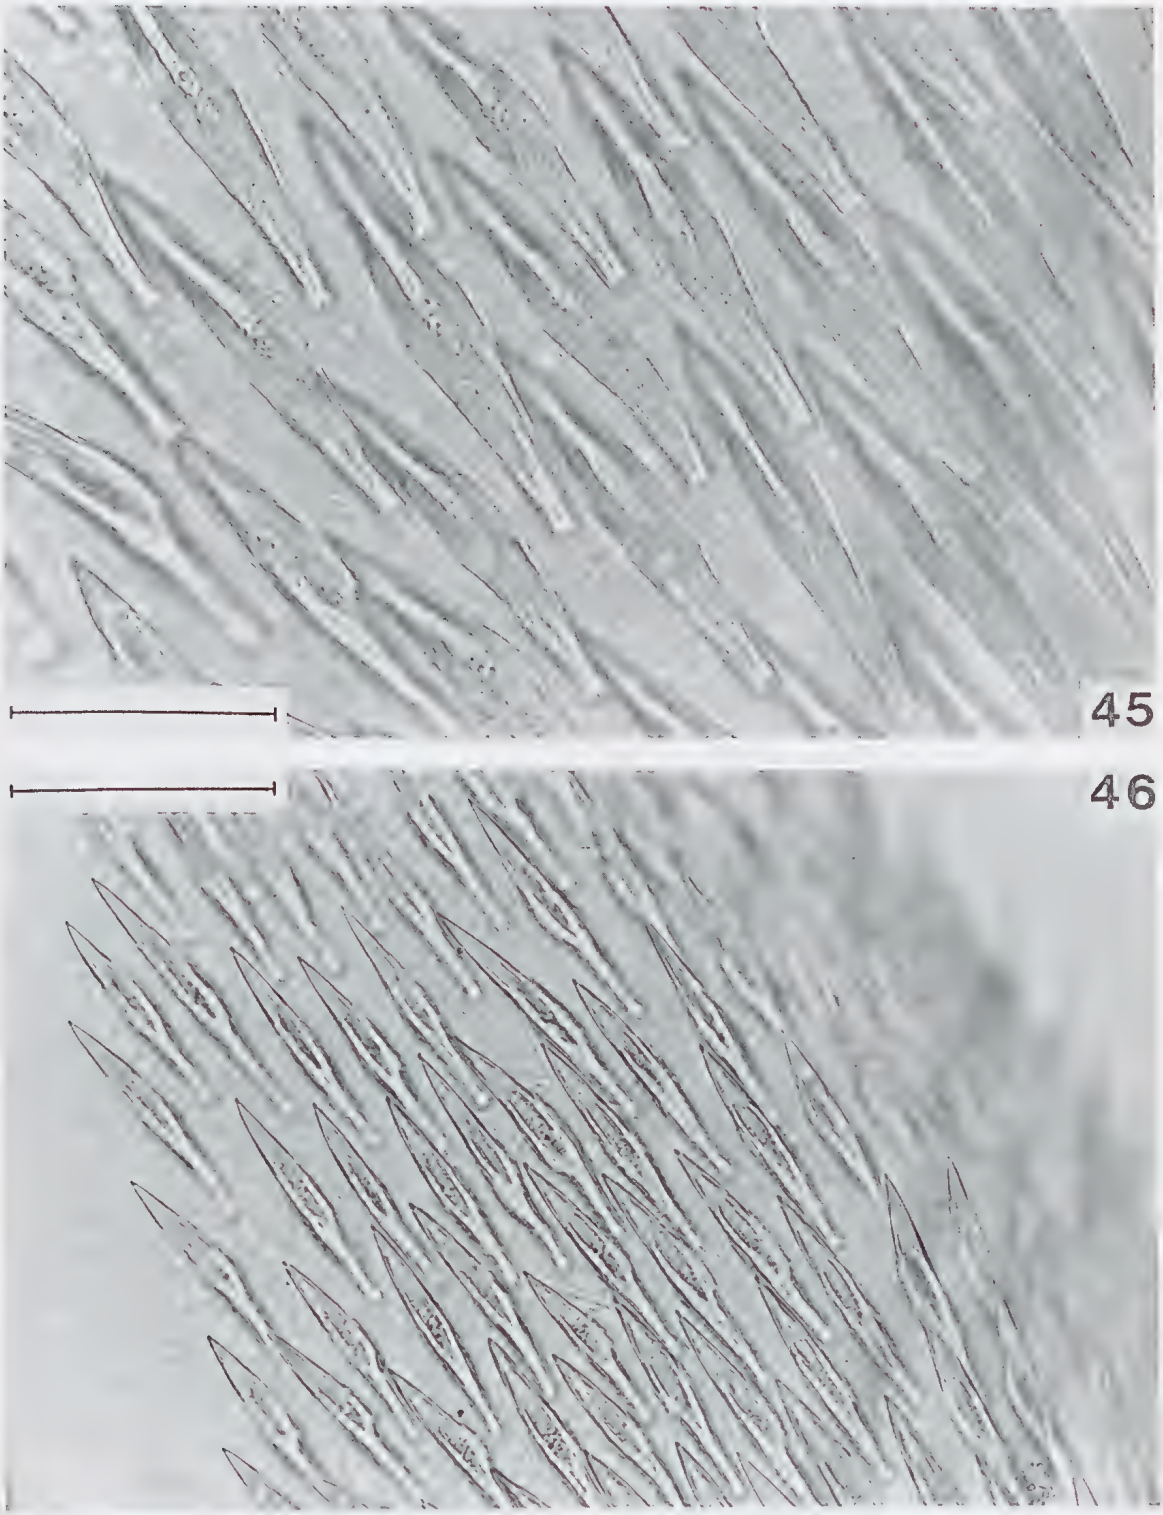
Microcosmus tuberculatus Kott, 1985, p.361. ? Monniot, 1991b, p.31.

DISTRIBUTION

RECORDED RANGE: The species is known for certain only from its type locality in the Swain Reefs.

REMARKS

The species is distinguished from *M. exasperatus* by its large conspicuous conical spines around and lining the apertures (see Kott 1985, Fig. 179b) and the deeply incised anal border. The specimen from New Caledonia (Monniot 1991) has neither of these features. The thick endocarp-like layer of the body wall Monniot observed over the gonads and gut occurs variably in most *Microcosmus* species, including *M. exasperatus*, to which the New Caledonian specimens very likely belong.



FIGS. 45, 46: *Pyura rapaformis* (SAM E2510) — siphonal spines (Scales: 45, 0.05mm; 46, 0.1mm).

Family HEXACROBYLIDAE Seeliger, 1906

The family was reviewed by Kott (1989a), and later, by Monniot and Monniot (1990).

The family is characterised by its large buccal cavity, surrounded by 6, usually large, branched branchial arms, a large kidney, and a reduced perforated pharynx, limited to a short band at the proximal end of the gut. Ciliated stigmata are small and rounded. The gut is well developed with a wide, and often long oesophagus, and there is evidence of adaptation for a carnivorous habit (see Kott 1989a). Although, successively, a new pleurogonid suborder, Aspiraculata Seeliger, 1906, and a new tunicate class Sorberacea Monniot, Monniot and Gaill, 1975 have been proposed for the family, there appears to be no justification for either of these higher taxa (see Kott 1989a).

The Hexacrobylidae have adaptations for deep water habitats, but their morphology is homologous with that of Molgulidae, with which they appear to have closer affinities than the latter family has with other extant ascidian taxa, even within the Pleurogona (see Kott 1989a).

The view (Monniot and Monniot 1990) that the family name Hexacrobylidae should be abandoned in favour of Oligotrematidae (sic. Oligotremidae Monniot and Monniot, 1990) is incorrect (ICZN Article 40). Further, the type genus is *Hexacrobylus* Sluiter, 1905a, a junior objective synonym of *Oligotrema* Bourne, 1903.

Although Kott (1985) thought the family was not represented in Australian waters, *Asajirus indicus* Oka, 1913 and *Oligotrema psammites* Bourne, 1903 have since been recorded (Kott 1989a).

Genus **Asajirus** Kott, 1989a

Type species: *Hexacrobylus indicus* Oka, 1913.

Kott (1989a) examined and redescribed the type specimen (ZMA TU564) of *Hexacrobylus psammatodes* Sluiter, 1905a, and found it to be a species of the genus *Oligotrema* Bourne 1903, possibly conspecific with its type species *O. psammites* Bourne, 1903 from New Britain. Thus was corrected a belief that *Hexacrobylus psammatodes* and *H. indicus* Oka, 1913 were congeneric, and *H. indicus* Oka was found to be a member of an undescribed genus. *Hexacrobylus indicus* Oka, 1913 was therefore designated type species of a new genus *Asajirus* Kott, 1989a (of which *Hexadactylus* Monniot and Monniot, 1990, with the same type species as *Asajirus*, is a junior synonym).

Monniot and Monniot (1990) recognise 12 species in the genus *Asajirus*, distinguished from one another primarily by differences in the length of the vas deferens and in the number and length of testis lobes. It may be difficult to sustain this number of species, in view of the probability that there is some intraspecific variation in taxa which, in many cases, have vast geographic ranges.

The differences are less compelling than the similarities between most of the species Monniot and Monniot (1990) have documented, and many are sympatric in at least part of their range, while some are over their whole range. For instance, *A. longitestis* (Monniot and Monniot, 1990), *A. ovirarus* (Monniot and Monniot, 1990), *A. hemisphericus* (Monniot and Monniot, 1990), *A. gulosus* (Monniot and Monniot, 1984b) and *A. indicus* (Oka, 1913) are all recorded from the vicinity of New Caledonia, *Asajirus millari* (Monniot and Monniot, 1991) also is from the West Pacific (the Bali Sea); *A. seeligeri* (Monniot and Monniot, 1990) and *A. gulosus* are from the Comoro Is in the Indian Ocean and some records of *A. indicus* are also from the Indian Ocean; *A. ledanoisi* and *A. eunuchus* are from wide ranges in the Atlantic, and *A. arcticus* is from the Norwegian Sea; while *A. antarcticus* is recorded from around the Southern Ocean and *A. dichotomus* is from the southeastern Atlantic (the Cape Basin).

It is not intended to review this genus in the present work, rather attention is drawn to some of the problems of species definition in this family. These will not be resolved if descriptions do not take account of the homologies of organs, of similarities in morphology as well as morphological differences, of probable artefacts resulting from contraction and distortion, and of differences that most likely arise from growth and maturity.

Hexadactylus seeligeri Monniot and Monniot, 1990, p.281.

DISTRIBUTION

NEW RECORDS: Coral Sea (12° 05' S 146° 24'E, *Cidaris* 3 site 6.1, 16.2.92, 3319–3105m, QM G300891; 13° 29'S 147° 13'E *Cidaris* 2 Site 15.1, 5.9.88, 2542–2457, QM G300892.

RECORDED RANGE: The recorded range for *A. indicus* and its probable synonyms is: *A. longitestis* — New Caledonian (both sides of the Norfolk Ridge); *A. indicus* — the Indian Ocean, New Caledonia, off eastern Australia from 151°27' to 148°38'E and 12° to 42°S from the Coral Sea to eastern Tasmania; *A. seeligeri* — the Indian Ocean and Comoro Is.; *A. millari* — the Bali Sea (western Pacific); *A. eunuchus* — southwestern and northern Atlantic; *A. arcticus* — northeastern Atlantic; *A. antarcticus* — South Indian and Pacific Oceans.

The species is found at depths from 1000 to 5000m. The record for the specimen AM Y2125 from off the New South Wales coast, is from 151°27'E, not 51°27'E as reported by Kott (1989a).

DESCRIPTION

The newly recorded specimens are rounded posteriorly, 1.2 cm long, but contracted anteriorly, causing the fine hairlike projections mixed with foraminifers and other paricles to appear more crowded than they are posteriorly. Internally the 2 ventral muscle bands are short and broad. the rectum is crowded with hard particles including foraminifers, polychaetes, ostracods, cladocerans, isopods, gastropods and what appears to be particles of ophiurid (including spines). The remainder of the gut (the long oesophagus and stomach) are empty.

REMARKS

Specimens from the northern Atlantic (*A. ledanoisi*) and from the Cape Basin, south-eastern Atlantic (*A. dichotomus*) with long sperm ducts are not included in the above synonymy of *A. indicus*, although *A. eunuchus* (Monniot and Monniot, 1976) from the south-western and northern Atlantic, *A. arcticus* (Hartmeyer, 1923) from the Norwegian Sea, *A. antarcticus* (Monniot and Monniot, 1982) from the southern (polar) Indian and Pacific Oceans and *A. millari* from the Bali Sea have short male ducts as in *A. indicus*, and are here included in its synonymy, as is *A. seeligeri* (with both short on long male follicles) from the Indian Ocean, and *A. longitestis* (with long male follicles) from New Caledonia. *Asajirus indicus* (Oka, 1913) as well as being taken from off the eastern Australian coast, is from the Indian Ocean and New Caledonia.

Also from New Caledonia, and, for the present, excluded from the synonymy of *A. indicus*, are *Asajirus hemisphericus* and *A. ovirarus*, with more or less entire testis; and *A. gulosus* with a long vas deferens like *A. ledanoisi* and *A. dichotomus*.

Genus **Oligotrema** Bourne, 1903

Type species: *Oligotrema psammites* Bourne, 1903.

Although not designated a neotype, Monniot and Monniot (1990) redescribed the species from a specimen taken from near the type locality.

Monniot and Monniot's definition of the genus omits certain significant characteristics described by Bourne, which also are present in the type specimen of *Hexacrobylus psammatodes* Sluiter, 1905a (see Kott 1989a). Monniot and Monniot (1990) refer to the widely separated apertures but not to the posterior position and orientation of the atrial aperture; they refer to muscles extending the length of the body wall, but fail to indicate that these are circular muscles, sometimes interrupted; and that longitudinal muscles are very limited; nor do they refer to the flagellated epithelial covering of the branchial tentacles described by Bourne (see also Kott 1989a).

Monniot and Monniot (1990) indicate, as Kott (1989a) had suggested, that the branchial stigmata are circular perforations, rather than the rectangular stigmata described by Bourne. This removes the principal restraint to the synonymy of *H. psammatodes* Sluiter, 1905a with the present species. Other characters, viz. the branchial

tentacles, the large endocarps and the large atrial cavity, are as described by Bourne, and by Kott (1989a) for the type specimen of *H. psammatodes* Sluiter, 1905a (ZMA TU564).

There is no additional evidence regarding the proposed synonymy of *Gasterascidia*, *Sorbera* with *Oligotrema* (see Kott 1989a). Nor is there any clarification regarding the apparent degeneration of the rectum in *Gasterascidia lyra*, which, if present, appears to be non-functional (see Monniot and Monniot, 1990 Fig. 5B).

?*Sorbera digonas* Monniot and Monniot, 1984b, p.209.

Oligotrema psammatodes: Kott, 1989a, p.529. Monniot and Monniot, 1990, p.258.

DISTRIBUTION

RECORDED RANGE: The species is recorded from New Britain (Bourne 1903; Monniot and Monniot 1990), Indonesia (ZMA TU564, Siboga, Station 211, Banda Sea, Sluiter 1905a), west of New Caledonia (Monniot and Monniot 1990); New South Wales coast (Kott 1989a) and the south-east Atlantic (the Cape Basin, Monniot and Monniot 1984b).

Sorbera digonas is recorded from the tropical Indian Ocean.

REMARKS

The specimens all have the shallow ventral groove in the pharynx; vertically flattened branchial tentacles with one or 2 short, pointed, projections anteriorly, an otolith-like black granule in the neural gland, and the parietal wall of the atrial cavity raised into long endocarps on each side of the oesophagus. These endocarps sometimes cover part of the gonads. In the thick pharyngeal wall the interconnected chambers (that the Monniots in 1984 and 1990 refer to as branching tubules) eventually open to the atrial cavity by small, rounded ciliated stigmata which vary in number according to the size of the specimen. The ligament attaching the oesophagus to the body wall (Kott 1989a) appears to be the ventral septum dividing the atrial cavity into two sections (Monniot and Monniot 1990). In fact, the atrial invagination is always from the dorsal surface and the cavity always is continuous over the dorsum. It never penetrates ventral to the pharynx, past the ventral sinus. The ligament or septum is merely the ventral body wall where it is not interrupted by the atrium.

CONTENTS

PART 1 (Issued 30 June, 1993)

BRUCE, N.L.
Two new genera of marine isopod crustaceans (Cirolanidae) from Madang, Papua New Guinea 1

CANNON, L.R.G.
New temnocephalans (Platyhelminthes): ectosymbionts of freshwater crabs and shrimps 17

CHIMONIDES, P.J. & COOK, P.L.
Notes on *Parmularia* MacGillivray (Bryozoa: Cheilostomida) from Australia 41

COOK, A.G.
Two bivalves from the Middle Devonian Burdekin Formation, north Queensland 49

SHORT, J.W.
Cherax cartalacoolah, a new species of freshwater crayfish (Decapoda: Parastacidae) from northeast Australia 55

HOOPER, J.N.A., KELLY-BORGES, M. & RIDDLE, M.
Oceanapia sagittaria from the Gulf of Thailand 61

RICHARDS, S.J. & JOHNSTON, G.R.
A new species of *Nyctimystes* from the Star Mountains, Papua New Guinea 73

VAN DYCK, S.
The taxonomy and distribution of *Petaurus gracilis* (Marsupialia: Petauridae), with notes on its ecology and conservation status 77

DWYER, P.D.
The production and disposal of pigs by Kubo people of Papua New Guinea 123

DAVID, B. & DAGG, L.
Two caves 143

COUPER, P.J.
A new species of *Lygisaurus* de Vis (Reptilia: Scincidae) from mideastern Queensland 163

DAVIES, M., WATSON, G.F., MCDONALD, K.R., TRENERRY, M.P. & WERREN, G.
A new species of *Uperoleia* (Anura: Leptodactylidae: Myobatrachinae) from northeastern Australia .. 167

DAVIES, V.T.
The spinning field and stridulating apparatus of penultimate male *Macrogradungula moonya* (Araneae: Austrochiloidea: Gradungulidae) 175

HAND, S.
First skull of a species of *Hipposideros*(*Brachipposideros*) (Microchiroptrea: Hipposideridae), from Australian Miocene sediments 179

HAND, S., ARCHER, M., GODTHELP, H., RICH, T.H. & PLEDGE, N.S.
Nimbadon, a new genus and three new species of Tertiary zygomaturines (Marsupialia: Diprotodontidae) from northern Australia, with a reassessment of *Neohelos* 193

HEALY, J.M., LAMPRELL, K.L. & STANISIC, J.
Description of a new species of *Chama* from the Gulf of Carpentaria with comments on *Pseudochama* Odhner (Mollusca: Bivalvia: Chamidae) 211

HUNT, G.S.
A new cavernicolous harvestman from lava tube caves in tropical Australia (Arachnida: Opiliones: Phalangodidae) 217

INGRAM, G.J., NATTRASS, A.E.O. & CZECHURA, G.V.
Common names for Queensland frogs 221

JAMIESON, B.G.M.
Spermatological evidence for the taxonomic status of *Trapezia* (Crustacea: Brachyura: Heterotremata) 225

JAMIESON, B.G.M.
A taxonomic revision of the eastern Australian earthworm genus *Perissogaster* Fletcher (Megascolecidae: Oligochaeta) 235

KELLY, S.R.A.
On the alleged occurrence of the Early Cretaceous ammonite *Simbirskites* in Queensland 245

LAMBKIN, K.J.
New information on the Australian small bittacids (Mecoptera) 253

LEACH, G.J. & HINES, H.B.
Frequency of observation of bird species in sub-coastal farmland in southeast Queensland 259

LIMPUS, C.L., COUPER, P.J. & COUPER, K.L.D.
Crab Island revisited: reassessment of the world's largest Flatback Turtle rookery after twelve years 277
PATERSON, R.A., QUAYLE, C.J. & VAN DYCK, S.M.
A Humpback Whale calf and two subadult Dense-beaked Whales recently stranded in southern Queensland 291
QUICKE, D.L.J. & INGRAM, S.N.
Braconine wasps of Australia 299
RICHARDS, S.J. & ALFORD, R.A.
The tadpoles of two Queensland frogs (Anura: Hylidae, Myobatrachidae) 337
INGRAM, G.J., COUPER, P.J. & DONNELLAN, S.
A new two-toed skink from eastern Australia 341
WEBSTER, G.D. & JELL, P.A.
Early Permian inadunate crinoids from Thailand 349
WILLIAMS, S., PEARSON, R. & BURNETT, S.
Survey of the vertebrate fauna of the Dotswood area, north Queensland 361
WILLIAMS, S., PEARSON, R. & BURNETT, S.
Vertebrate fauna of three mountain tops in the Townsville region, north Queensland: Mount Cleveland, Mount Elliot and Mount Halifax 379

NOTES

ARNOLD, P.
First record of ctenophore *Coeloplana* (*Benthoplana*) *meteoris* (Thiel, 1968) from Australia 16
CATTERALL, C.P.
A record of the Common Planigale at Myora Springs: the first dasyurid from North Stradbroke Island 54
PORTER, R. & HUSBAND, G.
A record of communal egg-laying in the skink *Carlia tetradactyla* 60
SHEA, G.M.
New records of *Lerista allanae* (Squamata: Scincidae) 220
JELL, P.A. & LAMBKIN, K.J.
Middle Triassic orthopteroid (Titanoptera) insect from the Esk Formation at Lake Wivenhoe 258
SIMPENDORFER, C.A.
Pandarid copepods parasitic on sharks from north Queensland waters 290
NATTRASS, A.E.O. & INGRAM, G.J.
New records of the rare Green-thighed Frog 348
JELL, P.A.
Late Triassic homopterous nymph from Dinmore, Ipswich Basin 360

PART 2 (Issued 11 November, 1993)

PROCEEDINGS OF THE XII INTERNATIONAL CONGRESS OF ARACHNOLOGY

INVITED PAPERS

SELDEN, P.A.
Fossil arachnids–recent advances and future prospects 389
POLIS, G.A.
Scorpions as model vehicles to advance theories of population and community ecology: the role of scorpions in desert communities 401
ELGAR, M.A.
Inter-specific associations involving spiders: kleptoparasitism, mimicry and mutualism 411

CONTRIBUTED PAPERS

ADIS, J. & MAHNERT, V.
Vertical distribution and abundance of pseudoscorpions (Arachnida) in the soil of two different neotropical primary forests during the dry and rainy seasons 431
AUSTIN, A.D.
Nest associates of *Clubiona robusta* L. Koch (Araneae: Clubionidae) in Australia 441
BAERT, L. AND JOCQUÉ, R.
A tentative analysis of the spider fauna of some tropical oceanic islands. 447

BENTON, T.G.
The reproductive ecology of *Euscorpius flavicaudis* in England 455
CANARD, A. & STOCKMAN, R.
Comparative postembryonic development of arachnids 461
CATLEY, K.M.
Courtship, mating and post-oviposition behaviour of *Hypochilus pococki* Platnick (Araneae, Hypochilidae) 469
CHURCHILL, T.B.

TWO NEW GENERA OF MARINE ISOPOD CRUSTACEANS (CIROLANIDAE) FROM MADANG, PAPUA NEW GUINEA

NIEL L. BRUCE

Bruce, N.L. 1993 06 30: Two new genera of marine isopod crustaceans (Cirolanidae) from Madang, Papua New Guinea. *Memoirs of the Queensland Museum* **31**(1): 1-15. Brisbane. ISSN 0079-8835.

Aatolana gen.nov. is characterized by lobate pleopod peduncles, medially indented cephalon anterior margin, and posteriorly acute epimera on pleonite 3. *Aatolana rapax* sp.nov., the type species, is described from specimens trapped at depths from 150-450m off the outer reef slope at Madang. *Aatolana schiodtei* comb.nov. is transferred from the genus *Cirolana*. *Plakolana* gen.nov. is characterised by flattened posterior pereopods provided with long setae and spines, a medially indented cephalon anterior margin, elongate frontal lamina, quadrate pleopod 1 peduncle and the unique shape of the epimera of pleonite 3. *Plakolana accola* sp.nov., the type species, is described from trapped specimens off the outer reef slope at Madang, at depths from 300 to 450m. *Plakolana nagada* sp.nov. occurs within the barrier reef in shallow (16-22m) silty or sandy bottoms. *Plakolana* sp. and *P. binyana* comb.nov. are transferred from *Cirolana*. Both genera are known only from the Southwest Pacific. □*Isopoda, Cirolanidae, new genera, new species, Aatolana, Plakolana, southwest Pacific, taxonomy.*

*Niel L. Bruce, Queensland Museum, PO Box 3300, Queensland 4101, Australia; present address: Zoologisk Museum, University of Copenhagen, Universitetsparken 15, DK 1200, København Ø, Denmark;**Contribution No.74 from the Christensen Research Foundation, POB 305, Madang, Papua New Guinea; 10 July, 1992.*

Published reports devoted to the marine isopod fauna of New Guinea are few (see Bruce, 1982, Jones et al., 1983) although a number of records have recently been published as part of longer reports (e.g. Bruce, 1986a,b; Bruce & Harrison-Nelson, 1988; Williams & Williams, 1992). The nearby region of tropical and subtropical Queensland has receeived more attention from isopod taxonomists, and there the family Cirolanidae is represented by 52 species in 12 genera (although numerous species still remain to be described).

In 1989, I spent three weeks at the Christensen Research Institute at Jais Aben, Madang surveying the isopod fauna of the reefs and, to a lesser extent, near-reef sediments, from the intertidal to a depth of about 30m. Cirolanids were sampled at greater depths by the use of baited traps. The area proved to have a rich and diverse isopod fauna with well in excess of 100 species. With more thorough sampling of particulate sedimentary habitats this total should rise even further.

The family Cirolanidae is represented in the Madang collection by about 27 species in 11 genera, indicating a very high diversity when compared to figures available for single localities elsewhere. For example, Heron Island, a well collected location at the southern end of the Great Barrier Reef has 16 species in 7 genera (Bruce, 1986a). The entire Caribbean region has a total 22 free-living species (Kensley & Schotte, 1989), while Aldabra Island, in the Western Indian Ocean, when surveyed by Kensley (1988), yielded only 3 species.

MATERIAL AND METHODS

Specimens were collected using methods described in Bruce (1986). Appendages were dissected from the right side of the specimen unless stated otherwise in the figure captions. All species described here were collected by setting baited traps overnight. The trap design is a 'minnow trap' made of storm drain piping fitted with end caps to which cut off funnels had been fitted.

Drawings of appendages were made using a compound microscope for *Plakolana* and a dissecting microscope for the larger *Aatolana*.

Pereopod orientation is identified as anterior (= superior) and posterior (= inferior); the margin to which the dactylus folds is regarded as posterior in both pereopods 1-3 and 4-7, even though the orientation of the posterior limbs is reversed; the lateral surface is the outward facing surface of the pereopod, and mesial is inward facing. Anterior (An) and posterior (Po) are identified on Fig 2.

Specimens have been deposited at the Queensland Museum (QM), Australian Museum (AM) and Museum of Victoria (NMV). Voucher samples have been donated to the San Diego Natural

History Museum. PMS= plumose marginal setae; BL= body length.

TAXONOMY

General Remarks

Bruce (1986a: 223) listed a number of cirolanid species as incertae sedis, all but one being retained in *Cirolana*. Since that time only one, *Protognathia bathypelagica* (Schultz, 1977) has been relocated (Wägele & Brandt, 1988). Two of the species described by Bruce (1986a), *Cirolana schiodtei* Miers and *Cirolana* sp., were regarded as not conforming to the concept and diagnosis of *Cirolana*, but establishment of new monotypic genera was regarded as premature. Bruce (1991) later described a species that was obviously very similar to *Cirolana* sp. of Bruce (1986a) with the same set of characters that precluded assignment to *Cirolana*. That species was placed in *Cirolana*, also with the caveat of incerta sedis. The discovery of the species described here now provides a solid foundation to establish new genera for these species. In so doing, the generic concept of *Cirolana* can also be refined. It can now be stated that in *Cirolana* (sensu stricto) the anterior margin of the cephalon is with a rostral point or smoothly rounded (never medially indented); pleonite 3 does not encompass pleonites 4 and 5, though pleonite 3 is often posteriorly produced; pleonite 3 (in all Australian species) is narrowly rounded or acute; pereopods 5-7 are without long setae or long spines, and are robust (i.e. have few short spines, and no flattened articles).

Aatolana gen.nov.

Body without tubercles or dorsal sculpture. Cephalon without rostral point, anterior margin medially indented. Eyes large, about 3 times as long as wide. Pereonite 1 about twice as long as pereonite 2. Pleon with 5 visible segments; pleonite 3 with epimera expanded, posteriorly acute, extending to or beyond pleonite 5. Pleotelson with stout spines and PMS.

Antennule peduncle articles of about equal length; article 2 shortest. Antennal peduncle with articles 1-3 short, 4 and 5 longest. Frontal lamina slightly longer than wide; anterior margin curved, visible in dorsal view, with dorsally deflected apical point. Mandible with spine row and molar process well developed; lacinia mobilis absent; incisors assymetrical, right with 3 prominent cusps, left with middle cusp reduced. Maxillule with stout spines on lateral lobe; 3 robust circumplumose spines on medial lobe. Maxilla with all lobes well developed. Maxilliped palp with lateral and medial margin setose; endite with 2 coupling hooks.

Pereopods 1-3 with anterodistal margins of ischium and carpus not produced; posterior margin without elongate spines. Pereopods 5-7 subsimilar. Pereopod 7 with all articles robust, not flattened or natatory; basis with row of setae on posterior margin and lateral carina. Pereopod dactylus without distinct secondary unguis. Penes present on sternite 7, flattened, rectilinear, about twice as long as wide.

Pleopod 1 exopod lateral margin convex, apex narrow. Pleopods 1-3 with both rami with PMS; pleopods 3 and 4 endopods with reduced PMS; endopod of pleopod 5 without PMS. Peduncles of pleopods 1-5 with lateral margin forming, complex refolded lobe. Pleopod 2 appendix masculina basally attached, elongate, longer than endopod. Pleopod 1-4 exopods with slender accessory lamella at posterior proximolateral angle. Uropods with stout spines; mediodistal angle of peduncle produced.

Female: Maxilliped with lamina vibrans in ovigerous specimens. Brood pouch composed of oostegites arising from coxae 1-5. Pleopods 2-5 with accessory lamellae more prominent than in male.

Type Species

Aatolana rapax sp.nov., here designated.

Etymology

From the Greek *Aatos* (insatiable, referring to the ability of this species to devour fish carcasses) combined with *-lana*. Gender is feminine.

Remarks

Characters by which this genus can be identified are the unique apomorphies of the pleopod peduncle lobes and the frontal lamina structure, and also the prominent and posteriorly acute epimera on pleonite 3. Other characters which also identify the genus, though not unique, are the medially indented anterior margin of the cephalon, the shape of pleopod 1 exopod, and the prominent flattened penes. The medially indented anterior margin of the cephalon is a subtle char-

acter, but is none the less clearly expressed by those genera that show it.

The genus *Cirolana* has no species with medially indented cephalon, flattened rectilinear penes, lobate pleopod peduncles or large epimera on pleonite 3. Additionally *Cirolana* species all have a prominent secondary unguis on the pereopod dactylus and more plumose marginal setae on the endopods of pleopods 3 and 4.

Other Species

Aatolana schioedtei (Miers, 1884) comb.nov. Tropical Australia, from Rottnest Island, Western Australia to Hayman Island (Bruce, 1986a).

Affinities

Aatolana is similar only to *Booralana* Bruce, 1986. Both genera share similar- shaped pleopod rami, have similar elongate eyes, prominent flattened penes, medially indented cephalon and prominent epimera on pleonite 3. The frontal lamina structure of the two genera differ, and in *Booralana* pleonite 2 has well developed epimera, pleonites 2 and 3 both having a ventral flange. Additionally in *Booralana* the pleotelson and uropods are without spines.

KEY TO THE SPECIES OF *AATOLANA*

1. Pleonite 4 posterolateral margin rounded; uropod endopod lateral margin straight; pleotelson dorsal surface never setose ..... *A. rapax*

   Pleonite 4 posterolateral margin acute; uropod endopod lateral margin sinuate; pleotelson dorsal surface of large males setose ..... *A. schioedtei*

Aatolana rapax sp.nov.
(Figs 1-3)

Material Examined

Holotype: ♂(28.7mm), outer reef slope, 5°8.4'S, 145°49.0'E, 3 May 1989, 200-150m depth, baited trap, coll. N.L. Bruce & M. Jebb (QM W17467).

Paratypes: 9♂♂(20.0-32.2mm, m=28.3), 4 ovig ♀♀(29-33mm, mean 30.5), 6 non ovig ♀♀(21-31mm, mean 24.7); 2 mancas (7.0, 7.7mm), subsampled from c.200 specimens, data as for holotype (QM W17468).

Other Material: 200 specimens, topotypic series, same station as holotype, (QM W17471, NMV J27477, San Diego Natural History Museum). 4♂♂, 38♀♀, as for holotype, but 28 Apr 1989, 450m (QM W17469). 200+ specimens, as for holotype, but 29 Apr 1989, 300m (QM W17470). 93 specimens (mostly immature) outer barrier reef, between Rasch Pass and Wongat Is., 5°8.7'S, 145°49.7'E, 26-27 Jan 1990, 240m depth, coll. J.K. Lowry, J. Mizeu, J.D. Thomas (AM P40160).

Description

Body about 2.6 times as long as wide; pereonite 1>2=3<4=5<6>7. Pleonite 1 largely concealed by pereonite 7, epimera of pleonite 3 with posterior margin acute, with 3 longitudinal carina, medial one of which is provided with long setae; posterior margins of pleonite 4 epimera rounded, with very weak longitudinal carina. Pleotelson with lateral margins convex, converging to acute apex either side of which are 6 stout spines set amongst single row of PMS; spines restricted to distal third of pleotelson; proximal half (0.48) of lateral margin without PMS.

Cephalon with anterior submarginal furrow, dorsal interocular furrow running along top of eyes, but not extending beyond eyes. Antennule peduncle article 1 longest, 2 shortest; 4th short terminal article present; flagellum composed of about 32 articles, 1.5 times as long as peduncle, extending to anterior of pereonite 1. Antenna flagellum with about 60 articles, extending to anterior of pereonite 6. Frontal lamina as for genus. Mandible spine row with 19 spines; molar process with 27 spines interspersed with stout serrate setae; palp article 2 longest, with dense setose fringe on outer distal margin; article 3 lateral margin with continuous setae. Maxilla with 10 and 13 setae on lateral and middle lobes respectively; medial lobe with 1 large and 4 smaller circumplumose setae; anterior to these are two ranks of setae, posterior rank of 13 simple setae, anterior rank of 8, distal 5 of which are long. Maxilliped palp with simple setae on lateral margins of articles 3-5, PMS on article 2; articles 2-5 with about 15, 35, 20 and 11 lateral setae respectively; medial margins of articles 2-5 with about 19, 20, 12 and 12 setae respectively; article 5 with some serrate setae; endite with 6 long plumose setae.

FIG. 2. *Aatolana rapax* sp.nov. All figs of♂paratype 32.2mm, except N. A, maxilliped; B, distal margin, maxilliped palp article 5; C, distal margin, antennule peduncle; D, antennal flagellum, articles 23-27; E, maxilliped endite; F, pereopod 1; G, pereopod 2; H, pereopod 7; I-L, pleopods 1,3,2,5 respectively; M, pleopod 2 peduncle lateral margin; N, apex of appendix masculina,♂31.5mm (An = anterior margin, Po = posterior margin).

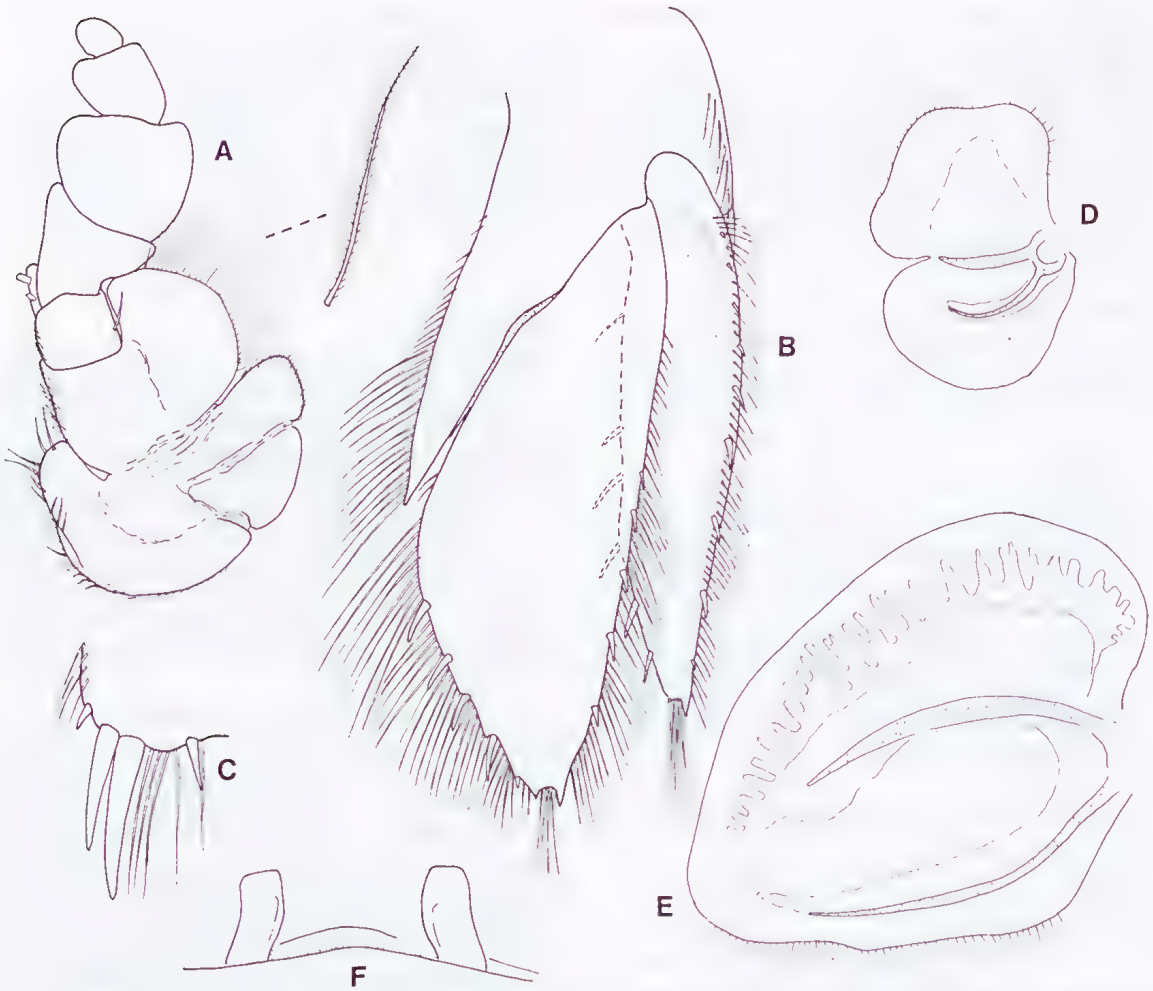

FIG. 3. *Aatolana rapax* sp.nov. A, D, E, ovig. ♀ paratype 29.4mm. A, maxilliped, showing lobes; D, oostegite 1; E, oostegite 5; B, uropod, ♂ paratype 32.2mm; C, ventrolateral angle, uropod peduncle, ♂ 32.2mm; F, penes, *in situ*, holotype.

Pereopod 1 basis with 5 setae at posterodistal angle; ischium with 6 setae at anterodistal angle; merus with 9 tubercular spines on posterior margin, 5 short simple setae at anterodistal angle; carpus with single spine on posterior margin; propodus with 3 spines on palm, 4th larger spine opposite base of dactylus. Pereopod 2 longer than 1; ischium with 6 long spines anterodistal angle, 2 robust spines posterodistal angle; merus with indented posterior margin, proximal portion with 6 stout spines, anterior portion with 2 large stout and 1 acute spine and 6 stout spines at anterodistal angle; carpus with 4 spines at anterodistal angle; propodus with 3 small spines, 4 spine at anterodistal angle; propodus with 3 small spines, 4th spine opposite base of dactylus. Pereopod 7 basis with fringe of setae on anterior margin and median carina; posterior margin of ischium with 3 clusters of short setae, 4 large spines at posterodistal angle; merus and carpus with cluster of spines on posterior margin and posterodistal angle; ischium-carpus with clusters of spines at anterodistal angles only; propodus with 3 pairs of spines on posterior margin.

FIG. 4. *Plakolana accola* sp.nov. A-E, holotype, ♂ remainder paratype 9.3mm. A, dorsal view; B, frons; C, lateral view; D, cephalon; E, pleonites, lateral view; F, antennule; G, distal margin, antennule peduncle; H, antennal peduncle; I, antenna, flagellum articles 9 and 10; J, antenna, flagellum terminal articles; K, right mandible; L, left mandible, incisor and spine row; M, maxillule; N, maxilla, O, maxilliped. Scale represents 2.0mm.

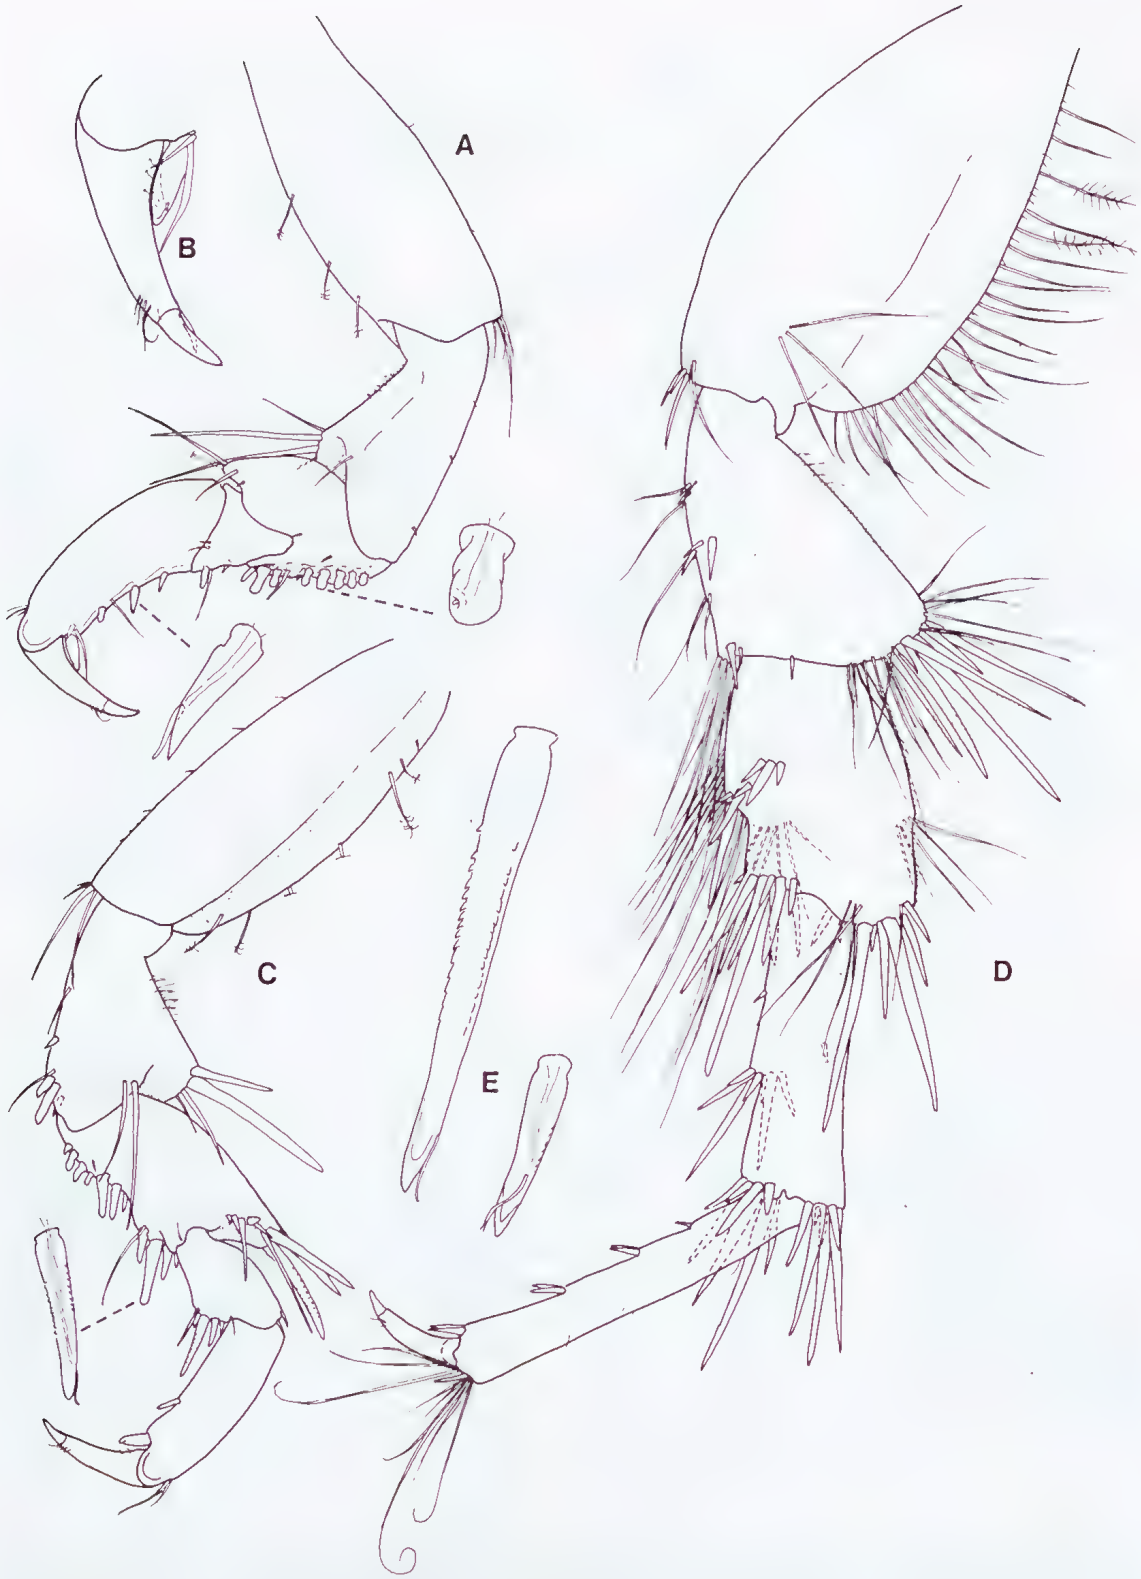

FIG. 5. *Plakolana accola* sp.nov. All figs of ♂ paratype 9.3mm. A, pereopod 1; B, dactylus, pereopod 1; C, pereopod 2; D, pereopod 7; E, spines from posterodistal angle of merus.

Pleopods as for genus. Appendix masculina with apex bent medially. Uropod exopod distinctly shorter than endopod, apex sub-bifid, lateral process prominent; lateral margin with 8-10 spines, medial with 5 spines set amongst PMS. Endopod lateral margin straight, with 5 spines, PMS for about 0.75 distal margin; medial margin with 5 spines set amongst PMS; apex sub-bifid, small spine set medially to apex.

Female. Similar to male but for: maxilliped with lamina vibrans (3 plates); pleopod endopod lobes slightly larger. Oostegites on coxae 1-5, largely overlapping; embryos retained with single large cavity formed by indentation of ventral body surface in body. Female of 29mm contained 28 ova, measuring 2.5-2.8mm in diameter.

Colour. Pale tan with abundant small reddish brown chromatophores giving a rusted appearance in life; eyes black.

Size. Males 19-32mm, non-ovigerous females 21-31mm, ovigerous females (4 specimens measured) 29-32mm. Two mancas, with pereopod 7 not present, measured 7.0 and 7.7mm.

Variation. Males, females and mancas present uniform appearance, but many specimens had malformed uropods and pleotelson. The spine counts presented here are based on 20 specimens, but damaged specimens have been omitted. Telson (n=17) with 6+6 spines (41.2%), 6+7 spines (29.4%) or 7+7 (29.4%). Exopod (n=38) lateral margin with 9 (47.4%), 8 (21.1%) or 10 (15.8%) spines; medial with 5 (94.7%) spines. Endopod (n=36) lateral margin with 5 (44.4%), 6 (41.7%) or 7 (5.6%) spines; medial margin with 5 (11.0%), 6 (63.9%) or 7 (27.8%) spines.

Remarks

This species is readily identified and distinguished from *A. schioedtei* by the pleotelson spines being restricted to the posterior third of the pleotelson, uropod lateral margins being straight not sinuate, posterior margin of pleonite 4 being rounded not acute and in lacking an entire dorsal interocular furrow. *Aatolana rapax* never has the dorsal surface of the pleotelson setose, which occurs in large males of *A. schioedtei*.

Plakolana gen.nov.

Body smooth, unornamented. Cephalon anterior margin medially indented, without rostral point. Pereonite 1 about twice as long as 2; pleonite 1 partly or wholly concealed by pereonite 7. Pleonite 3 with epimera prominent, with postero ventral incision; longitudinal carina with row of setae; extends posterior to pleonites 4 and 5. Telson with prominent spines and PMS.

Antennule peduncle articles 1 and 2 subequal in length, article 3 slightly longer than combined lengths of articles 1 and 2. Antenna with articles 1-3 short, 4 and 5 long, with article 5 longest. Frontal lamina slender, elongate, about 5 times longer than basal width. Mandibles with prominent spine row and molar process. Maxillule lateral lobe with stout spines on gnathal surface, medial lobe with 3 stout circumplumose spines. Maxilla with all lobes well developed. Maxilliped palp articles 2-5 with both margins setose; endite with 2 coupling hooks and prominent plumose setae.

Pereopods 1-3 with long spines at anterodistal angles of ischium and merus; pereopods 4-7 with ischium, merus and carpus, expanded, markedly flattened, abundantly provided with long spines, and long simple setae on anterior margin of basis, and posterior margins ischium and merus. All pereopods with slender secondary unguis on dactylus. Penes opening flush (or nearly so) to ventral surface of sternite 7.

Pleopod 1 peduncle quadrate, slightly longer (1.2) than wide; pleopod 2 appendix masculina attached basally. PMS present on all rami except the endopod of pleopod 5. Uropod peduncle with prominent row of simple setae along lateral margin.

Female: Maxilliped with lamina vibrans, in ovigerous specimens. Brood pouch composed of oostegites arising from coxae 1–5.

Type Species

Plakolana accola sp.nov., here designated.

Etymology

From the Greek *Plakos* ('anything flat and wide') combined with *-lana*. Gender is feminine.

Remarks

The genus is characterized by having flattened and densely spined and setose posterior pereopods, slender secondary unguis on the dactylus, the unique shape of pleonite 3 (with an a cute posterior point and ventrolateral incision), the elongate frontal lamina and the quadrate peduncle of pleopod 1. The flattened basis pereopaods 4-7 with a row of simple setae along the anterior margin, is the only character that can be recognized as a potential unique apomorphy. Nonetheless the combination of characters delimits the genus.

Species of *Cirolana* never have flattened posterior pereopods, nor pereopods with abundant setae or elongate spines, and the peduncle of pleopod 1 is about twice as wide as long; in

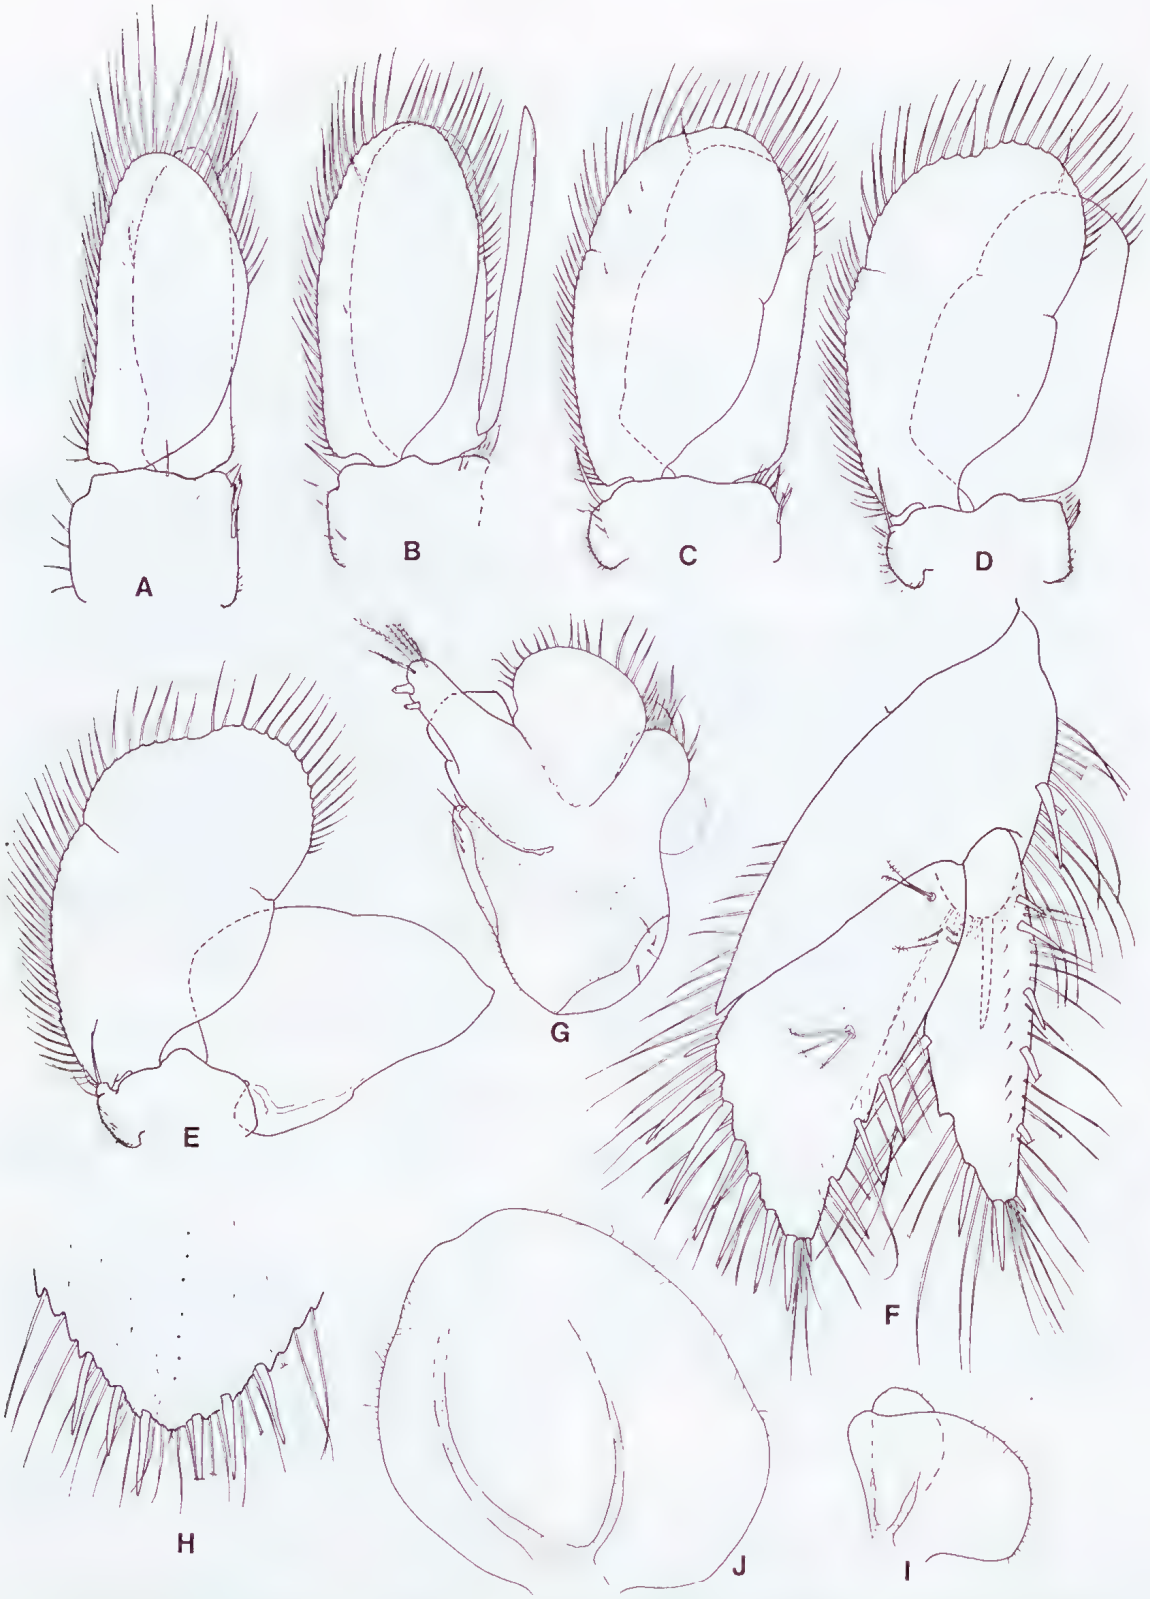

FIG. 6. *Plakolana accola* sp.nov. G, I, J, ♀paratype 10.5mm, remainder ♂ paratype 9.3mm. A-E, pleopods 1-5 respectively; F, uropod; G, maxilliped, showing lobes; H, pleotelson apex; I, oostegite 1; J, oostegite 5.

Cirolana the cephalon has a rostral point or smoothly rounded, but never medially indented. Those species that do show some of these character (see below) are in need of redescription and their generic placement reassessed.

DISTRIBUTION

The genus is currently known from the western South Pacific.

OTHER SPECIES

Plakolana binyana (Bruce, 1991). comb.nov. Southeastern Australia.

Plakolana nagada sp.nov. Madang, Papua New Guinea.

Plakolana sp. (as *Cirolana* sp. Bruce, 1986). Eastern Australia. Known from a single immature specimen.

It is possible that *Cirolana bougartii* Kensley, 1984 belongs in *Plakolana* because the morphology of the antennule, frontal lamina, pereopods and pleopods all agree with the generic diagnosis. Characters that differ include the anterior margin of the cephalon being apparently smoothly rounded (possibly due to the perspective of the figure), pleonite 1 is largely visible, and the pleotelson and uropods are not described as having spines. This species needs further examination to assess its correct generic placement. Similarly *Cirolana stebbingi* Nierstrasz, 1931 shows a similar pleon, antennule, pereopod and pleopod morphology, and also needs to be described in detail before it can be assigned to the correct genus.

AFFINITIES

The pereopod morphology, smooth body surface, elongate pleopod 1 peduncle, and frontal lamina shape suggest that this genus is closest to *Politolana* Bruce, 1981. *Politolana* however differs in having the anterodistal margin of the ischium and merus of pereopod 1 strongly produced, in having the basis anterior margin without setae and furthermore lacks the long spines of *Plakolana*. The appendix masculina is sword shaped and sub-basally attached. In *Politolana* the antennal morphology, with peduncle articles 1 and 2 short, 3-5 long, is more similar to that of *Natatolana* than to *Plakolana* which has antennal peduncle articles 1-3 short, 4 and 5 long.

KEY TO THE SPECIES OF *PLAKOLANA*

1. Frontal lamina widest anteriorly; uropod endopod spines long (15-35% length of endopod); uropod endopod distally narrowed, medial margin approximately straight 2

   Frontal lamina with straight lateral margins; uropod endopod spines short (less than 12% length of endopod); uropod endopod distally wide, medial margin sinuate. 3

2. Antenna flagellum extending to pereonite 4 or 5; uropod endopod medial margin with 7 spines, distalmost spine about equal in length to adjacent spine. . . . . *P. accola*

   Antenna flagellum extending to pereonite 2 or 3; uropod endopod medial margin with 5 spines, distal most of which is twice as long as adjacent spine . . . . . *P. nagada*

3. Cephalon with complete dorsal interocular furrow; frontal lamina anteriorly rounded; pleotelson with 7* spines. . . . . *Plakolana* sp.

   Cephalon dorsal interocular furrow incomplete; frontal lamina distally acute; pleotelson with 4 spines . . . . . *P. binyana*

**Plakolana* sp. was described from a juvenile (Bruce, 1986: 143, fig. 96). In cirolanids pleotelson spines are nearly always paired, in which case the 'normal' spination for this species would be 6 or 8.

Plakolana accola sp.nov.
(Figs 4-6)

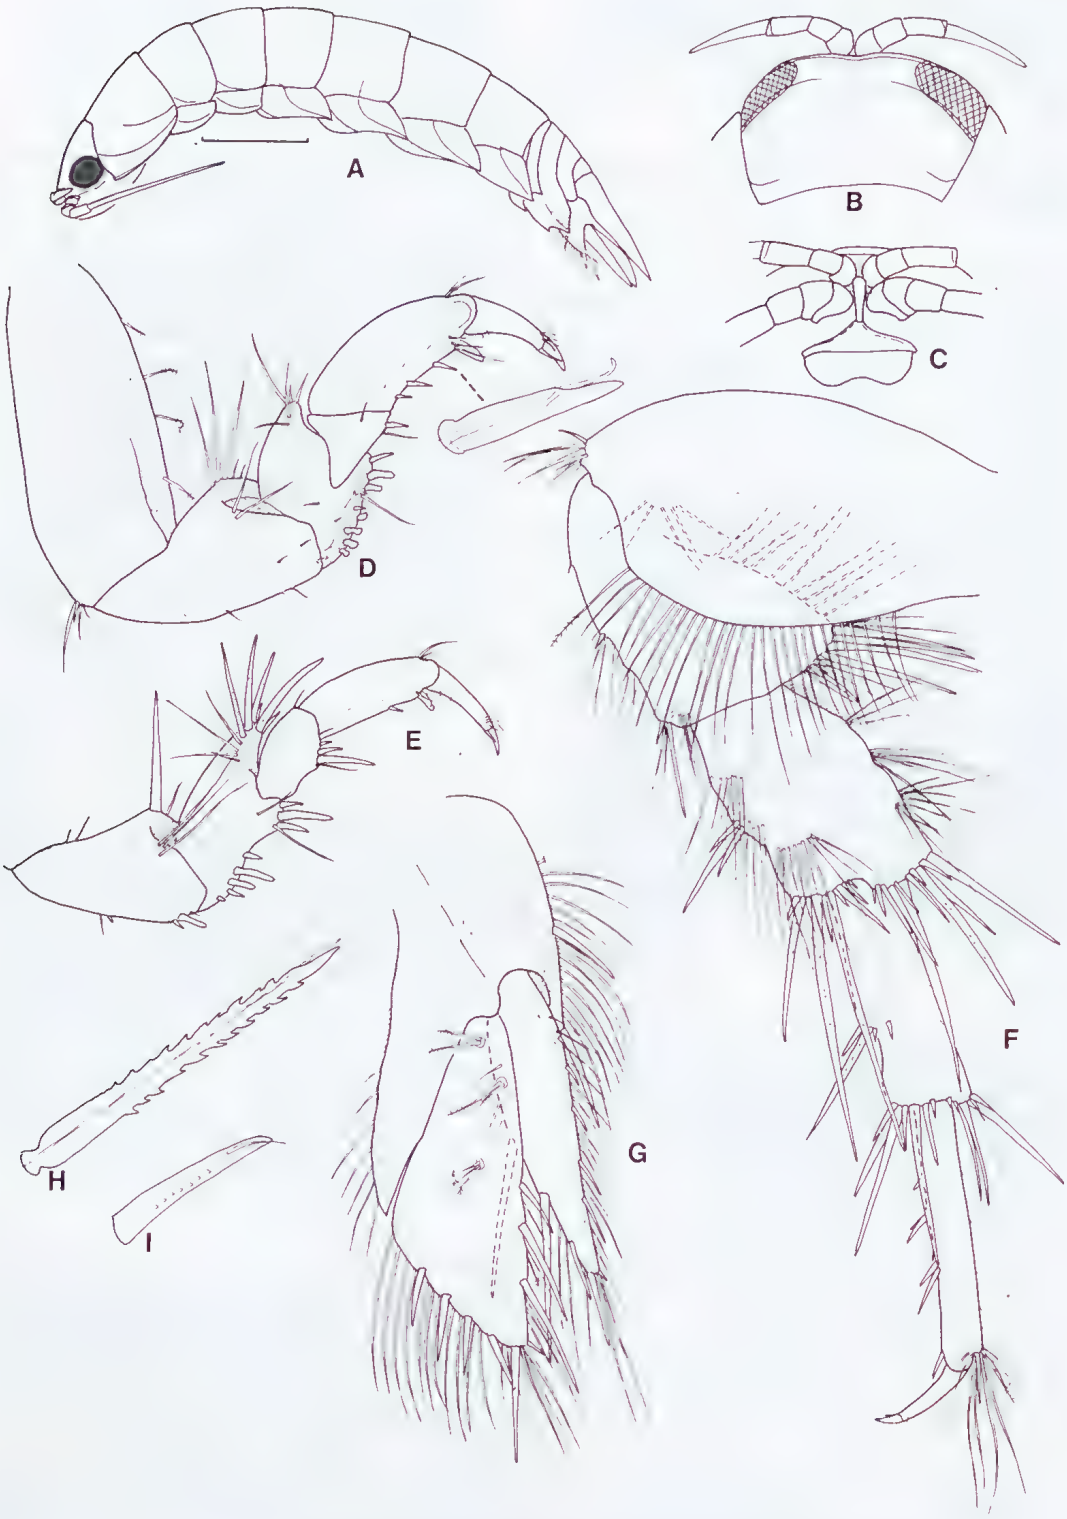
MATERIAL EXAMINED

HOLOTYPE: ♂ (9.5mm), off outer reef slope, south of Wongat Is., 5°08.4'S, 145°51.0'E, 29 Apr 1989, 300m depth, coll. N.L. Bruce & M. Jebb (QM W17993).

PARATYPES: 4♂♂ (9.3 dissected, 9.0, 7.8, 7.0mm), 9 ♀♀(10.5mm ovig, 10.5, 8.0, 8.0, 7.5, 7.0, 6.5, 6.5, 6.0mm), 3 imm (5.5, 5.0, 5.0mm), same data as holotype (QM W 17994-17996). 2♂♂(7.5, 6.8mm), ♀(7.0 non-ovig), as for holotype but 29 Apr 1989, 450m depth (NMV J27475). 9♂♂, 5♀♀, 8 mancas, off outer reef slope between Rasch Pass and Wongat Is, 5°8.7'S, 145°49.7'E, 26-27 Jan 1990; 440m depth, coll J.K. Lowry, J. Mizeu, and J.D. Thomas (AM P40161; 1♂, 1♀ San Diego Museum).

DESCRIPTION

Body about 2.7 times as long as wide. Cephalon with anterior submarginal furrow, dorsal interocular furrow absent. Pereonite 1>2=3<4<5=6>7. Coxae of only pereonites 7 clearly visible in dorsal view. Pleon short, ca. 10% of BL, all of pleonite 1 and most of pleonite 2 concealed by pereonite 7. Pleotelson about as long as wide, lateral margin convex, converging smoothly to subacute apex; posterior margin with 6 acute spines and PMS.



A
B
C
D
E
F
G
H
I

Antennule peduncle article 3 longer than lengths of article 1 and 2 combined; flagellum composed of 11 articles, article 1 longest, and extending to anterior of pereonite 1. Antenna with flagellum of 32 articles, extending to anterior of pereonite 5. Frontal lamina anteriorly widest, with anterior margin rounded; about 2.5 times as long as maximum width. Mandibles with 8 (right) or 11 (left) spines on spine row; molar process with about 28 teeth; palp article 2 with about 11 simple and 4 serrate spines; article 3 with 20 spines. Maxilla with 11 spines on gnathal surface setae on lateral and middle lobes respectively; medial lobe with 7 plumose setae (proximal) and 5 simple seta. Maxilliped with simple setae on lateral shorter, those of article 5 serrate and simple; endite with 5 long circumplumose setae.

Pereopod 1 with 4 setae at posterodistal angle of basis; 3 terminally plumose setae on anterodistal margin; ischium posterior margin with 2 small spines, anterodistal angle with 3 long setae; merus with 7 blunt tubercular spines and 2 acute spines on posterior margin, anterodistal angle with 3 setae; carpus posterior margin with 2 spines and single seta; propodus with 3 spines on palm, 4th large spine opposing base of dactylus; dactylus without distinct secondary unguis. Pereopod 2 with long spines at anterodistal angles of ischium and merus; ischium posterior margin with 2 setae and 1 acute spine, distally with 2 blunt spines; merus posterior margin with 1 long seta and 1 stout spine; carpus with 4 spines, 1 long, and 2 setae; propodus with 1 spine on palm, 1 opposing dactylus. Pereopod 7 basis with margins convex, posterior margin with about 28 feebly PMS; ischium carpus with large clusters of long spines and simple setae at distal margins; posterior margin ischium and merus with 2 and 1 cluster of spines, merus with long setae; propodus with 3 groups of paired spines and a single spine proximally; anterodistal angle with long setae.

Pleopod 3-5 exopods with partial suture only. Uropod peduncle with prominent row of setae on lateral margin; with single lateral spine and 2 spines at distoventral angle; exopod lateral margin with 5 prominent and 1 small subapical spine, medial margin with 4 spines, distal spine not much larger than adjacent spine; endopod lateral margin weakly sinuate, with 3 prominent spines, longest 18% length of lateral margin, and 1 small subapical spine, medial margin with 7 spines, distal spine not much larger than adjacent spine. All margins with PMS, except proximal half (0.45) of endopod lateral margin without setae.

Female: Similar to male; oostegites on coxae 1-5; maxilliped with lamina vibrans (3 plates). Females with embryos not observed.

Colour. White to translucent in life and alcohol; chromatophores absent. Eyes pale, reddish brown to yellow.

Size. Males 7.0 - 9.5 (mean = 8.1, *n*=7), females 6.0-10.5 (mean = 7.8, *n*=10), mancas up to 5.5mm.

Variation. Pleotelson and uropod spine counts were near constant. Exopod (*n*=23) lateral margin with 5 prominent spines (95.6%), medial margin with 4 spines (64.7%) or 5 (29.4%). Endopod (*n*=23) lateral margin with 3 prominent spines (100%), medial margin with 6 (8.7%), 7 (86.9%) or 8 (4.3%).

Remarks

Plakolana accola can be distinguished from others of the genus by the short pleon which has segment 1 and most of 2 concealed by pereonite 7. *P. binyana* from southern Australia has the frontal lamina with a narrow anterior margin and broader uropods which have far shorter spines. *P. nagada*, which occurs in shallow water within the barrier reef system at Madang, is readily distinguished by a longer pleon, longer spines on the uropods, and by having the distalmost spine on the medial margin of each uropod ramus far longer than the adjacent spine.

Distribution

Outer reef slope at Madang, between 300 and 450m depth.

Etymology

Accola is a Latin word meaning neighbour.

Plakolana nagada sp.nov.
(Figs 7, 8)

Material Examined

Holotype: ♂ (6.9mm), east of CRI jetty, Nagada Harbour, 5°09.6'S, 145°48.7'E, 2 Feb 1990, 16m depth, soft mud bottom, coll. J.K. Lowry and J.K. Elliot (AM P41015).

Paratypes: ♂ (7.8mm, dissected), 5♀♀ (8.0 dissected, 7.5, 7.3, 7.2, 7.2mm), imm (4.9mm), same data as holotype (AM P40172). ♀ (7.1mm, ovig), south of

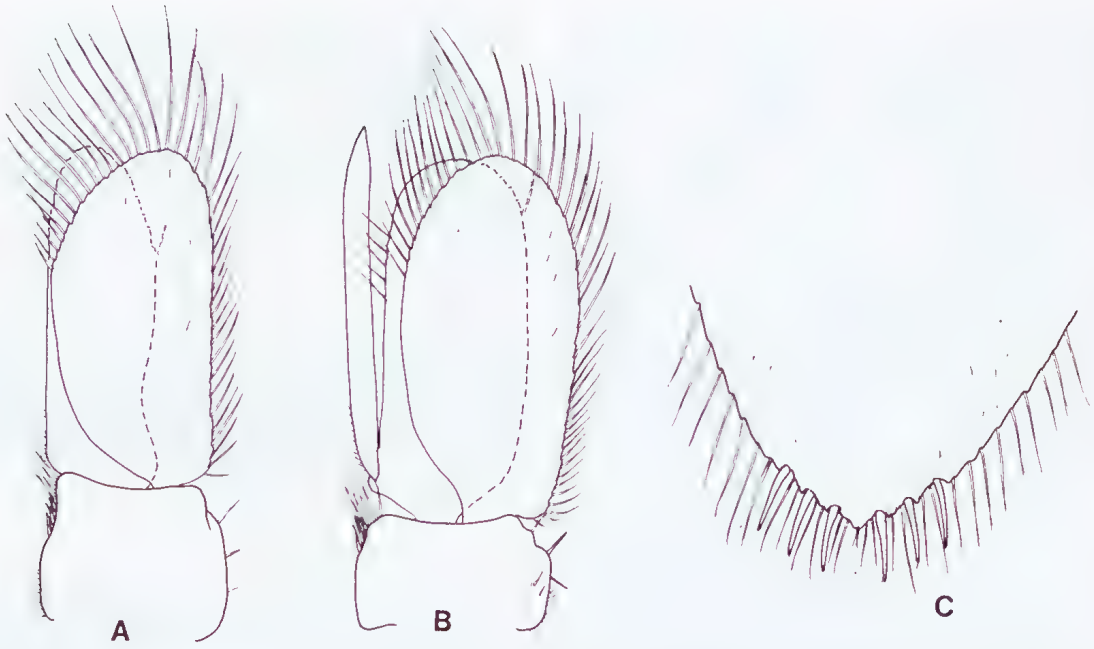

FIG. 8. *Plakolana nagada* sp.nov. All figs of ♂ paratype 7.8mm. A, pleopod 1; B, pleopod 2; C, pleotelson apex.

Tripod Reef, 5°09.7'S, 145°51.3'E, 30 Apr 1989, 22m depth, on sand, coll. N.L. Bruce (QM W18001).

DESCRIPTION

Pleon about 12.5% BL, pleonite 2 largely visible. Pleotelson with 6 spines.

Antenna flagellum extending to posterior of pereonite 3.

Pereopod 1 merus posterior margin with 6 blunt spines and 2 short acute spines. Pereopod 2 merus posterior margin with 1 long seta and 8 stout spines. Pereopod 7 merus with 3 clusters of setae on anterior margin; posterior margin with 2 ranks of simple setae.

Uropod exopod lateral margin with 5 prominent and 1 small subapical spine; medial margin with 4 spines, proximal two longest, distal spine distinctly longer than adjacent spine. Endopod lateral margin with 3 prominent and 1 small subapical spine; 2 longest spines are 32 and 35% length of lateral margin; medial margin with 5 spines, distalmost spine about twice as long as adjacent spine.

Colour. Pale brown in alcohol; eyes pale brown.

Size. Adults 6.9 - 8.0mm.

Variation. Pleotelson and uropod spine counts are near constant. Exopod lateral margin with 5 large and 1 small (100%); medial margin with 4 spines, 3 once. Endopod lateral margin 3 large spines and 1 small (86.6%) or with 2 large spines (13%); lateral margin with 5 (54.5%) or 6 (45.5%) spines (n=15 for all percentages). Pleotelson posterior margin with 6 (62.5%) or 5 (37.5%) spines (n=8).

REMARKS

Plakolana nagada is very similar to *P. accola*, but differs both in habitat (inshore, shallow sedimentary bottom compared to deeper reef slope) and numerous morphological features.

P. nagada in the first instance has much longer pereopod and uropod spines, and also has more of the pleon visible. Specifically the two species can be separated by *P. nagada* having most of pleonite 2 visible, 5 spines on endopod medial margin (vs 7), the terminal spines on the endopod and exopod medial margins being far longer than the adjacent spine, and the spines on the lateral margin of the endopod being much longer (32-35% ramus length vs 18% in *P. accola).*

DISTRIBUTION

Shallow muddy and sand bottoms within the barrier reef at Madang; recorded depths 16 and 22m.

ETYMOLOGY

The epithet is taken from the type locality, and treated as a noun in apposition.

ACKNOWLEDGEMENTS

This contribution was made possible by a Christensen Research Institute Fellowship, for which I thank the Christensen Fund. I also thank Dr Matthew Jebb for his considerable field assistance.

FIRST RECORD OF CTENOPHORE *COELOPLANA* (*BENTHOPLANA*) *METEORIS* (THIEL, 1968) FROM AUSTRALIA. *Memoirs of the Queensland Museum 33(1): 16. 1993*:- There are only two records of benthic ctenophores (Ctenophora: Platyctenida) from Australian waters: *Coeloplana* sp. and *C.* cf *willeyi* Abbott, 1907 (Stephenson et al., 1931; Smith & Plant, 1976). I record here a third species, *Coeloplana* (*Benthoplana*) *meteoris* (Thiel, 1968), previously known from Somalia, east Africa (08°26.2'N, 50°20.2'E) (Thiel, 1968) and NW Madagascar (13°24'40-13°35'15"S, 47°48'50-48°19'10"E) (Fricke & Plante, 1971). The specimens were collected while diving at 12-13m depth in Pioneer Bay, Orpheus Island, NEQ (18°36'S, 146°29'E). Two specimens were preserved (Queensland Museum G35888). The following description is based primarily on living animals in which taxonomic features are clearest.

The animals were living free on terrigenous muddy-sand. They had a characteristic body profile with erect tentacular horns (see Thiel, 1968, figs 1,2; Fricke & Plante, 1971, pl.1). The aboral surface was covered by a yellowish-white reticulate pattern. Fine red pigment occurred on the aboral surface above the meridional canals, around the tentacle sheaths and marginal ampoules. One live specimen, when expanded on glass, measured 36×31mm. The preserved specimens measure 8×10 and 10×16mm.

The apical organ had four polar fields, which were multiply branched (see Fricke & Plante, 1971, fig. 3). The fields did not contract, however, as observed by those authors.

Tentacles were typical with a primary axis and tentilla. They extended from beneath the tip of the tentacular horn, i.e., the opening of the tentacle sheath was oral.

The preserved specimens are folded along the tentacular axis; a faint crease runs along the oral surface from the mouth to the base of the tentacular horns, but no oral groove or oral lappets were seen.

The following description of the gastrovascular system uses the terms of Thiel (1968). Radial canals gave rise on either side to 2 pairs of adradial canals that led directly to the meridional canals. There were 3-4 digitate to trifid aboral papillae over each of the meridional canals. A pair of subparallel tentacular canals ran on either side of the tentacle sheath, arising beyond the distal adradial canals. The peripheral gastrovascular system branched dichotomously to form a complex network, best developed on the oral surface.

Cydippid larvae were found next to the meridional canals (the specimens were collected in January). Peripheral sacs were each connected by a transparent tube to a marginal pore. These seem to be testicular ampoules (see Fricke & Plante, 1971).

Body profile, marginal position of tentacle sheath openings and variable aboral papillae are consistent with *Vallicula* Rankin, 1956 and some species of *Coeloplana* Kowalevsky, 1880 as defined by Fricke (1970), Harbison & Madin (1982) and Rankin (1956). However, I did not see the oral lappets, oral groove, spherical vesicle of the gastrovascular system or additional cross-piece of the tentacular sheath that characterize *Vallicula*.

Of the 21 nominal species of *Coeloplana* (Fricke, 1970), three have a gastrovascular system similar to that in my specimens: *C. perrieri* Dawydoff, 1938, *C. mesnili* Dawydoff, 1938 and *C. meteoris* Thiel, 1968 (Thiel, 1968; Fricke & Plante, 1971). All were reported as free-living (*C. mesnili* in the plankton, *C. perrieri* on rocks and seagrass, *C. meteoris* on soft-sediment). The present specimens differ from *C. mesnili* and *C. perrieri* (Dawydoff; 1938a,b) in body profile, position of openings of the tentacle sheath and testes, colour pattern, structure of the apical organ and aboral papillae. They conform well with *C. meteoris* in (1) the free-living habit on soft-sediment, (2) high body profile with tentacular horns, (3) oral openings of the tentacle sheath, (4) distinctive apical organ with four polar fields, (5) tentacular canals bifurcating beyond the distal adradial canals, (6) colour pattern, (7) complex aboral papillae, and (8) marginal position of ampoules (otherwise known only from *Ctenoplana* (*Diploctena*) *neritica* Fricke & Plante, 1971). This combination of features was so distinctive that Fricke & Plante (1971) created a new subgenus, *Benthoplana*, for *C. meteoris*.

This record considerably extends the range of *C. meteoris*. Fricke & Plante (1971) showed it can be abundant (up to 64/m^2). The paucity of published records probably reflects the lack of direct observations in soft-sediment habitat.

Specimens were collected during a study on soft-sediment epibenthos with Dr R.A. Birtles (James Cook University), funded by an Australian Marine Sciences and Techology grant. I thank Drs A. Birtles and C. Wallace for their comments.

NEW TEMNOCEPHALANS (PLATYHELMINTHES): ECTOSYMBIONTS OF FRESHWATER CRABS AND SHRIMPS

L.R.G. CANNON

Cannon, L.R.G. 1993 06 30: New temnocephalans (Platyhelminthes): ectosymbionts of freshwater crabs and shrimps. *Memoirs of the Queensland Museum* **33**(1): 17-40. Brisbane. ISSN 0079-8835.

Six new species of *Temnocephala* are described from freshwater crabs and shrimps from Queensland, *Temnohaswellia* Pereira & Cuocolo, 1941 is re-erected for two new species with 6 tentacles and *Achenella* n. gen. is proposed for two new species of worms with only one pair of testes. This is the first time temnocephalans have been reported from crabs and shrimps in Australia. □ *Temnocephala, Temnohaswellia, Achenella , ectosymbiont, crab, shrimp.*

Lester R.G. Cannon, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; *2 November, 1992.*
